Up to a certain point in phylogenetic history the human embryo parallels all embryonic life, fish, amphibians, reptils.

But where can we mark the departure of the human from the Amph. & Rept?

TEXT-BOOK OF ANATOMY

THE OXFORD MEDICAL PUBLICATIONS

CUNNINGHAM'S TEXT-BOOK OF ANATOMY

EDITED BY

ARTHUR ROBINSON, M.D., F.R.C.S. Ed.

PROFESSOR OF ANATOMY, UNIVERSITY OF EDINBURGH

FIFTH EDITION

ILLUSTRATED BY 1109 FIGURES FROM ORIGINAL DRAWINGS,
613 OF WHICH ARE PRINTED IN COLOURS,
AND TWO PLATES

NEW YORK
WILLIAM WOOD AND COMPANY
LONDON, EDINBURGH, AND GLASGOW
HENRY FROWDE AND HODDER & STOUGHTON
MDCCCCXXIII

IN RECOGNITION OF

HIS EMINENCE AS AN ANATOMIST

AND HIS INFLUENCE AS A TEACHER

THIS VOLUME

IS DEDICATED

BY THOSE OF HIS FORMER PUPILS AND ASSISTANTS

WHO HAVE CONTRIBUTED

TO ITS PAGES

PREFACE TO THE FIFTH EDITION.

THE regretted death of Professor A. M. Paterson, the inability of Professor Arthur Thomson, of Oxford, to revise his article on Osteology, on account of the pressure of other work, and the transference of Professor A. Campbell Geddes of Montreal from the anatomical to the diplomatic world, have necessitated changes in the authorship of several sections of this edition of Cunningham's *Text-book of Anatomy*.

The readers who contrast the fifth edition with its predecessors will find that the section on Ductless Glands, originally written by the late Professor D. J. Cunningham, and afterwards revised and partly rewritten by Professor A. Campbell Geddes, has been entirely rewritten and its scope greatly enlarged, in association with the growing importance of the subject, by Professor J. T. Wilson of Cambridge; that two sections, originally written by the late Professor A. M. Paterson—Myology and the Peripheral Nervous System—have been revised and largely rewritten by different authors, Myology by Professor T. B. Johnston of Guy's Hospital, London, and the Spinal and Cerebral Nerves and the Sympathetic Nervous System by Professor S. E. Whitnall of the McGill University, Montreal; and that the greater part of the section on Osteology has been rewritten and the remainder revised by Dr. E. B. Jamieson of the University of Edinburgh.

The other sections have remained in the hands of the authors who revised them for the last edition, and two of them, the Alimentary System and the Vascular System, have been considerably recast, whilst all have been carefully revised and brought up to date.

Each of the contributors has attempted to keep his section within the bounds allowable in a text-book primarily intended for the use of students and practitioners of medicine and surgery.

Some of the figures present in the last edition which were considered unessential have been removed, and many new figures, both monochrome and coloured, have been introduced.

As in the preceding editions, where sections written by different authors necessarily overlap one another, it may be found that varying statements occur regarding phenomena concerning which our knowledge is still in an indefinite stage, and it must be understood that the authors of the various sections are alone responsible for the opinions expressed in their own sections.

As editor I wish to express my thanks to all the authors for their kind, considerate and willing help.

I am indebted to Dr. J. S. Fraser for the use of specimens from which two new figures of the labyrinth of the internal ear were prepared, and to Messrs.

J. & A. Churchill for permission to use and modify the diagram of the Sympathetic Nervous System originally made by the late Professor Flower.

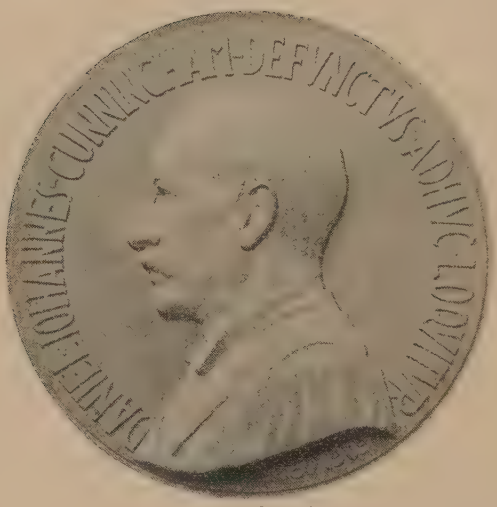
Sir Harold Stiles wishes me to express his indebtedness to Dr. Logan Turner for assistance in revising the section of his article dealing with the nose and its accessory air sinuses, and to Dr. J. S. Fraser for help with the portion concerned with the ear. He also desires to thank Dr. Goldthwait of Boston and his pupil Dr. W. A. Cochrane for their contribution to the description of certain conditions of the vertebral column.

Professor Whitnall desires to acknowledge the help he has received from his Associate Professor in Histology and Embryology—Professor J. C. Simpson—in the revision of the developmental portion of the article on the Peripheral Nervous System and in the preparation of some of the new figures.

The drawings for the majority of the new figures were made, with perhaps even more than his usual skill of technique and interpretation, by Mr. J. T. Murray, but three of the new figures in the section on Myology were made by Mr. W. T. Shiells, the new line drawings in Professor Whitnall's article by Professor J. C. Simpson, and the new half-tone drawings in the same section by Mr. N. M. Fralm.

ARTHUR ROBINSON.

July 11, 1922.



Oliver Sheppard, R.H.A., fecit.

DANIEL JOHANNES CUNNINGHAM ADHUC LOQUITUR.

Demonstrator of Anatomy, University of Edinburgh, 1874–1882.
Professor of Anatomy, Royal College of Surgeons, Dublin, 1882–1883.
Professor of Anatomy, Trinity College, Dublin, 1883–1903.
Professor of Anatomy, University of Edinburgh, 1903–1909.

LIST OF CONTRIBUTORS

RICHARD J. A. BERRY, M.D., F.R.C.S. Ed.,
Professor of Anatomy, University of Melbourne.
(*The Respiratory System.*)

A. FRANCIS DIXON, M.B., D.Sc. (Dubl.),
Professor of Anatomy, Trinity College, Dublin.
(*The Uro-genital System.*)

DAVID HEPBURN, M.D., F.R.S.E., C.M.G.,
Professor of Anatomy, University College, Cardiff.
(*Arthrology.*)

ROBERT HOWDEN, M.A., M.B.,
Professor of Anatomy, University of Durham.
(*The Organs of Sense and the Integument.*)

E. B. JAMIESON, M.D.,
Lecturer on Anatomy, University of Edinburgh.
(*Osteology.*)

T. B. JOHNSTON, M.B., Ch.B.
Professor of Anatomy, Guy's Hospital, London.
(*Myology.*)

ARTHUR ROBINSON, M.D., F.R.C.S. Ed.,
Professor of Anatomy, University of Edinburgh.
(*General Embryology, The Vascular System.*)

G. ELLIOT SMITH, M.D., F.R.S.,
Professor of Anatomy, University College, London.
(*The Central Nervous System.*)

SIR HAROLD J. STILES, M.B., F.R.C.S. Ed.,
Professor of Clinical Surgery, University of Edinburgh.
(*Surface and Surgical Anatomy.*)

DAVID WATERSTON, M.A., M.D., F.R.C.S. Ed.,
Professor of Anatomy, University of St. Andrews.
(*The Digestive System.*)

S. E. WHITNALL, M.A. Oxon. M.D.,
Professor of Anatomy, McGill University, Montreal.
(*The Peripheral Nervous System.*)

J. T. WILSON, M.D., F.R.S.,
Professor of Anatomy, University of Cambridge.

A GLOSSARY

OF THE

INTERNATIONAL (B.N.A.)

ANATOMICAL TERMINOLOGY

GENERAL TERMS.

Terms indicating Situation and Direction.

Longitudinalis	Longitudinal	Referring to the long axis of the body.
Verticalis	Vertical	Referring to the position of the long axis of the body in the erect posture.
Anterior Posterior	Anterior Posterior	Referring to the front and back of the body or the limbs.
Ventral Dorsal	Ventral Dorsal	Referring to the anterior and posterior aspects, respectively, of the body, and to the flexor and extensor aspects of the limbs, respectively.
Cranial Caudal	Cranial Caudal	Referring to position nearer the head or the tail end of the long axis. Used only in reference to parts of the head, neck, or trunk. *Cephalic* is sometimes used instead of *cranial*.
Superior Inferior	Superior Inferior	Used in reference to the head, neck, and trunk. Equivalent to cranial and caudal respectively.
Proximalis Distalis	Proximal Distal	Used only in reference to the limbs. Proximal, nearer the attached end. Distal, nearer the free end.
Sagittalis	Sagittal	Used in reference to planes parallel with the sagittal suture of the skull, *i.e.* vertical antero-posterior planes.
Frontalis	Frontal	Used in reference to planes parallel with the coronal suture of the skull, *i.e.* vertical transverse planes.
Horizontalis	Horizontal	Used in reference to planes at right angles to vertical planes.
Medianus	Median	Referring to the median vertical antero-posterior plane of the body.
Medialis Lateralis	Medial Lateral	Referring to structures relatively nearer to or further away from the median plane.
Intermedius	Intermediate	Referring to structures situated between more medial and more lateral structures.
Superficialis Profundus	Superficial Deep	Referring to structures nearer to and further away from the surface.
Externus Internus	External Internal	Referring, with few exceptions, to the walls of cavities and hollow organs. **Not to be used as synonymous with medial and lateral.**
Ulnaris Radialis	Ulnar Radial	Used in reference to the medial and lateral borders, respectively, of the forearm and hand.
Tibial Fibular	Tibial Fibular	Used in reference to the medial and lateral borders, respectively of the leg and foot.

THE BONES.

B.N.A. Terminology.	Old Terminology.
Vertebræ	**Vertebræ**
Fovea costalis superior	Incomplete facet for head of rib, upper
Fovea costalis inferior	Incomplete facet for head of rib, lower
Fovea costalis transversalis	Facet for tubercle of the rib
Radix arcus vertebræ	Pedicle
Atlas	**Atlas**
Fovea dentis	Facet for odontoid process
Epistropheus	**Axis**
Dens	Odontoid process
Sternum	**Sternum**
Corpus sterni	Gladiolus
Processus xiphoideus	Ensiform process
Incisura jugularis	Supra-sternal notch
Planum sternale	Anterior surface
Ossa Cranii.	**Bones of Skull.**
Os frontale	**Frontal**
Spina frontalis	Nasal spine
Processus zygomaticus	External angular process
Facies cerebralis	Internal surface
Facies frontalis	Frontal surface
Pars orbitalis	Orbital plate
Os parietale	**Parietal**
Lineæ temporales	Temporal ridges
Sulcus transversus	Groove for lateral sinus
Sulcus sagittalis	Groove for sup. longitudinal sinus
Os occipitale	**Occipital**
Canalis hypoglossi	Anterior condyloid foramen
Foramen occipitale magnum	Foramen magnum
Canalis condyloideus	Posterior condyloid foramen
Sulcus transversus	Groove for lateral sinus
Sulcus sagittalis	Groove for sup. long. sinus
Clivus	Median part of upper surface of basi-occipital
Linea nuchæ suprema	Highest curved line
Linea nuchæ superior	Superior curved line
Linea nuchæ inferior	Inferior curved line
Os sphenoidale	**Sphenoid**
Crista infratemporalis	Pterygoid ridge
Sulcus chiasmatis	Optic groove
Crista sphenoidalis	Ethmoidal crest
Spina angularis	Spinous process
Lamina medialis processus pterygoidei	Internal pterygoid plate
Lamina lateralis processus pterygoidei	External pterygoid plate
Canalis pterygoideus [Vidii]	Vidian canal
Fossa hypophyseos	Pituitary fossa
Sulcus caroticus	Cavernous groove
Conchæ sphenoidales	Sphenoidal turbinal bones
Hamulus pterygoideus	Hamular process
Canalis pharyngeus	Pterygo-palatine canal
Tuberculum sellæ	Olivary eminence
Fissura orbitalis superior	Sphenoidal fissure
Os temporale	**Temporal Bone**
Canalis facialis [Fallopii]	Aqueduct of Fallopius
Hiatus canalis facialis	Hiatus Fallopii
Vagina processus styloidei	Vaginal process of tympanic plate
Incisura mastoidea	Digastric fossa
Impressio trigemini	Impression for Gasserian ganglion
Eminentia arcuata	Eminence for sup. semicircular canal
Sulcus sigmoideus	Sigmoid fossa
Fissura petrotympanica	Glaserian fissure
Fossa mandibularis	Glenoid cavity
Semicanalis tubæ auditivæ	Eustachian tube
Os ethmoidale	**Ethmoid**
Labyrinthus ethmoidalis	Lateral mass
Lamina papyracea	Os planum
Processus uncinatus	Unciform process
Os lacrimale	**Lachrymal Bone**
Hamulus lacrimalis	Hamular process
Crista lacrimalis posterior	Lachrymal crest
Os nasale	**Nasal Bone**
Sulcus ethmoidalis	Groove for nasal nerve
Maxilla	**Superior Maxillary Bone**
Facies anterior	Facial or external surface
Facies infratemporalis	Zygomatic surface
Sinus maxillaris	Antrum of Highmore
Processus frontalis	Nasal process
Processus zygomaticus	Malar process
Canales alveolares	Posterior dental canals
Canalis naso-lacrimalis	Lachrymal groove
Os incisivum	Premaxilla
Foramen incisivum	Anterior palatine foramen
Os palatinum	**Palate Bone**
Pars perpendicularis	Vertical plate
Crista conchalis	Inferior turbinate crest
Crista ethmoidalis	Superior turbinate crest
Pars horizontalis	Horizontal plate

B.N.A. Terminology.	Old Terminology.
Os zygomaticum	**Malar Bone**
Processus temporalis	Zygomatic process
Processus fronto-sphenoidalis	Frontal process
Foramen zygomatico-orbitale	Temporo-malar canal
Foramen zygomatico-faciale	Malar foramen
Mandibula	**Inferior Maxillary Bone**
Spina mentalis	Genial tubercle or spine
Linea obliqua	External oblique line
Linea mylohyoidea	Internal oblique line
Incisura mandibulæ	Sigmoid notch
Foramen mandibulare	Inferior dental foramen
Canalis mandibulæ	Inferior dental canal
Protuberantia mentalis	Mental process

The Skull as a Whole.

Ossa suturarum	Wormian bones
Foveolæ granulares (Pacchioni)	Pacchionian depressions
Fossa pterygo-palatina	Spheno-maxillary fossa
Canalis pterygo-palatinus	Posterior palatine canal
Foramen lacerum	Foramen lacerum medium
Choanæ	Posterior nares
Fissura orbitalis superior	Sphenoidal fissure
Fissura orbitalis inferior	Spheno-maxillary fissure

Upper Extremity.

Clavicula	**Clavicle**
Tuberositas coracoidea	Impression for conoid ligament
Tuberositas costalis	Impression for rhomboid ligament
Scapula	**Scapula**
Incisura scapularis	Supra-scapular notch
Angulus lateralis	Anterior or lateral angle
Angulus medialis	Superior angle
Humerus	**Humerus**
Sulcus intertubercularis	Bicipital groove
Crista tuberculi majoris	External lip
Crista tuberculi minoris	Internal lip
Facies anterior medialis	Internal surface
Facies anterior lateralis	External surface
Margo medialis	Internal border
Margo lateralis	External border
Sulcus nervi radialis	Musculo-spiral groove
Capitulum	Capitellum
Epicondylus medialis	Internal condyle
Epicondylus lateralis	External condyle
Ulna	**Ulna**
Incisura semilunaris	Greater sigmoid cavity
Incisura radialis	Lesser sigmoid cavity
Crista interossea	External or interosseous border
Facies dorsalis	Posterior surface
Facies volaris	Anterior surface
Facies medialis	Internal surface
Margo dorsalis	Posterior border
Margo volaris	Anterior border
Radius	**Radius**
Tuberositas radii	Bicipital tuberosity
Incisura ulnaris	Sigmoid cavity
Crista interossea	Internal or interosseous border
Facies dorsalis	Posterior surface
Facies volaris	Anterior surface
Facies lateralis	External surface
Margo dorsalis	Posterior border
Margo volaris	Anterior border
Carpus	**Carpus**
Os naviculare	**Scaphoid**
Os lunatum	**Semilunar**
Os triquetrum	**Cuneiform**
Os multangulum majus	**Trapezium**
Os multangulum minus	**Trapezoid**
Os capitatum	**Os magnum**
Os hamatum	**Unciform**

Lower Extremity.

Os coxæ	**Innominate Bone**
Linea glutæa anterior	Middle curved line
Linea glutæa posterior	Superior curved line
Spina ischiadica	Spine of the ischium
Incisura ischiadica major	Great sacro-sciatic notch
Incisura ischiadica minor	Lesser sacro-sciatic notch
Tuberculum pubicum	Spine of pubis
Ramus inferior ossis pubis	Descending ramus of pubis
Ramus superior ossis pubis	Ascending ramus of pubis
Ramus superior ossis ischii	Body of ischium
Ramus inferior ossis ischii	Ramus of ischium
Pecten ossis pubis	Pubic part of ilio-pectineal line
Facies symphyseos	Symphysis pubis
Pelvis	**Pelvis**
Pelvis major	False pelvis
Pelvis minor	True pelvis
Apertura pelvis minoris superior	Pelvic inlet
Linea terminalis	Margin of inlet of true pelvis
Apertura pelvis minoris inferior	Pelvic outlet
Femur	**Femur**
Fossa trochanterica	Digital fossa
Linea intertrochanterica	Spiral line
Crista intertrochanterica	Post. intertrochanteric line

B.N.A. Terminology.	Old Terminology.
Condylus medialis	Inner condyle
Condylus lateralis	Outer condyle
Epicondylus medialis	Inner tuberosity
Epicondylus lateralis	Outer tuberosity
Tibia	**Tibia**
Condylus medialis	Internal tuberosity
Condylus lateralis	External tuberosity
Eminentia intercondyloidea	Spine
Tuberositas tibiæ	Tubercle
Malleolus medialis	Internal malleolus
Fibula	**Fibula**
Apex capituli fibulæ	Styloid process
Malleolus lateralis	External malleolus

B.N.A. Terminology.	Old Terminology.
Bones of the Foot.	
Talus	**Astragalus**
Calcaneus	**Os calcis**
Tuber calcanei	Tuberosity of os calcis
Processus medialis tuberis calcanei	Inner } tuberosities of os calcis
Processus lateralis tuberis calcanei	Outer } tuberosities of os calcis
Os cuneiforme primum	**Inner cuneiform**
Os cuneiforme secundum	**Middle cuneiform**
Os cuneiforme tertium	**Outer cuneiform**

THE LIGAMENTS.

Ligaments of the Spine.

Lig. longitudinale anterius	Anterior common ligament
Lig. longitudinale posterius	Posterior common ligament
Lig. flava	Ligamenta subflava
Membrana tectoria	Posterior occipito-axial ligament
Articulatio atlanto-epistrophica	Joint between the atlas and the axis
Lig. alaria	Odontoid or check ligaments
Lig. apicis dentis	Suspensory ligament

The Ribs.

Lig. capituli costæ radiatum	Anterior costo-vertebral or stellate ligament
Lig. sterno-costale interarticulare	Interarticular chondro-sternal ligament
Lig. sterno-costalia radiata	Anterior and posterior chondro-sternal ligament
Lig. costoxiphoidea	Chondro-xiphoid ligaments

The Jaw.

Lig. temporo-mandibulare	External lateral ligament of the jaw
Lig. spheno-mandibulare	Internal lateral ligament of the jaw
Lig. stylo-mandibulare	Stylo-maxillary ligament

Upper Extremity.

Lig. costo-claviculare	Rhomboid ligament
Labrum glenoidale	Glenoid ligament
Articulatio radio-ulnaris proximalis	Superior radio-ulnar joint
Lig. collaterale ulnare	Internal lateral ligament of elbow-joint
Lig. collaterale radiale	External lateral ligament
Lig. annulare radii	Orbicular ligament
Chorda obliqua	Oblique ligament of ulna
Articulatio radio-ulnaris distalis	Inferior radio-ulnar joint
Discus articularis	Triangular fibro-cartilage
Recessus sacciformis	Membrana sacciformis
Lig. radio-carpeum volare	Anterior ligament of the radio-carpal joint
Lig. radio-carpeum dorsale	Posterior ligament of the radio-carpal joint
Lig. collaterale carpi ulnare	Internal lateral ligament of the wrist-joint
Lig. collaterale carpi radiale	External lateral ligament of the wrist-joint
Articulationes intercarpeæ	Carpal joints
Lig. accessoria volaria	Palmar ligaments of the metacarpo-phalangeal joints
Lig. capitulorum ossium metacarpalium transversa	Transverse metacarpal ligament
Lig. collateralia	Lateral phalangeal ligaments

The Lower Extremity.

Lig. arcuatum	Subpubic ligament
Lig. sacro-tuberosum	Great sacro-sciatic ligament
Processus falciformis	Falciform process
Lig. sacro-spinosum	Small sacro-sciatic ligament
Labrum glenoidale	Cotyloid ligament
Zona orbicularis	Zonular band
Ligamentum ilio-femorale	Y-shaped ligament
Lig. ischio-capsulare	Ischio-capsular band
Lig. pubo-capsulare	Pubo-femoral ligament
Lig. popliteum obliquum	Ligament of Winslow
Lig. collaterale fibulare	Long external lateral ligament
Lig. collaterale tibiale	Internal lateral ligament
Lig. popliteum arcuatum	Arcuate popliteal ligament
Meniscus lateralis	External semilunar cartilage

B.N.A. Terminology.	Old Terminology.
Meniscus medialis	Internal semilunar cartilage
Plica synovialis patellaris	Lig. mucosum
Plicæ alares	Ligamenta alaria
Articulatio tibio-fibularis	Superior tibio-fibular articulation
Lig. capituli fibulæ	Anterior and posterior superior tibio-fibular ligaments
Syndesmosis tibio-fibularis	Inferior tibio-fibular articulation
Lig. deltoideum	Internal lateral ligament of ankle
Lig. talo-fibulare anterius	Anterior fasciculus of external lateral ligament
Lig. talo-fibulare posterius	Posterior fasciculus of external lateral ligament
Lig. calcaneo-fibulare	Middle fasciculus of external lateral ligament
Lig. talo-calcaneum laterale	External calcaneo-astragaloid ligament
Lig. talo-calcaneum mediale	Internal calcaneo-astragaloid ligament
Lig. calcaneo-naviculare plantare	Inferior calcaneo-navicular ligament
Lig. talo-naviculare	Astragalo-scaphoid ligament
Pars calcaneo-navicularis } lig. bifurcatum	Superior calcaneo-scaphoid ligament
Pars calcaneo-cuboidea } lig. bifurcatum	Internal calcaneo-cuboid ligament

THE MUSCLES.

Muscles of the Back.

Superficial.

Levator scapulæ	Levator anguli scapulæ

Muscles of the Chest.

Serratus anterior	Serratus magnus

Muscles of Upper Extremity.

Biceps brachii	Biceps
Lacertus fibrosus	Bicipital fascia
Brachialis	Brachialis anticus
Triceps brachii	Triceps
Caput mediale	Inner head
Caput laterale	Outer head
Pronator teres	Pronator radii teres
Caput ulnare	Coronoid head
Brachio-radialis	Supinator longus
Supinator	Supinator brevis
Extensor carpi radialis longus	Extensor carpi radialis longior
Extensor carpi radialis brevis	Extensor carpi radialis brevior
Extensor indicis proprius	Extensor indicis
Extensor digiti quinti proprius	Extensor minimi digiti
Abductor pollicis longus	Extensor ossis metacarpi pollicis
Abductor pollicis brevis	Abductor pollicis
Extensor pollicis brevis	Extensor primi internodii pollicis
Extensor pollicis longus	Extensor secundi internodii pollicis
Lig. carpi transversum	Anterior annular ligament
Lig. carpi dorsale	Posterior annular ligament

Muscles of Lower Extremity.

Tensor fasciæ latæ	Tensor fasciæ femoris
Canalis adductorius (Hunteri)	Hunter's canal
Trigonum femorale (fossa Scarpæ major)	Scarpa's triangle
Canalis femoralis	Crural canal
Annulus femoralis	Crural ring
M. quadriceps femoris—	Quadriceps—
Rectus femoris	Rectus femoris
Vastus lateralis	Vastus externus
Vastus intermedius	Crureus
Vastus medialis	Vastus internus
M. articularis genu	Subcrureus
Tibialis anterior	Tibialis anticus
Tendo calcaneus	Tendo Achillis
Tibialis posterior	Tibialis posticus
Quadratus plantæ	Accessorius
Lig. transversum cruris	Upper anterior annular ligament
Lig. cruciatum cruris	Lower anterior annular ligament
Lig. laciniatum	Internal annular ligament
Retinaculum musculorum peronæorum superius }	External annular ligament
Retinaculum musculorum peronæorum inferius }	External annular ligament

Axial Muscles.

Muscles of the Back.

Serratus posterior superior	Serratus posticus superior
Serratus posterior inferior	Serratus posticus inferior
Splenius cervicis	Splenius colli
Sacro-spinalis	Erector spinæ
Ilio-costalis—	**Ilio-costalis—**
Lumborum	Sacro-lumbalis
Dorsi	Accessorius
Cervicis	Cervicalis ascendens
Longissimus—	**Longissimus—**
Dorsi	Dorsi
Cervicis	Transversalis cervicis
Capitis	Trachelo-mastoid

B.N.A. Terminology.	Old Terminology.
Spinalis—	**Spinalis—**
Dorsi	Dorsi
Cervicis	Colli
Capitis	Capitis
Semispinalis—	**Semispinalis—**
Dorsi	Dorsi
Cervicis	Colli
Capitis	Complexus
Multifidus	Multifidus spinæ

Muscles of Head and Neck.

Epicranius	Occipito-frontalis
Galea aponeurotica	Epicranial aponeurosis
Procerus	Pyramidalis nasi
Pars transversa (nasalis)	Compressor naris
Pars alaris (nasalis)	Dilatores naris
Auricularis anterior	Attrahens aurem
Auricularis posterior	Retrahens aurem
Auricularis superior	Attollens aurem
Orbicularis oculi	Orbicularis palpebrarum
Pars lacrimalis	Tensor tarsi
Triangularis	Depressor anguli oris
Quadratus labii superioris—	
Caput zygomaticum	Zygomaticus minor
Caput infraorbitale	Levator labii superioris
Caput angulare	Levator labii superioris alæque nasi
Zygomaticus	Zygomaticus major
Caninus	Levator anguli oris
Quadratus labii inferioris	Depressor labii inferioris
Mentalis	Levator menti
Platysma	Platysma myoides
Sterno-thyreoid	Sterno-thyroid
Thyreo-hyoid	Thyro-hyoid

Muscles and Fascia of the Orbit.

Fascia bulbi	Capsule of Tenon
Septum orbitale	Palpebral ligaments
Rectus lateralis	Rectus externus
Rectus medialis	Rectus internus

Muscles of the Tongue.

Genio-glossus	Genio-hyo-glossus
Longitudinalis superior	Superior lingualis
Longitudinalis inferior	Inferior lingualis
Transversus linguæ	Transverse fibres
Verticalis linguæ	Vertical fibres

Muscles of the Pharynx.

Pharyngo-palatinus	Palato-pharyngeus
M. uvulæ	Azygos uvulæ
Levator veli palatini	Levator palati
Tensor veli palatini	Tensor palati
Glosso-palatinus	Palato-glossus

Deep Lateral Muscles of Neck.

B.N.A. Terminology.	Old Terminology.
Scalenus anterior	Scalenus anticus
Scalenus posterior	Scalenus posticus
Longus capitis	Rectus capitis anticus major
Rectus capitis anterior	Rectus capitis anticus minor

Muscles of Thorax.

Transversus thoracis	Triangularis sterni
Diaphragma, pars lumbalis	Diaphragm, lumbar part—
Crus mediale, Crus intermedium, Crus laterale	Crus and origin from internal arcuate ligaments
Arcus lumbo-costalis medialis (Halleri)	Ligamentum arcuatum internum
Arcus lumbo-costalis lateralis (Halleri)	Ligamentum arcuatum externum

Muscles of the Abdomen.

Ligamentum inguinale (Pouparti)	Poupart's ligament
Ligamentum lacunare (Gimbernati)	Gimbernat's ligament
Fibræ intercrurales	Intercolumnar fibres
Ligamentum inguinale reflexum (Collesi)	Triangular fascia
Annulus inguinalis subcutaneus	External abdominal ring
Crus superius	Internal pillar
Crus inferius	External pillar
Falx (aponeurotica) inguinalis	Conjoined tendon
M. transversus abdominis	Transversalis muscle
Linea semicircularis (Douglasi)	Fold of Douglas
Annulus inguinalis abdominalis	Internal abdominal ring

Perineum and Pelvis.

Transversus perinei superficialis	Transversus perinei
M. sphincter urethræ membranaceæ	Compressor urethræ
Diaphragma urogenitale	Deep transverse muscle and compressor urethræ
Fascia diaphragmatis urogenitalis superior	Deep layer of triangular ligament
Fascia diaphragmatis urogenitalis inferior	Superficial layer of the triangular ligament
Arcus tendineus fasciæ pelvis	White line of pelvis
Ligamenta pubo-prostatica	Anterior and lateral true ligaments of bladder
Fascia diaphragmatis pelvis superior	Visceral layer of pelvic fascia
Fascia diaphragmatis pelvis inferior	Anal fascia

THE NERVOUS SYSTEM.

Spinal Medulla.

B.N.A. Terminology.	Old Terminology.
Fasciculus anterior proprius (Flechsig)	Anterior ground or basis bundle
Fasciculus lateralis proprius	Lateral ground bundle
Nucleus dorsalis	Clarke's column
Pars thoracalis	Dorsal part of spinal medulla
Sulcus intermedius posterior	Paramedian furrow
Columnæ anteriores, etc.	Anterior grey horns, etc.
Fasciculus cerebro-spinalis anterior	Direct pyramidal tract
Fasciculus cerebro-spinalis lateralis (pyramidalis)	Crossed pyramidal tract
Fasciculus cerebello-spinalis	Direct cerebellar tract
Fasciculus antero-lateralis superficialis	Gowers' tract

The **Brain** or **Encephalon** is divided into parts as follows:—

RHOMBENCEPHALON = Myelencephalon (medulla oblongata) (after-brain)
Metencephalon (pons and cerebellum) (hind-brain) } Posterior primary vesicle.

CEREBRUM
- **MESENCEPHALON** (mid-brain—peduncles, corpora quadrigemina, etc.—) Middle primary vesicle
- **PROSENCEPHALON** (fore-brain)
  - **Diencephalon** = (inter-brain)
    - Thalamencephalon
      - Thalamus (optic thalamus).
      - Metathalamus (geniculate bodies).
      - Epithalamus (pineal body, etc.).
    - Mamillary portion of hypothalamus.
    - Posterior part of 3rd ventricle.
  - **Telencephalon**
    - Optic portion of hypothalamus (hypophysis).
    - Optic nerves.
    - Anterior part of 3rd ventricle.
    - Pallium (cortex cerebri).
    - Lateral ventricles.

Brain.

Rhombencephalon

Eminentia medialis	Eminentia teres
Ala cinerea	Trigonum vagi
Area acustica	Trigonum acusticum
Nucleus nervi abducentis	Nucleus of 6th nerve
Nuclei n. acustici	Auditory nucleus
Fasciculus longitudinalis medialis	Posterior longitudinal bundle
Corpus trapezoideum	Corpus trapezoides
Incisura cerebelli anterior	Semilunar notch (of cerebellum)
Incisura cerebelli posterior	Marsupial notch
Sulcus horizontalis cerebelli	Great horizontal fissure
Lobulus centralis	Lobus centralis
Folium vermis	Folium cacuminis
Tuber vermis	Tuber valvulæ
Lobulus quadrangularis	Quadrate lobule
Brachium conjunctivum cerebelli	Superior cerebellar peduncle
Brachium pontis	Middle cerebellar peduncle
Restiform body	Inferior cerebellar peduncle
Lobulus semilunaris superior	Postero-superior lobule
Lobulus semilunaris inferior	Postero-inferior lobule

Cerebrum

Pedunculus cerebri	Crus cerebri
Colliculus superior	Anterior corpus quadrigeminum
Colliculus inferior	Posterior corpus quadrigeminum
Aquæductus cerebri	Iter e tertio ad quartum ventriculum, or aqued. of Sylvius
Foramen interventriculare	Foramen of Monro
Hypothalamus	Subthalamic region
Sulcus hypothalamicus	Sulcus of Monro
Massa intermedia	Middle commissure
Fasciculus thalamo-mamillaris	Bundle of Vicq d'Azyr
Pars opercularis	Pars basilaris
Thalamus	Optic thalamus
Pallium	Cortex cerebri
Gyri transitivi	Annectant gyri
Fissura cerebri lateralis	Fissure of Sylvius
Gyrus temporalis superior	First temporal gyrus
Gyrus temporalis medius	Second temporal gyrus
Gyrus temporalis inferior	Third temporal gyrus
Sulcus centralis (Rolandi)	Fissure of Rolando
Sulcus temporalis superior	Parallel sulcus

B.N.A. Terminology.	Old Terminology.
Sulcus temporalis medius	Second temporal sulcus
Sulcus circularis	Limiting sulcus of Reil
Sulcus temporalis inferior	Occipito-temporal sulcus
Gyrus fusiformis	Occipito-temporal convolution
Sulcus interparietalis	Intraparietal sulcus
Sulcus corporis callosi	Callosal sulcus
Sulcus cinguli	Calloso-marginal fissure
Fissura hippocampi	Dentate fissure
Gyrus cinguli	Callosal convolution
Stria terminalis	Tænia semicircularis
Trigonum collaterale	Trigonum ventriculi
Hippocampus	Hippocampus major
Digitationes hippocampi	Pes hippocampi
Fascia dentata hippocampi	Gyrus dentatus
Columna fornicis	Anterior pillar of fornix
Septum pellucidum	Septum lucidum
Cornu inferius	Descending horn of lateral ventricle
Commissura hippocampi	Lyra
Nucleus lentiformis	Lenticular nucleus
Pars frontalis capsulæ internæ	Anterior limb (of internal capsule)
Pars occipitalis capsulæ internæ	Posterior limb (of internal capsule)
Radiatio occipito-thalamica	Optic radiation
Radiatio corporis callosi	Radiation of corpus callosum
Pars frontalis	Forceps minor
Pars occipitalis	Forceps major

Membranes of Brain.

Cisterna cerebello-medullaris	Cisterna magna
Cisterna interpeduncularis	Cisterna basalis
Granulationes arachnoideales	Pacchionian bodies
Tela chorioidea ventriculi tertii	Velum interpositum
Tela chorioidea ventriculi quarti	Tela choroidea inferior

Cerebral Nerves.

N. oculomotorius	Third nerve
N. trochlearis	Fourth nerve
N. trigeminus	Fifth nerve
Ganglion semilunare (Gasseri)	Gasserian ganglion
N. naso-ciliaris	Nasal nerve
N. maxillaris	Superior maxillary nerve
N. meningeus (medius)	Recurrent meningeal nerve
N. zygomaticus	Temporo-malar nerve
Rami alveolares superiores posteriores	Posterior superior dental
Rami alveolares superiores medi	Middle superior dental
Rami alveolares superiores anteriores	Anterior superior dental
Ganglion sphenopalatinum	Meckel's ganglion
N. palatinus medius	External palatine nerve
N. mandibularis	Inferior maxillary nerve
Nervus spinosus	Recurrent nerve
N. alveolaris inferior	Inferior dental
N. abducens	Sixth nerve
N. facialis	Seventh nerve
N. intermedius	Pars intermedia of Wrisberg
N. acusticus	Eighth or auditory nerve
Ganglion superius	Jugular ganglion of 9th nerve
N. recurrens	Recurrent laryngeal nerve
Ganglion jugulare	Ganglion of root of vagus
Ganglion nodosum	Ganglion of trunk of vagus
Plexus œsophageus anterior / Plexus œsophageus posterior	Plexus gulæ
Nervus accessorius	Spinal accessory
Ramus internus	Accessory portion of spinal accessory nerve
Ramus externus	Spinal portion

Spinal Nerves.

Rami posteriores	Posterior primary divisions
Rami anteriores	Anterior primary divisions
N. cutaneus colli	Transverse superficial cervical nerve
Nn. supraclaviculares anteriores	Suprasternal nerves
Nn. supraclaviculares medii	Supraclavicular nerves
Nn. supraclaviculares posteriores	Supra-acromial nerves
N. dorsalis scapulæ	Nerve to the rhomboids
Nn. intercosto-brachiales	Intercosto-humeral nerves
N. thoracalis longus	Nerve of Bell
N. thoraco-dorsalis	Long subscapular nerve
N. cutaneus brachii medialis	Lesser internal cutaneous nerve
N. cutaneus brachii lateralis	Cutaneous branch of circumflex nerve
Fasciculus lateralis	Outer cord (of plexus)
Fasciculus medialis	Inner cord
N. cutaneus antibrachii lateralis	Cutaneous branch of musculo-cutaneous nerve
N. cutaneus antibrachii medialis	Internal cutaneous nerve
Ramus volaris	Anterior branch
Ramus ulnaris	Posterior branch
N. axillaris	Circumflex nerve

B.N.A. Terminology.	Old Terminology.
N. interosseus volaris	Anterior interosseous
Ramus palmaris N. mediani	Palmar cutaneous branch of the median nerve
Nn. digitales volares proprii	Collateral palmar digital branches of median nerve
Ramus dorsalis manus	Dorsal cutaneous branch of ulnar nerve
Ramus cutaneus palmaris	Palmar cutaneous branch of ulnar nerve
N. radialis	Musculo-spiral nerve
N. cutaneus brachii posterior	Internal cutaneous branch of musculo-spiral nerve
N. cutaneus antibrachii dorsalis	External cutaneous branches of musculo-spiral nerve
Ramus superficialis	Radial nerve
N. interosseus dorsalis	Posterior interosseous nerve
Nn. digitales dorsales	Dorsal digital nerves
N. ilio-hypogastricus	Ilio-hypogastric nerve
Ramus cutaneus lateralis	Iliac branch of ilio-hypogastric nerve
Ramus cutaneus anterior	Hypogastric branch of ilio-hypogastric nerve
N. genito-femoralis	Genito-crural nerve
N. lumbo-inguinalis	Crural branch of genito-crural nerve
N. spermaticus externus	Genital branch of genito-crural nerve
N. cutaneus femoris lateralis	External cutaneous nerve
N. femoralis	Anterior crural nerve
N. saphenus	Long saphenous nerve
Ramus infrapatellaris	Patellar branch of long saphenous nerve
N. ischiadicus	Great sciatic nerve
N. peronæus communis	External popliteal nerve
Ramus anastomoticus peronæus	Nervus communicans fibularis
N. peronæus superficialis	Musculo-cutaneous nerve
N. peronæus profundus	Anterior tibial nerve
N. tibialis	Internal popliteal and posterior tibial nerves
N. cutaneus suræ medialis	Nervus communicans tibialis
N. suralis	Short saphenous nerve
N. plantaris medialis	Internal plantar
N. plantaris lateralis	External plantar
N. pudendus	Pudic nerve

THE HEART AND BLOOD-VESSELS

Heart.

Atrium	Auricle
Auricula cordis	Auricular appendix
Incisura cordis	Notch at apex of heart
Trabeculæ carneæ	Columnæ carneæ
Tuberculum intervenosum	Intervenous tubercle of Lower
Sulcus longitudinalis anterior	Anterior interventricular groove
Sulcus coronarius	Auriculo-ventricular groove
Limbus fossæ ovalis	Annulus ovalis
Valvula venæ cavæ	Eustachian valve
Valvula sinus coronarii	Valve of Thebesius

Arteries.

Sinus aortæ	Sinuses of Valsalva
A. profunda linguæ	Ranine artery
A. maxillaris externa	Facial artery
A. alveolaris inferior	Inferior dental artery
Ramus meningeus accessorius	Small meningeal artery
A. buccinatoria	Buccal artery
A. alveolaris superior posterior	Posterior superior dental artery
Aa. alveolares superiores anteriores	Anterior superior dental arteries
Ramus carotico-tympanicus	Tympanic branch of int. carotid
A. chorioidea	Anterior choroidal artery
A. auditiva interna	Auditory artery
Rami ad pontem	Transverse arteries (branches of basilar artery)
A. pericardiaco-phrenica	Arteria comes nervi phrenici
Rami intercostales	Anterior intercostal arteries
Truncus thyreo-cervicalis	Thyroid axis
A. transversa scapulæ	Suprascapular artery
A. intercostalis suprema	Superior intercostal
A. transversa colli	Transversalis colli
A. thoracalis suprema	Superior thoracic artery
A. thoraco-acromialis	Acromio-thoracic artery
A. thoracalis lateralis	Long thoracic artery
A. circumflexa scapulæ	Dorsalis scapulæ
A. profunda brachii	Superior profunda
A. collateralis radialis	Anterior branch of superior profunda
A. collateralis ulnaris superior	Inferior profunda
A. collateralis ulnaris inferior	Anastomotica magna
Ramus carpeus volaris	Anterior radial carpal

B.N.A. Terminology.	Old Terminology.
Ramus carpeus dorsalis	Posterior radial carpal
Aa. metacarpeæ dorsales	Dorsal interosseous arteries
A. volaris indicis radialis	Radialis indicis
Arcus volaris superficialis	Superficial palmar arch
Arcus volaris profundus	Deep palmar arch
A. interossea dorsalis	Posterior interosseous artery
A. interossea recurrens	Posterior interosseous recurrent artery
A. interossea volaris	Anterior interosseous artery
Ramus carpeus dorsalis	Posterior ulnar carpal
Ramus carpeus volaris	Anterior ulnar carpal
Aa. digitales volares communes	Palmar digital arteries
Aa. digitales volares propriæ	Collateral digital arteries
Arteriæ intestinales	Intestinal branches of sup. mesenteric
A. suprarenalis media	Middle capsular artery
A. hypogastrica	Internal iliac artery
A. umbilicalis	Obliterated hypogastric
A. pudenda interna	Internal pudic artery
A. epigastrica inferior	Deep epigastric artery
A. spermatica externa	Cremasteric artery
Aa. pudendæ externæ	Superficial and deep external pudic arteries
A. circumflexa femoris medialis	Internal circumflex artery
A. circumflexa femoris lateralis	External circumflex artery
A. genu suprema	Anastomotica magna
A. genu superior lateralis	Superior external articular artery
A. genu superior medialis	Superior internal articular artery
A. genu media	Azygos articular artery
A. genu inferior lateralis	Inferior external articular artery
A. genu inferior medialis	Inferior internal articular artery
A. malleolaris anterior lateralis	External malleolar artery
A. malleolaris anterior medialis	Internal malleolar artery
A. peronæa	Peroneal artery
Ramus perforans	Anterior peroneal artery
A. malleolaris posterior lateralis	Posterior peroneal artery
A. malleolaris posterior medialis	Internal malleolar artery
Rami calcanei laterales	External calcanean artery
Rami calcanei mediales	Internal calcanean artery
A. plantaris medialis	Internal plantar artery
A. plantaris lateralis	External plantar artery
Aa. metatarsæ plantares	Digital branches
Aa. digitales plantares	Collateral digital branches

Veins.

V. cordis magna	Great cardiac vein
V. obliqua atrii sinistri	Oblique vein of Marshall
Lig. venæ cavæ sinistræ	Vestigial fold of Marshall
Vv. cordis minimæ	Veins of Thebesius
Sinus transversus	Lateral sinus
Confluens sinuum	Torcular Herophili
Plexus basilaris	Basilar sinus
Sinus sagittalis superior	Superior longitudinal sinus
Sinus sagittalis inferior	Inferior longitudinal sinus
Sinus spheno-parietalis	Sinus alæ parvæ
V. cerebri internæ	Veins of Galen
V. cerebri magna	Vena magna Galeni
V. terminalis	Vein of the corpus striatum
V. basalis	Basilar vein
V. transversa scapulæ	Suprascapular vein
V. thoraco-acromialis	Acromio-thoracic vein
Vv. transversæ colli	Transversalis colli veins
V. thoracalis lateralis	Long thoracic vein
V. azygos	Vena azygos major
V. hemiazygos	Vena azygos minor inferior
V. hemiazygos accessoria	Vena azygos minor superior
V. hypogastrica	Internal iliac vein
V. epigastrica inferior	Deep epigastric vein
V. saphena magna	Internal saphenous vein
V. saphena parva	External saphenous vein

Lymphatics.

Cisterna chyli	Receptaculum chyli

THE VISCERA.

Digestive Apparatus.

Arcus glosso-palatinus	Anterior pillar of fauces
Arcus pharyngo-palatinus	Posterior pillar of fauces
Gl. lingualis anterior	Gland of Nuhn
Ductus submaxillaris	Wharton's duct
Gl. parotis accessoria	Socia parotidis
Ductus parotideus (Stenonis)	Stenson's duct
Dentes præmolares	Bicuspid teeth
Dens serotinus	Wisdom tooth
Papillæ vallatæ	Circumvallate papillæ
Recessus pharyngeus	Lateral recess of pharynx
Tela submucosa	Pharyngeal aponeurosis
Plicæ circulares	Valvulæ conniventes
Gl. intestinales	Crypts of Lieberkuhn
Valvula coli	Ileo-cæcal valve
Columnæ rectales	Columns of Morgagni

B.N.A. Terminology.	Old Terminology.
Plicæ transversales recti	Valves of Houston
Valvula spiralis	Valve of Heister
Noduli lymphatici aggregati (Peyeri)	Peyer's patches
Intestinum jejunum	Jejunum
Intestinum ileum	Ileum
Noduli lymphatici lienales (Malpighii)	Malpighian corpuscles

Respiratory Apparatus.

Larynx

Prominentia laryngea	Adam's apple
Incisura thyreoidea superior	Superior thyroid notch
M. ary-epiglotticus	Aryteno-epiglottidean muscle
M. vocalis	Internal thyro-arytenoid muscle
M. thyreo-epiglotticus	Thyro-epiglottidean muscle
Appendix ventriculi laryngis	Laryngeal sac
Plica vocalis	True vocal cord
Plica ventricularis	False vocal cord
Ligamentum ventriculare	Superior thyro-arytenoid ligament
Ligamentum vocale	Inferior thyro-arytenoid ligament
Glottis	Glottis vera
Rima vestibuli	Glottis spuria
Cartilago thyreoidea	Thyroid cartilage
Membrana hyothyreoidea	Thyro-hyoid membrane
Cartilago corniculata (Santorini)	Cartilage of Santorini
Tuberculum epiglotticum	Cushion of epiglottis
Pars intermembranacea (rimæ glottidis)	Glottis vocalis
Pars intercartilaginea (rimæ glottidis)	Glottis respiratoria
Conus elasticus (membranæ elasticæ laryngis)	Crico-thyroid membrane
Glandula thyreoidea	Thyroid gland
Glomus caroticum	Intercarotid gland or body

Nose

Concha nasalis suprema (Santorini)	Highest turbinate bone
Concha nasalis superior	Superior turbinate bone
Concha nasalis media	Middle turbinate bone
Concha nasalis inferior	Inferior turbinate bone

Urogenital Apparatus.

Corpuscula renis	Malpighian corpuscles
Paradidymis	Organ of Giraldés
Appendix testis	Hydatid of Morgagni (male)
Ductus deferens	Vas deferens
Gl. urethrales	Glands of Littré
Glandula bulbo-urethralis (Cowperi)	Cowper's gland
Folliculi oophori vesiculosi	Graafian follicles
Cumulus oophorus	Discus proligerus
Tuba uterina	Fallopian tube
Epoophoron	Parovarium
Appendices vesiculosi	Hydatids of Morgagni (female)
Ductus epoophori longitudinalis	Gärtner's duct
Orificium internum uteri	Internal os (of uterus)
Orificium externum	External os
Processus vaginalis	Canal of Nuck
Glandula vestibularis major	Bartholin's gland

Peritoneum.

Bursa omentalis	Lesser peritoneal sac
Foramen epiploicum	Foramen of Winslow
Lig. phrenico-colicum	Costo-colic ligament
Excavatio recto-uterina (cavum Douglasi)	Pouch of Douglas
Lig. gastro-lienale	Gastro-splenic omentum

THE SENSE ORGANS.

The Eye.

Sclera	Sclerotic coat
Lamina elastica anterior (Bowmani)	Bowman's membrane
Lamina elastica posterior (Descemeti)	Descemet's membrane
Spatia anguli iridis	Spaces of Fontana
Angulus iridis	Irido-corneal junction
Zonula ciliaris	Zonule of Zinn
Septum orbitale	Palpebral ligament
Fascia bulbi	Capsule of Tenon
Commissura palpebrarum lateralis	External canthus
Commissura palpebrarum medialis	Internal canthus
Tarsus superior	Superior tarsal plate
Tarsus inferior	Inferior tarsal plate
Lig. palpebrale mediale	Internal tarsal ligament
Raphe palpebralis lateralis	External tarsal ligament
Tarsal glands	Meibomian glands

The Ear.

Canalis semicircularis lateralis	External semicircular canal
Ductus reuniens	Canalis reuniens
Ductus cochlearis	Membranous cochlea
Recessus sphæricus	Fovea hemispherica
Recessus ellipticus	Fovea hemi-elliptica
Paries jugularis	Floor of tympanum
Paries labyrinthica	Inner wall
Fenestra vestibuli	Fenestra ovalis
Fenestra cochleæ	Fenestra rotunda
Paries mastoidea	Posterior wall
Antrum tympanicum	Mastoid antrum
Paries carotica	Anterior wall
Processus lateralis	Processus brevis (of malleus)
Processus anterior	Processus gracilis

TEXT-BOOK OF ANATOMY.

INTRODUCTION.

ANATOMY is a comprehensive term, which includes several closely related branches of study. Primarily it is employed to indicate the study of the parts which build up the body, and the relationship which these present to each other. But the structure of an individual is not the same at all stages of its life, for many changes occur during the period of its existence. The ovum and the spermatozoon, which are the starting-points of every individual, are very different from the finished organism as represented by the adult, and the series of changes through which the organism passes until its structure is perfected and full growth is attained constitute the phenomena of **development.** The general term "development" includes not only the various and striking structural changes which occur during the intra-uterine life of the individual, to the study of which the term **embryology** is more specially applied, but also many growth processes which occur after birth, such as the later stages in the ossification and growth of the bones, the eruption of the two series of teeth, the adjustment of the vascular system to its new requirements, etc. The actual observation of the processes by which the parts of the body are gradually formed, and of the structural arrangements by means of which a temporary connexion is established between the ovum and the mother, through which an interchange of nutritive and other matters between the two takes place, renders embryology one of the most interesting of all the departments of anatomy. The term **ontogeny** also is used to denote the development of the individual. There is, however, another form of development, slower, but just as certain in its processes, which affects not only the individual, but all the members of the animal group to which it belongs. The theory of descent or evolution leads us to believe that between man of the present day and his remote ancestors there is a wide structural gap, which, if the geological record were perfect, would be seen to be completely occupied by long-lost intermediate forms. In the process of evolution, therefore, structural changes have gradually taken place which have modified the entire race. These evolutionary phases constitute the ancestral history or **phylogeny** of the race. Ontogeny and phylogeny are intertwined in a remarkable manner, and present certain extraordinary relationships. In other words, the ancestral evolutionary development appears to be so stamped upon an individual that it repeats certain of the phylogenetic stages with more or less clearness during the process of its own individual development. Thus, at an early period in the embryology of man evanescent gill-pouches appear which are comparable with those of a fish, whilst a study of the development of his heart shows that it passes through transitory structural conditions similar, in many respects, to the permanent

conditions of the heart in certain of the lower animals. It is in connexion with this that the phrase has arisen that every animal in its individual development or ontogeny climbs up its own genealogical tree—a saying which, taking it even in the broadest sense, is only partially true.

The broader conceptions of anatomy, which are obtained by taking a general survey of the structural aspects of the entire animal kingdom, constitute **morphology**. The morphologist investigates the laws of form and structure, and in his generalisations he gives attention to detail only in so far as this is necessary for the proper establishment of his views. The knowledge of anatomy which is required by the student of medicine is different. It is essentially one of detail, and often details important from the practical and utilitarian points of view have little or no morphological value. This want of balance in the interest attached to anatomical facts, according to the aspect from which they are examined, so far from being unfortunate, affords the teacher the means of making the study of anatomy at once fascinating and instructive. Almost every fact which is brought under the notice of the student can be accompanied by a morphological or a practical application. These possibilities of application lighten a study which, presented to the student of medicine in any other way, would be at once dry and tedious.

Certain terms employed in morphology require early and definite explanation. These are homology, serial homology, and homoplasy. The same organ repeated in two different animals is said to present a case of **homology**. But the morphological identity between the two organs must be proved beyond dispute before the homology between them can be allowed. In deciding the identity the great and essential test is that the two organs in question should have a similar developmental origin. Thus, the fore-limb of a quadruped is homologous with the upper limb of man; the puny collar-bone of a tiger, the fibrous thread which is the only representative of this bone in the horse, and the strongly marked clavicle of the ape or man, are all, strictly speaking, homologous with one another. Homologous organs in different animals usually occupy a similar position and possess a similar structure, but not invariably so. It is not uncommon for a muscle to wander somewhat from its original position, and many cases could be quoted in which parts have become completely transformed in structure, either from disuse or for the purpose of meeting some special demand in the animal economy. In the study of the muscles and ligaments instances of this will be brought under the notice of the reader.

Often organs which perform totally different functions are yet perfectly homologous. Thus the wing of a bat or the wing of a bird, both of which are subservient to flight, are homologous with the upper limb of man, the office of which is the different one of prehension. Identity or correspondence in the function performed by two organs in two different animals is not taken into consideration in deciding questions of homology. The gills of a fish and the lungs of a higher vertebrate perform very much the same physiological office, and yet they are not homologous. The term **analogy** is often used to express functional correspondence of this kind.

In the construction of vertebrates and certain other animal groups a series of similar parts are repeated along a longitudinal axis, one after the other. Thus the series of vertebræ which build up the backbone, the series of ribs which gird round each side of the chest, the series of intercostal muscles which fill up the intervals between the ribs, the series of nerves which arise from the brain and spinal medulla, are all examples of this. An animal exhibiting such a condition of parts is said to present the **segmental type** of organisation. In the early stages of development this segmentation is much more strongly marked, and is to be seen in parts which

subsequently lose all trace of such a subdivision. The parts thus repeated are said to be **serially homologous**. But there are other instances of serial homology besides those which are manifestly produced by segmentation. The upper limb is serially homologous with the lower limb: each is composed of parts which, to a large extent, are repeated in the other, and the correct adjustment of this comparison between the several parts of the upper and lower limbs constitutes one of the most difficult and yet interesting problems of morphology.

Homoplasy is a term which has been introduced to express a form of correspondence between organs in different animals which cannot be included under the term homology. Two animal groups, which originally have sprung from the same stem-form, may independently develop a similar structural character which is altogether absent in the ancestor common to both. Thus the common ancestor of man and the carnivora in all probability possessed a smooth brain, and yet the human brain and the carnivore brain are both richly convoluted. Not only this, but certain anatomists seek to reconcile the convolutionary pattern of the one with the convolutionary pattern of the other. What correspondence there is does not, in every instance, constitute a case of homology, because there is not in every case a community of origin. Correspondence of this kind is included under the term "homoplasy." Another example is afforded by the heart of the mammal and that of the bird. In both of these groups the ventricular portion of the heart consists of a right and a left chamber, and yet the ventricular septum in the one is not homologous with the corresponding septum in the other, because the common ancestor from which both have sprung possessed a heart with a single ventricular cavity, and the double-chambered condition has been a subsequent and independent development in the two groups.

Systematic Anatomy.—The human body is composed of a combination of several systems of organs, and the several parts of each system not only present a certain similarity in structure, but also fulfil special functions. Thus there are—

1. The *skeletal system*, composed of the bones and certain cartilaginous and membranous parts associated with them, the knowledge of which is known as **osteology.**

2. The *articulatory system*, which includes the joints or articulations, the knowledge of which is termed **arthrology.**

3. The *muscular system*, comprising the muscles, the knowledge of which constitutes **myology.**

4. The *nervous system*, in which are included the brain, the spinal medulla, the ganglia of the spinal and cerebral nerves, the sympathetic ganglia, and the various nerves proceeding from and entering these. The knowledge of these parts is expressed by the term **neurology.** In this system the organs of sense may also be included.

5. The *blood vascular* and *lymphatic system*, including the heart, blood-vessels, the lymph vessels, and the lymph glands. **Angeiology** is the term applied to the knowledge of this system.

6. The *respiratory system*, in which we place the lungs, windpipe, and larynx.

7. The *digestive system*, which consists of the alimentary canal and its associated glands, and parts such as the tongue, teeth, liver, pancreas, etc.

8. The *urogenital system*, composed of the urinary organs and the reproductive organs—the latter differing in the two sexes.

The term **splanchnology** denotes the knowledge of the organs included in the respiratory, digestive, and urogenital systems.

9. The *integumentary system* consists of the skin, nails, hair, etc. The knowledge of this system is termed **dermatology.**

The numerous organs which form the various systems are themselves built up of tissues, the ultimate elements of which can be studied only by the aid of the microscope. The knowledge of these elements and of the manner in which they are grouped together to form the various tissues of the body forms an important branch of anatomy, which is termed **histology**.

The structure of the human body may be studied in two different ways. The several parts may be considered with reference to their relative positions, either as they are met with in the course of an ordinary dissection, or as they are seen on the surface of a section through the body. This is the *topographical method*. On the other hand, the several systems of organs may be treated separately and in sequence. This constitutes the *systematic method*, and it is the plan which is adhered to in this treatise.

Descriptive Terms.—Anatomy is a descriptive science founded on observation, and in order that precision and accuracy may be attained it is necessary that we should be provided with a series of well-defined descriptive terms. It must

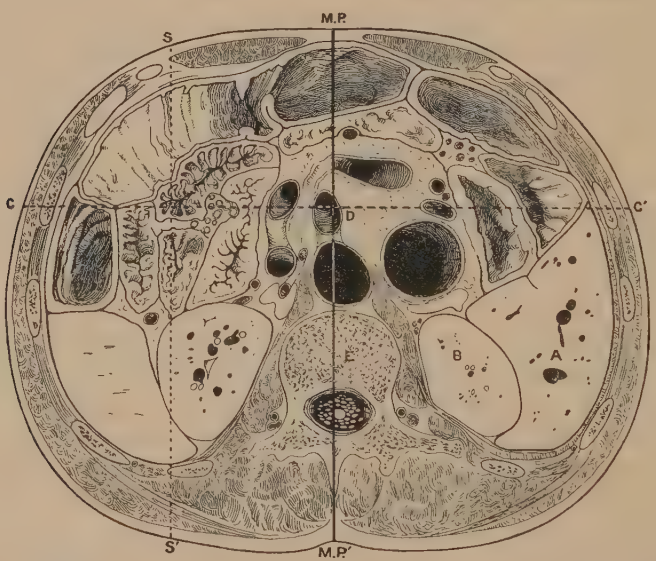

Fig. 1.—Horizontal Section through the Trunk at the Level of the First Lumbar Vertebra.

be clearly understood that all descriptions are framed on the supposition that the body is in the erect position, with the arms by the side, and the hands held so that the palms look forwards and the thumbs laterally. An imaginary plane of section, passing longitudinally through the body so as to divide it accurately into a right and a left half, is called the **median plane**, Fig. 1 (M.P.). When the right and left halves of the body are studied it will be found that both are to a large extent formed of similar parts. The right and left limbs are alike; the right and left halves of the brain are the same; there are a right and a left kidney and a right and a left lung, and so on. So far the organs are said to be **symmetrically** arranged. But still a large amount of **asymmetry** may be observed. Thus, the chief bulk of the liver lies to the right side of the median plane, and the spleen is an organ which belongs wholly to the left half of the body. Indeed, it is well to state that perfect symmetry never does exist. There always will be, and always must be, a certain want of balance between symmetrically placed parts of the body. Thus the right upper limb is, as a rule, constructed upon a heavier and more massive plan than the left, and even in those organs where the symmetry appears most

perfect, as for instance the brain and spinal medulla, it requires only a closer study to reveal many points of difference between the right and left halves.

The line on the front of the body along which the median plane reaches the surface is termed the **anterior median line**; whilst the corresponding line behind is called the **posterior median line.**

It is convenient to employ other terms to indicate other imaginary planes of section through the body. The term **sagittal**, therefore, is used to denote any plane which cuts through the body along a path which is parallel to the median plane (S S′); and the term **coronal** or **frontal** is given to any vertical plane which passes through the body in a path which cuts the median plane at right angles (C C′). The term **horizontal**, as applied to a plane of section, requires no explanation.

Any structure which lies nearer to the median plane than another is said to be **medial** to it; and any structure placed further from the median plane than another is said to lie **lateral** to it. Thus in Fig. 1, A is lateral to B; whilst B is medial to A.

The terms internal and external are applied to the walls of hollow cavities or organs; thus, the ribs possess external surfaces, that is, surfaces away from the cavity of the thorax, and internal surfaces adjacent to the cavity.

The terms **anterior** and **ventral** are synonymous, and are used to indicate a structure (D) which lies nearer to the front or ventral surface of the body than another structure (E) which is placed nearer to the back or dorsal surface of the body, and which is thus said to be **posterior** or **dorsal.** In some respects it would be well to discard the terms "anterior" and "posterior" in favour of "ventral" and "dorsal," seeing that the former are only applicable to man in the erect attitude, and cannot be applied to an animal in the prone or quadrupedal position. They are, however, so deeply ingrained into the descriptive language of the human anatomist that they cannot be entirely discarded. A similar objection may be raised to the terms **superior** and **inferior**, which are employed to indicate the relative levels at which two structures lie with reference to the upper and lower ends of the body. The equivalent terms of **cephalic** or **cranial** and **preaxial** are, therefore, sometimes used in place of "superior," and **caudal** and **postaxial** in place of "inferior."

The terms **proximal** and **distal** should be applied only in the description of the limbs. They denote relative nearness to or distance from the root of the limb. Thus, the hand is distal to the forearm, whilst the arm or brachium is proximal to the forearm.

HUMAN EMBRYOLOGY.

By A. H. Young and Arthur Robinson.

Rewritten by Arthur Robinson.

The **ontogenetic** or **developmental history** of every human individual is separable into two main periods, **pre-natal** and **post-natal**.

It is to the knowledge of the phenomena of the earlier or pre-natal period that the term **human embryology** is applied, and, as pre-natal development takes place in an organ called the uterus, it is frequently spoken of as *intra-uterine development*.

The period of pre-natal development extends through nine lunar months, and may be divided into three sub-periods: (1) the **pre-embryonic period**, during which the **zygote**, from which the embryo is formed, shows no definite separation into embryonic and non-embryonic portions. That period possibly lasts about fourteen days; (2) the **period of the embryo**, in which the zygote is definitely separated into embryonic and non-embryonic portions, but the embryonic part has not yet assumed a clearly human form. The embryonic period terminates at the end of the second month; (3) the **fœtal period**, which commences at the end of the second month, when the embryo assumes a definitely human form and is called, thenceforth, a fœtus. The fœtal period ends at birth, when the fœtus becomes a child and *post-natal development* commences.

Only the general phenomena of the pre-natal period of development are considered in this section; the details of the pre- and post-natal development of the various organs and systems will be dealt with in the sections devoted to the descriptions of their adult conditions.

THE STRUCTURE OF ANIMAL CELLS.

The human body is formed by the multiplication and differentiation of animal cells, therefore it is essential that the student should possess a knowledge of the main features and capabilities of such cells before he commences the study of the details of human embryology.

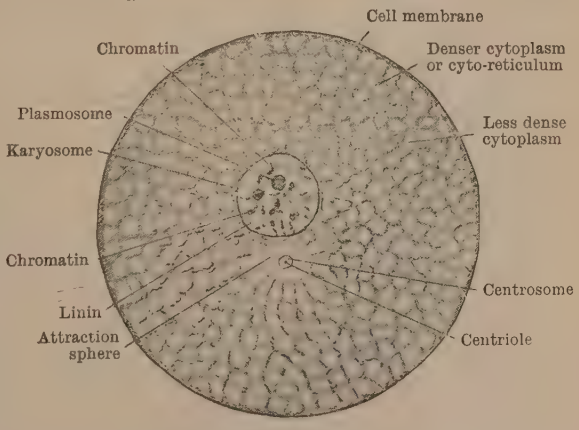

Fig. 2.—Diagram of an Animal Cell.

Animal cells differ from each other in minor points of structure, in association with the positions they occupy and the functions they perform; nevertheless, they all possess some common and essential structural features, and, in the younger stages of their history, some common capabilities.

The constituent parts of a typical animal cell are:—

The **cell body** surrounded by the **cell membrane** and containing:—

(*a*) The **nucleus** with its **nucleolus** or **nucleoli**;
(*b*) The **centrosome** with one or more **centrioles**;
(*c*) **Chondriosomes.**

In addition there may be other substances, in the form of granules, or globules, or both, which are sometimes temporary and sometimes permanent parts of the cell.

All the essential parts of the cell consist of a substance called **protoplasm.**

In its simplest form protoplasm is the semifluid, viscous, irritable, and contractile substance which forms the "physical basis of life." It consists of C., H., N., O., and S., combined together, in different ways and in differing proportions, to form various modifications of protoplasm which possess definite physical and chemical characteristics, and which receive, therefore, different names.

The Cell Body.—The protoplasm of the cell body is called **cytoplasm.** It consists of two fluid or semi-fluid substances of different densities, of which one, the more dense and less abundant, forms thin films round the globules of the less dense and more abundant substance. When examined under the microscope the films of the more dense substance appear as a network which encloses the globules of the less dense substance, and they are frequently spoken of as the *cyto-reticulum,* whilst the less dense portions are called either *cytolymph* or *hyaloplasm*; but as both parts are either fluid or semi-fluid, neither of them offers an obstruction to the passage of the other contents of the cell from one position to another.

The Cell Membrane.—Most animal cells, with the exception of leucocytes (white blood corpuscles), are surrounded by a thin and more resistant layer of substance called the cell membrane. It is either a condensation of the cytoplasm or it is secreted by the cytoplasm.

The Nucleus.—The constituent parts of the nucleus are (1) chromatin, (2) linin, (3) karyoplasm, and (4) the nuclear membrane. It contains one or more nucleoli which may be (*a*) karyosomes or (*b*) plasmosomes or both.

The **chromatin** consists of granules which are easily and strongly stainable. They are embedded in or connected with the linin.

The **linin** forms a network in which the chromatin granules are usually embedded. It is either unstainable or very slightly stainable, and is therefore frequently spoken of as *achromatin.*

The **karyoplasm** is a more fluid protoplasm which occupies the interstices of the linin reticulum.

The Nucleoli.—(*a*) The *karyosomes* usually lie in the nodes of the linin reticulum. They stain like chromatin and are probably aggregated nodules of that substance. (*b*) The *plasmosomes* are globules of a form of protoplasm called *plastin,* whose reactions to stains are not the same as those of chromatin. One is usually present, but there may be two or more. They lie in the karyoplasm.

Some nucleoli appear to be compounds of chromatin and plastin, and are therefore called *karyo-plasmosomes.*

The **nuclear membrane** surrounds the nucleus, except at certain periods of cell division, but whether it is formed from the nuclear substance or from the surrounding cytoplasm is uncertain.

The **centrosome** is a small deeply staining spherical body which lies in the cytoplasm, usually in the immediate neighbourhood of the nucleus. In its interior there are usually one or more still more deeply staining particles called **centrioles.**

The cytoplasm in a small area around the centrosome is often visibly different from the remainder of the cell protoplasm, usually clearer. This specialised area is known as the *attraction sphere.*

The **chondriosomes,** which themselves consist of minute particles called *mitochondria,* are believed to play very important parts in the life-history of the cells, but their exact functions are not yet definitely known. They appear as fine rods or filaments which are embedded in the denser parts of the cytoplasm.

Their reactions to some stains are very similar to those of chromatin, but in other respects, especially in their behaviour under the influence of organic acids, such as acetic acid, they differ widely from chromatin.

In addition to the various parts already noted, many cells, at some or all periods of their existence, contain (1) granules of substance formed by the activity of the cytoplasm from materials which it absorbs from its surroundings; (2) vacuoles filled with fluid; (3) granules or masses of lipoid or fatty substance;

and (4) particles or small masses of chromatic substance which have been extruded from the nucleus and which are called *chromidia*.

The various structures mentioned are found in cells, in the positions indicated, in the so-called *resting stage*, which is the period intervening between any two periods of cell division. It is during the resting stage that cells grow and perform the functions deputed to them.

THE LIFE-HISTORY AND CAPABILITIES OF ANIMAL CELLS.

Every animal cell is formed by the division of a pre-existing cell called the *mother cell*. The mother cell divides into two equal parts—the *daughter cells*, each of which, under ordinary conditions, possesses all the capabilities of its mother.

Reproduction of Cells.—Ordinary tissue cells increase in number by the division of the pre-existing cells into equal parts, and each part possesses similar capabilities. Every new cell has a definite life-history; it grows, performs its proper functions, and ceases to exist, either by dividing into two daughter cells, or by dying and breaking up into fragments which disappear.

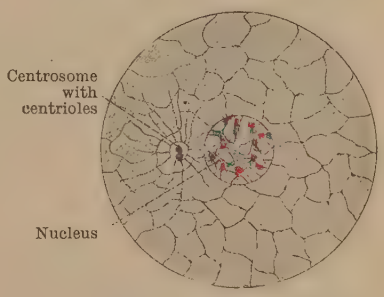

FIG. 3.—SCHEMA OF ANIMAL CELL IN RESTING STAGE.

Whilst the multiplication rate exceeds the death-rate in any given tissue or organ, that tissue or organ grows. When the multiplication rate and the death-rate are equal, the tissue or organ is in a state of equilibrium. As soon as the death-rate exceeds the multiplication rate, decay and atrophy set in; and when the decay and atrophy have proceeded to such an extent that an important tissue or organ can no longer perform its proper functions, general death ensues.

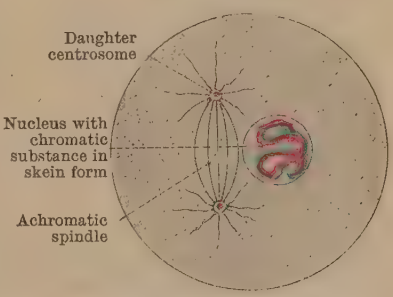

FIG. 4.—SCHEMA OF ANIMAL CELL IN EARLY PART OF PROPHASE OF HOMOTYPE MITOSIS.

General decay and death are, therefore, the natural results of the loss of multiplication power of the cells of the body, but life may persist after multiplication power is lost, so long as the cells last produced retain their capabilities, and death may result whilst multiplication power of the cells is retained, if the newly produced cells are incapable of performing their proper functions. Nevertheless, speaking generally, it may be said that cell multiplication is a vital necessity, and it takes place in two ways—(1) by **amitotic** and (2) by **mitotic division** of pre-existing cells.

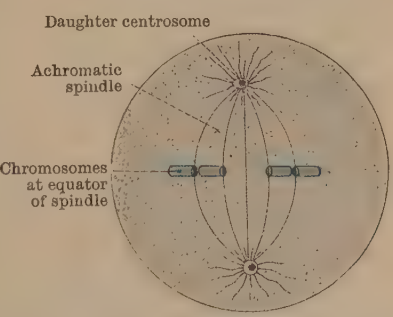

FIG. 5.—SCHEMA OF ANIMAL CELL AT COMPLETION OF PROPHASE OF HOMOTYPE MITOSIS.

Amitotic Division.—The phenomena of amitotic division of cells are much simpler, so far as they are known, than those of mitotic division. First the nucleus is divided by an advancing constriction; thereafter, the cell body is constricted and divided, and so two similar daughter cells are formed.

Whether the daughter cells produced by amitotic division can live and in their turn divide by amitotic or mitotic division is not known, therefore it is uncertain whether or not the process of amitosis is degenerative or formative. At all events, so far as information is at present available, the process of amitosis is relatively unimportant as compared with that of mitosis.

Mitotic Division.—Mitosis or mitotic division is the more common, the more important and the more complicated method of cell division.

There are, however, two forms of mitosis, *homotype* and *heterotype*. Of the two homotype mitosis is so much the more common that it may be regarded as the usual form, for heterotype mitosis, which is also known as *meiosis*, is limited to one of the two cell divisions which occur during the maturation of the germ cells, though it is said to have been met with in the cell divisions which occur during the growth of some malignant tumours.

Homotype Mitosis. — The phenomena of homotype mitosis occur in four phases termed (1) the prophase, (2) the metaphase, (3) the anaphase, and (4) the telophase.

The Prophase.—During the prophase the centrosome and the nucleus undergo very obvious changes.

The centrosome divides into two daughter centrosomes, of which one passes to one and the other to the opposite side of the nucleus.

At the same time a spindle of achromatic fibrils appears, and extends from one daughter centrosome to the other.

In some cases the achromatic spindle is formed entirely outside the nucleus (Fig. 4); but, more often, it passes through the nucleus and is derived from the linin reticulum of the nucleus.

The peripheral fibrils of the spindle are the mantle fibrils, those which form the core of the spindle are the central fibrils.

At the same time fibrils radiate peripherally from the daughter centrosomes into the surrounding cytoplasm, and the whole structure, so formed, the daughter centrosomes, the spindle, and the radiating fibrils constitute, collectively, the *achromatic figure.*

The nuclear transformation, however, affects not only the linin of the nucleus, but also the nucleoli, the nuclear membrane, and the chromatin.

The nucleoli, whether they are karyosomes, or plasmosomes, or both, disappear; sometimes after passing from the nucleus into the cytoplasm, but, more commonly, independently of such migration.

The chromatin, which during the resting period is dispersed in the linin network, in what appears to be an irregular and inconstant manner, is aggregated, at the commencement of the prophase, into small nodules, called *chromomeres*, which are strung together on the linin network to form a series of nodulated filaments which are called **chromosomes.**

The filamentous chromosomes of the early prophase are bent, twisted, and intimately intermingled, so that, for a time, they simulate a convoluted skein (Fig. 4), and, indeed, in some cases the individual filaments are united end to end. Such a condition is, however, but a transitory connection of the individual chromosomes which soon reassert their independence.

Gradually the thread-like chromosomes become shorter until the chromomeres are so compressed together that they are no longer distinguishable from one another.

The process of shortening is called *synizesis.*

When the shortening is completed the chromosomes appear in the form of rods, hooks, or V-shaped bars, of varying size, which are gathered together at the equator of the achromatic spindle, where they form, collectively, the *equatorial plate* of the prophase (Fig. 5). At this period, which is the end of the prophase, each chromosome is attached at some point of its extent to one or more of the mantle fibrils of the achromatic spindle.

At the end of the prophase the nucleus, as such, and the nucleoli have disappeared, and have been replaced by an achromatic spindle with an equatorial plate of chromosomes.

The Metaphase.—During this phase each chromosome divides into two equal daughter chromosomes (Fig. 6).

The division commences at the point where the chromosome is attached to the achromatic spindle and, as it proceeds, it becomes evident that one daughter chromosome is attached by one or more of the mantle fibrils of the achromatic spindle to one centrosome and the other to the opposite centrosome.

When the division is completed the metaphase is ended and two daughter equatorial plates are present.

The division of the chromosomes is often indicated in the prophase by the appearance of fine clear lines which run through the long axes of the chromosomes, but it occurs during the metaphase.

The Anaphase.—In the anaphase the daughter chromosomes of each daughter equatorial plate move along the mantle fibrils of the achromatic spindle towards the corresponding daughter centrosome, and, as they approach the immediate neighbourhood of the daughter centrosome, the body of the cell begins to be divided by a circular constriction, which appears at the level of the equator of the achromatic spindle. The appearance of the constriction indicates the end of the anaphase and the commencement of the telophase (Fig. 7).

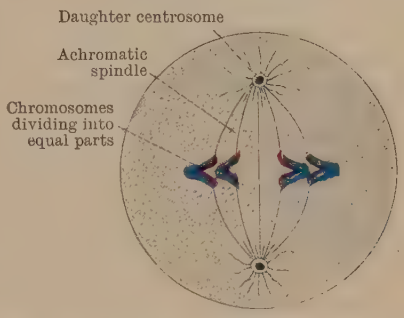

FIG. 6.—SCHEMA OF ANIMAL CELL IN METAPHASE OF HOMOTYPE MITOSIS.

The Telophase.—In this terminal period of mitotic cell division the circular constriction of the cell body deepens until the cell is divided into two daughter cells.

As the division of the cell body proceeds the constituent parts of the daughter chromosomes become dispersed along a linin network which is formed in the immediate neighbourhood of the corresponding daughter centrosome. A nuclear membrane appears around the linin network and nucleoli appear in the meshes of the network. Thus a new daughter nucleus is formed in each daughter cell, and as the daughter nucleus is evolved the portions of the achromatic figure external to it disappear.

The result of mitotic division, therefore, is the formation of two daughter cells from a mother cell, each daughter cell having the same constituent parts, and the same number of chromosomes in its nucleus as the mother cell from which it was derived, but it is necessarily smaller than the mother cell (Fig. 8).

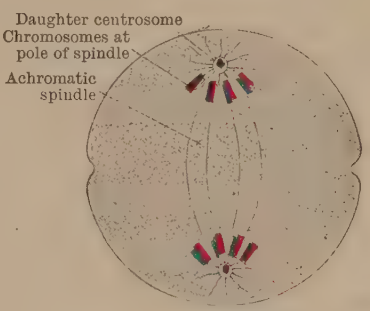

FIG. 7.—SCHEMA OF ANIMAL CELL AT END OF ANAPHASE OF HOMOTYPE MITOSIS.

The Resting Stage.—During the resting stage, which lasts for a variable time, the daughter cells grow until they attain the adult size and they perform the function of the group of cells to which they belong.

The capability of cells to perform functions depends upon the availability of proper nutriment, warmth, and moisture, their chromatin contents, their relative positions in the body of which they form a part, and the provision of means whereby the products of the cell activity can be removed.

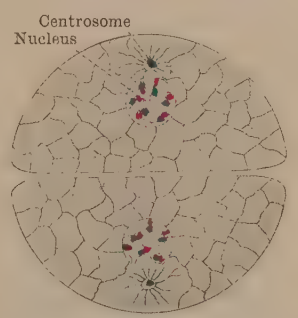

FIG. 8.—SCHEMA OF ANIMAL CELL AT END OF TELOPHASE OF HOMOTYPE MITOSIS. The cell has divided into two daughter cells. Red and blue indicate the original paternal and maternal derivatives.

As the chromosomes of the mother cells are split longitudinally, during homotype mitosis, each daughter cell receives exactly the same number of chromosomes and presumably the same number of chromomeres as the mother cell from which it was derived, and in the case of cells in fully differentiated tissues it seems probable that the chromosomes carry with them the same possibilities for functional capability that the mother cell possessed. This, however, cannot always be the case in the early stages of development, before the different tissues of the body are differentiated from one another, for in those stages some of the daughter cells of a group of mother cells take part in the formation of one, and others in the formation of other tissues which ultimately perform quite different functions. It must be

assumed, therefore, that whilst the number of the chromosomes in the various daughter cells is the same, the qualities of their chromomeres may be different.

The Period of Cell Life.—The period of cell life varies, but in all cases it ultimately ends in death; for a time comes when cells no longer transmit to their descendants the power of division, or the capability of growth and function. If it were not so, growth and function, or at least maintenance and function, would continue uninterruptedly, and, in the absence of accident or disease, individual life would continue for ever, and " old age " would be unknown.

It appears, therefore, that the ancestors of certain tissue cells are capable of producing only a certain number of descendants, which grow to the normal size and perform their proper functions for a more or less fixed period, whilst in other cases the power of division appears to be transmitted continuously, but the more remote descendants become less and less capable of performing their proper functions. The result in both cases is the same: gradual decay, terminating in death.

No individual cell has an indefinite period of life, but there are certain cells, called germ cells, upon which the continuance of life depends.

Germ cells are of two kinds: female germ cells or oocytes, which lie in the ovaries, which are the genital glands of females, and male germ cells or sperm cells, which are formed in the testicles, which are the genital glands of males.

The primitive female and male germ cells undergo many mitotic divisions, resulting in the formation of numerous descendants, but a time eventually comes when each of the numerous descendants of the primitive germ cells is only capable of producing four more descendants, by means of two final divisions which are spoken of as the maturation divisions of the germ cells.

In the case of the female germ cells the final descendants are one relatively large cell, called the *mature oocyte,* and three much smaller cells which are known as *polar bodies.*

The final descendants of each male germ cell are four *spermatozoa.*

The three polar bodies always die, and each mature ovum and spermatozoon also dies, unless it meets and unites with a mature germ cell of the opposite sex to form a new cell called a **zygote.**

The zygote formed by the union of a mature ovum with a spermatozoon is a rejuvenated cell, and there are produced from it, by numerous mitotic divisions, a multitude of descendants, some of which become germ cells, and repeat the history already noted, whilst others, called somatic cells, form the tissues of a new individual in which the germ cells are lodged.

How the period of life of somatic cells is fixed is not known, but there are reasons for believing that it is fixed at the moment the zygote is formed, with the result that some of the new individuals, or offsprings, formed from different zygotes die before they are born, and others live to periods which vary from a few minutes to one hundred or more years after birth.

Eventually, however, all die, some being killed by accident, others by micro-organic attacks, but many because they are unable to live any longer in spite of the aid of physicians and surgeons, who, at most, can only prolong slightly the period of life originally fixed by nature.

Heterotype Mitosis or **Meiosis.**—The number of chromosomes in the somatic and primitive germ cells of different groups of living creatures varies, so far as is known, from two to two hundred and eight, but the number in the cells of any given group is always the same, and it is believed that they are arranged in pairs, called *homologous chromosomes,* one member of each pair being derived from the previous male parent and the other from the previous female parent.

In one of the last divisions of the descendants of the germ cells, the so-called maturation divisions, the homologous chromosomes are separated, one of them going to one and the other to the other daughter cell, and the process by which this result is attained is called heterotype mitosis or meiosis.

In mammals, including human beings, meiosis occurs in the first of the two maturation divisions.

During the early prophase the homologous chromosomes approach one another and join together side by side (Fig. 16) forming *diploid* or twin chromosomes, the

process of junction being called *syndesis*. Thus the apparent number of chromosomes is reduced to half the original number of the so-called *haploid chromosomes*, which are the ordinary chromosomes present in somatic and non-maturing germ cells.

At the end of the prophase of the meiotic division the diploid chromosomes are assembled at the equator of the achromatic spindle where they are attached to the mantle fibrils (see p. 17).

When the metaphase commences the homologous chromosomes separate from one another and, during the anaphase, they pass to the opposite ends of the achromatic spindle; therefore, when the cell divides, in the telophase, one daughter cell contains one group of haploid chromosomes which are the homologues of the haploid chromosomes in the other daughter cell, and each daughter cell has only half the number of haploid chromosomes which were present in the mother cell.

In other words, the meiotic division is a reduction division by means of which homologous chromosomes are separated from one another, with the result that the mother's inheritance of homologous chromosomes is equally divided between the two daughter cells.

It is known that a cell which contains only half the typical number of chromosomes can divide once, therefore from each original cell which underwent heterotype mitosis four grand-daughter cells may be produced. It is still uncertain, however, whether or not cells which contain only half the typical number of chromosomes can further subdivide, or whether they can continue to live and function. So far as the observations made can be relied upon, it appears that such cells either die or they unite with another cell containing half the typical number of chromosomes to produce a new cell which contains the typical number of chromosomes and which possesses also the capability of reproducing itself by division.

The Gametes.—Gametes are cells by means of which life and hereditary characteristics are transmitted from one generation to another.

They are derived from cells called primitive germ cells, whose origin will be considered in association with the development of the cells of the zygote (see p. 25).

They are of two kinds: female gametes or mature oocytes, and male gametes or spermatozoa.

Each form has its own special characteristics, but they are both peculiar cells, inasmuch as each possesses only half the chromosome inheritance of its parent; moreover each is incapable, under ordinary circumstances, of undergoing ordinary cell division, and must either die or unite with a gamete of the opposite sex to produce a new rejuvenated cell called a zygote.

As the result of the union of the chromosome inheritance of the two gametes the zygote possesses the same number of homologous chromosomes as the parent of each gamete possessed, and it is capable of undergoing repeated divisions of its substance, by means of which large numbers of cells are formed and from them a new individual is evolved. The new individual is similar in all essential respects to the two individuals from which the gametes whose union produced the zygote were derived; that is, it is similar in all essential respects to its parents, using the term parent in its ordinary sense.

The germ cells, from which the gametes are evolved, pass through their developmental stages in special sex glands, the female germ cells in the ovaries of females, and the male germ cells in the testicles of males.

After the descendants of the primitive germ cells have increased, by homotype mitosis, to a number which is probably fixed and unchangeable, but which is not definitely known, they begin to increase in size, that is, they enter upon a period of growth. At that time the female germ cells are called **oocytes of the first order**, oocytes I, and the male germ cells are called **spermatocytes of the first order**, spermatocytes I. Both the oocytes I and the spermatocytes I possess all the essential parts of a typical animal cell, and, in addition, each has special peculiarities which differentiate it both from the germ cells of the opposite sex and also from ordinary

animal cells. Therefore the oocyte and the spermatocyte must be considered separately; but before this is done it must again be noted that each oocyte I and each spermatocyte I is capable of producing only four descendants. The mitotic cell divisions by which the descendants are produced are called the

maturation divisions, and they result, in the case of the oocyte, in the formation of one large functional cell—the **mature oocyte**, and three small impotent cells—the **polar bodies**; whilst in the case of the spermatocyte the four descendants are of equal size and each becomes transformed into a presumably potent **spermatozoon**.

THE OVUM.

When each oocyte I commences its growth it lies in the cortical part of the ovary, surrounded by a single layer of cells which are known collectively as the

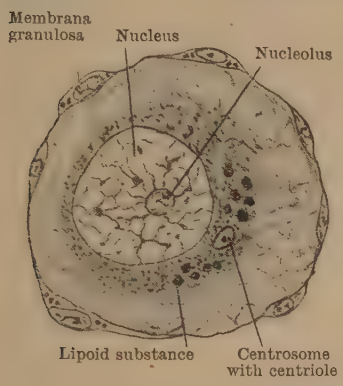

FIG. 11.—A HUMAN OOCYTE AT THE BEGINNING OF THE GROWTH PERIOD. Oocyte 38 $\mu \times 33$ μ. The small black granules in the granulosa cells are lipoid granules.

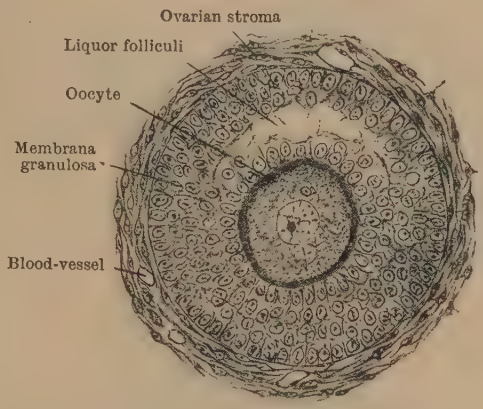

FIG. 12.—A HUMAN OVARIAN FOLLICLE AT THE COMMENCEMENT OF THE VESICULAR STAGE. Diameter of follicle 155 $\mu \times 155$ $\mu \times 120$ μ.

membrana granulosa (Fig. 11), and the oocyte and the membrana granulosa constitute, together, a **primary ovarian follicle** (O.T. Graafian Follicle).

As growth proceeds the oocyte increases in size until it attains a diameter of from 100 μ to 200 μ and so becomes a relatively large cell.

During the growth period changes occur in both the surroundings and in the contents of the oocyte.

The changes in the surroundings include increase in number of the cells of the membrana granulosa, changes in their form, subdivision of them into two groups by the appearance of a cavity amidst them, and the formation of a new envelope, called the *oolemma*, around the oocyte.

The first membrana granulosa cells which are flat plates become cubical, then they increase in number, by homotype mitosis, until they form several layers, thereafter a fluid-filled cavity appears amidst the cells, separating them into two multicellular layers, one around the oocyte and the other bounding the periphery of the cavity. The primary ovarian follicle is thus converted into a *vesicular ovarian follicle* (Figs. 12 and 13).

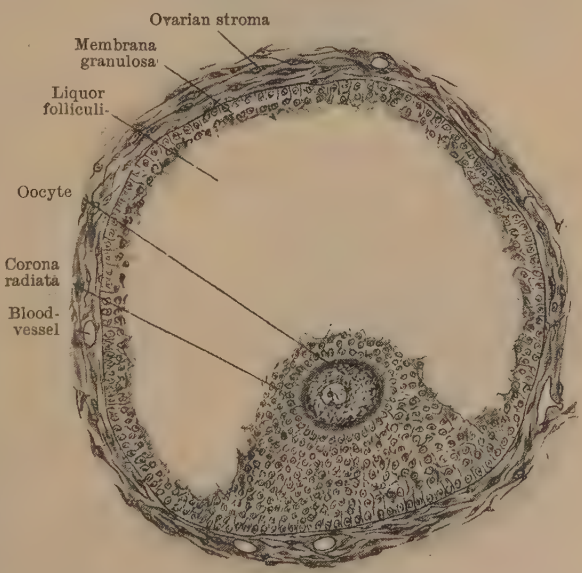

FIG. 13.—A HUMAN VESICULAR OVARIAN FOLLICLE. Diameters of follicle 620 $\mu \times 465$ $\mu \times 465$ μ.

As the cavity of the vesicular follicle rapidly increases in size the section of the membrana granulosa which surrounds the oocyte, and which is known as the *ovarian cumulus*, becomes widely separated by the liquor folliculi, from the peripheral or boundary part of the membrana, except in a small area where the

two parts always remain in continuity; therefore, when the vesicular follicle is fully developed, the ovarian cumulus with the contained oocyte and its oolemma projects from the wall into the cavity of the follicle (Fig. 13).

The oolemma begins to appear around the oocyte as soon as the membrana cells have formed two layers, and it increases in thickness until the maturation of the oocyte commences, when it is an elastic pellucid membrane (zona pellucida), sometimes faintly striated (zona striata), varying from 7 μ to 10 μ in thickness.

The oolemma is probably formed by the cells of the membrana granulosa, and it appears to be traversed by processes of the immediately adjacent membrana cells, which gradually assume an elongated columnar form constituting the *corona radiata* (Figs. 14 and 23).

It is the fine prolongations of the corona radiata cells, passing through the oolemma to the surface of the oocyte, which give rise to the striated appearance which has already been noted.

The changes which take place in the oocyte itself during the growth period concern the contents of the cytoplasm, and the position and relative size of the nucleus.

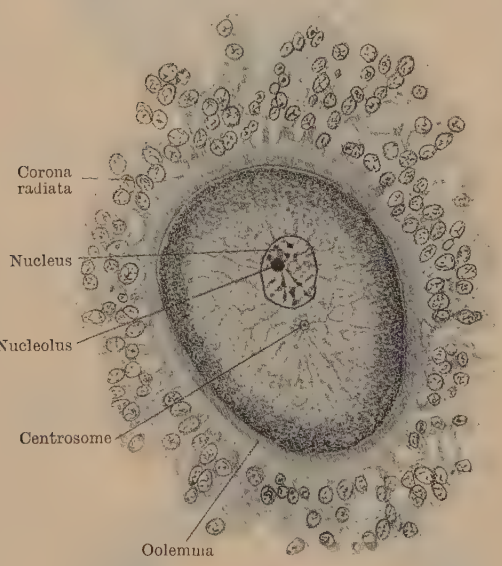

FIG. 14.—A HUMAN OOCYTE NEAR THE END OF THE GROWTH PERIOD. Diameter of oocyte exclusive of oolemma 140 $\mu \times 110$ $\mu \times 84$ μ. Average thickness of oolemma 5 μ.

At the commencement of the growth period oocyte I is an approximately spherical cell, but it soon becomes ovoid and it retains its ovoid form in all subsequent periods.

It consists of a cell body, in which lies a relatively large excentrically placed nucleus and a centrosome. The centrosome lies near the central pole of the nucleus and contains one or two centrioles (Fig. 11).

The nucleus possesses one or two karyo-plasmatic nucleoli (see p. 8), and its chromatic substance is dispersed through the linin reticulum.

Vitelline substance or deutoplasm is already present in the oocyte; it lies in the cytoplasm, around the nucleus, and it is most abundant at the central pole of the nucleus around the centrosome (Fig. 11).

As growth proceeds the deutoplasm becomes more diffused, but it is always most abundant in the central part of the cytoplasm, around the nucleus which gradually attains a central position in the oocyte (Fig. 12).

Later, at the termination of the growth period, the nucleus migrates to the periphery of the oocyte, the centrosome disappears, and the process of maturation commences. At this period the nucleus, as contrasted with the oocyte, is relatively smaller than it was at the commencement of the growth period, but it is actually larger than it was at that time. In other words, during the growth period the body of the oocyte grows more rapidly than the nucleus.

When growth is completed, and all the above-mentioned changes have taken place, the full-grown oocyte I lies in the ovarian cumulus of a vesicular ovarian follicle in the cortical part of the ovary, and it consists of a cell body which contains a nucleus, numerous highly refractive granules, called yolk granules, and chondriosomes.

It possesses no proper cell membrane continuous with the cytoplasm, but it is enclosed in a definite sheath, called the oolemma, zona pellucida, or zona striata.

The diameter of the cell body measured along its major axis varies from 100 μ to 200 μ, for full-grown oocytes are not all of the same size, and the diameter

of the nucleus is about one-fourth that of the oocyte, that is, it varies from 25 μ to 50 μ.

The mature oocyte differs from a typical cell partly on account of its relatively large size as compared with other animal cells, but mainly because it does not possess a demonstrable centrosome, and also because it is surrounded by a special protective envelope, the oolemma.

The nucleus of the fully grown oocyte is frequently called the germinal vesicle and the nucleolus the germinal spot, whilst the cell body is spoken of as the vitellus or yolk, consequently the cell membrane, which some observers have described, but which does not exist, has been termed the vitelline membrane, therefore the space which sometimes appears between the body of the oocyte and the oolemma is called the *perivitelline space.*

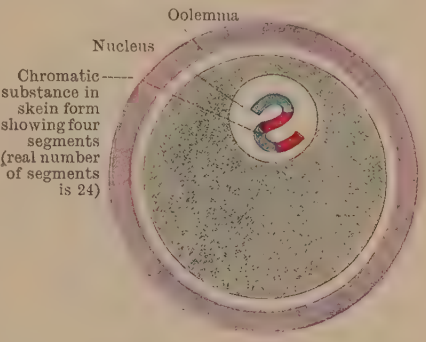

FIG. 15.—SCHEMA OF MATURATION OF OVUM, EARLY PART OF PROPHASE OF FIRST DIVISION.

The amount of deutoplasm or yolk substance in the human ovum is relatively small as contrasted with the amount present in the oocytes of fishes, amphibians, reptiles, and birds. Human oocytes are said, therefore, to be oligolecithal or small yolked; the term telolecithal being applied to oocytes, such as those of the frog, in which the amount of deutoplasm is considerable, whilst the oocytes of birds, of many reptiles, and of monotremes amongst mammals, in which the deutoplasm greatly preponderates over the cytoplasm, are called eutelolecithal.

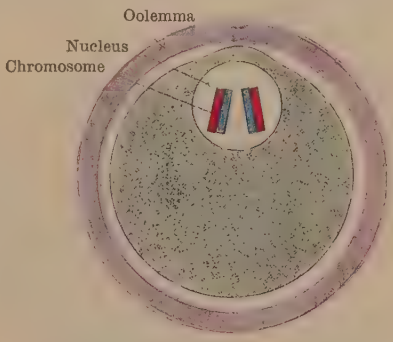

FIG. 16.—SCHEMA OF MATURATION OF OVUM IN PROPHASE OF FIRST DIVISION. The chromatic thread has divided into twin chromosomes. Each twin may be assumed to consist of a maternal and a paternal part.

The deutoplasmic granules serve as a store of nutritive material which is utilised during some of the early stages of the growth of the zygote in mammals, and up to the period of birth in many other vertebrates.

The Maturation of the Oocyte.—Maturation is the term applied to the phenomena which occur during the two cell divisions which take place after the full growth of the oocyte is terminated.

We have no thoroughly satisfactory knowledge of the phenomena of maturation in the case of human oocytes and must therefore, at present, presume that they are the same as those which occur and which have been clearly demonstrated in many other mammals.

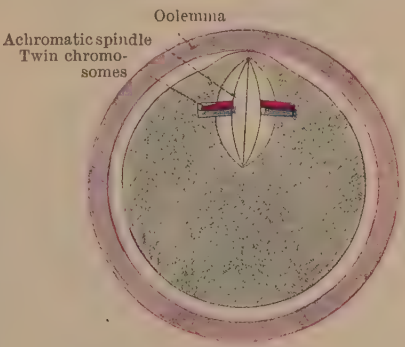

FIG. 17.—SCHEMA OF MATURATION OF OVUM AT END OF PROPHASE OF FIRST DIVISION. The twin chromosomes lie at the equator of the achromatic spindle.

If that is so then the first of the two divisions is meiotic (see p. 12) or heterotypical. During its progress the nuclear membrane and the nucleolus or nucleoli disappear, and an achromatic spindle appears at one pole of the oocyte, in the situation previously occupied by the nucleus.

The spindle has no centrosomes at its extremities, and, at first, its long axis lies parallel with the surface of the oocyte.

The chromosomes are aggregated together in pairs as twin or diploid chromosomes, they are therefore only half the number of the haploid chromosomes originally present in the oocyte, and, at the end of the prophase, they lie at the

periphery of the equator of the spindle. When this condition is attained the spindle rotates on its long axis, and one pole, carrying a little cytoplasm around it, projects beyond the general surface of the oocyte, forming the *first polar projection* (Fig. 19).

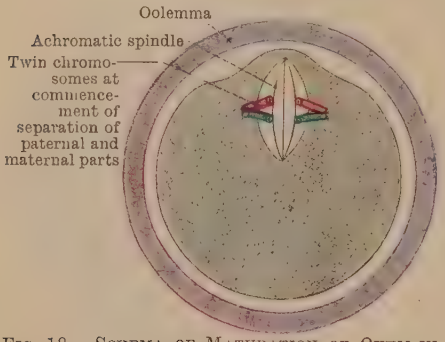

FIG. 18.—SCHEMA OF MATURATION OF OVUM IN METAPHASE OF FIRST DIVISION. One pole of the spindle projects into the first polar bud, and the maternal and paternal parts of the chromosomes are separating from each other.

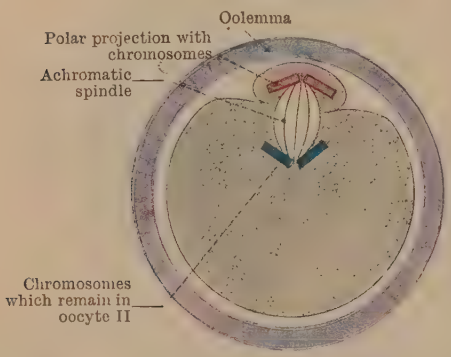

FIG. 19.—SCHEMA OF MATURATION OF OVUM AT END OF THE ANAPHASE OF THE FIRST DIVISION. Two chromosomes (paternal or maternal) lie in the first polar bud and two in the larger part of the ovum which becomes oocyte II.

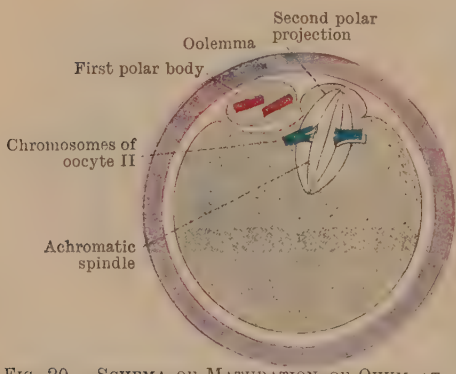

FIG. 20.—SCHEMA OF MATURATION OF OVUM AT THE COMMENCEMENT OF THE METAPHASE OF THE SECOND DIVISION.

During the metaphase the two halves of each twin chromosome separate from one another, two haploid chromosomes being formed from each diploid chromosome.

In the anaphase the halves of each twin chromosome travel to the opposite poles of the achromatic spindle, therefore those which travel to the peripheral pole enter the first polar projection (Figs. 18, 19).

During the telophase the first polar projection, with its included haploid chromosomes and the peripheral part of the achromatic spindle, is cut off from the main part of the oocyte, and the first maturation division is completed; *oocyte I* being divided into a large segment, *oocyte II*, and a small segment, the first polar body, both of which lie inside the oolemma and each of which contains half the number of haploid chromosomes originally present in oocyte I (Figs. 19, 23).

After the first maturation division is completed a nucleus may appear in the first polar body and a new achromatic spindle is formed in oocyte II. The new achromatic spindle lies at the periphery of oocyte II near the first polar body, and the haploid chromosomes of the oocyte are grouped at its equator (Figs. 20, 24).

When the condition described is attained the vesicular ovarian follicle ruptures, and the liquor folliculi, carrying with it the oocyte surrounded by its corona radiata of granulosa cells, is forced through the orifice in the surface of the ovary and is swept into the uterine tube.

If oocyte II does not now meet and unite with a spermatozoon to form a zygote it passes through the uterine tube, the uterus, and the vagina and is cast out of the body and dies; but if it meets and is penetrated by a spermatozoon it undergoes a second maturation division.

The phenomena of the second maturation division are those of homotype mitosis; one pole of the achromatic spindle, already present in oocyte II (Fig. 20), projects beyond the general surface of the oocyte carrying with it a small amount of cytoplasm, and so forming the *second polar projection*, thereafter each of the haploid chromosomes at the equator of the achromatic spindle, which it must be remembered are only half as numerous as those originally present in oocyte I, splits longitudinally into equal parts. The opposite halves of the divided chromosomes then travel to the opposite ends of the achromatic spindle, consequently one group enters the second polar projection and the other remains in the body of the oocyte (Fig. 21).

When the chromosomes reach the ends of the achromatic spindle the second polar projection is cut off from the body of the oocyte to form the *second polar body*. Thus oocyte II is segmented, in the second maturation division, into a smaller part the second polar body, and a larger part the *mature oocyte*, each of which contains half the number of haploid chromosomes which was present in oocyte I.

As soon as the second polar body is separated off a nuclear membrane appears around the chromosomes in the body of the oocyte, a linin reticulum is formed within the membrane, and the particles of the chromosomes are distributed along the reticulum; a nucleolus also is developed, and the new nucleus, thus formed, is called the **female pronucleus.**

As the female pronucleus is evolved the head and body of the spermatozoon already in the oocyte are transformed into a nucleus, the **male pronucleus** and two centrosomes. The male pronucleus naturally contains only half the number of haploid chromosomes which were present in the spermatocyte I from which it descended (p. 14).

When the maturation of the oocyte is completed, therefore, the mature oocyte contains a female pronucleus, a male pronucleus, and two centrosomes.

As the second polar body is separated off the first polar body not uncommonly

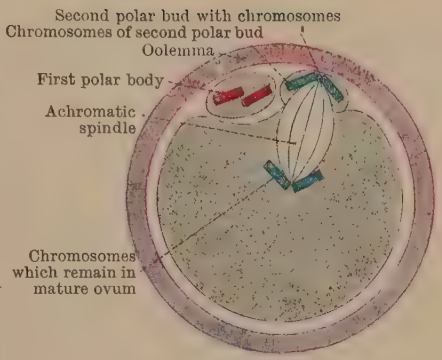

FIG. 21.—SCHEMA OF MATURATION OF OVUM AT END OF ANAPHASE OF SECOND DIVISION. The chromosomes of oocyte II have separated into equal parts which have passed to the opposite poles of the spindle.

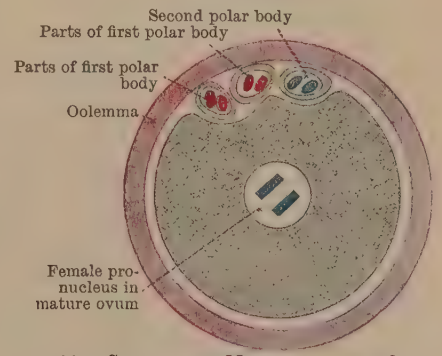

FIG. 22.—SCHEMA OF MATURATION OF OVUM. END OF TELOPHASE OF SECOND DIVISION where the four descendants of oocyte I are the mature ovum, with half the original number of chromosomes, and three polar bodies.

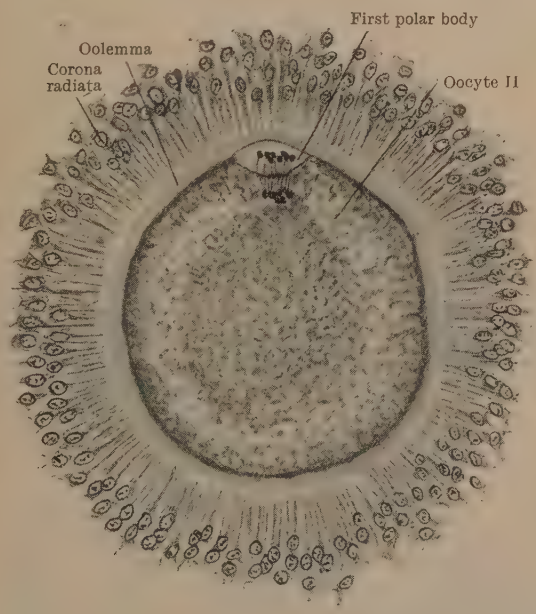

FIG. 23.—OOCYTE OF A FERRET IN THE TELOPHASE OF THE FIRST MATURATION DIVISION. Diameter of oocyte exclusive of oolemma, 150 $\mu \times 125\ \mu \times 110\ \mu$.

divides into two parts. When that occurs the result of the two maturation divisions of the oocyte is the formation of three small cells destined to disappear, the three polar bodies, and one large cell, the mature oocyte, all of which are enclosed within the oolemma (Fig. 22).[1]

If the mature oocyte does not meet with a spermatozoon it passes through the genital passages and is cast off and lost; or it breaks down, whilst still in the genital passages, into a detritus which disappears; but if it meets and unites with a spermatozoon a **zygote** is formed, from which a new individual may arise, and in that case the polar bodies persist until

[1] Professor Arthur Thomson of Oxford believes that, in the case of the human oocyte, the second maturation division occurs whilst the oocyte is still in the ovary, therefore before it is penetrated by a spermatozoon.

the zygote has undergone one or two divisions; but sooner or later they disappear, probably breaking down into fragments which are absorbed by the cells of the zygote.

Spermatocytes.—When the male germ cells reach the period of growth they are called **spermatocytes of the first order**, or spermatocytes I, which correspond, morphologically, with oocytes I (Fig. 10).

The spermatocytes lie in the walls of the tubules of the testes or male sex glands, where their descendants become converted into spermatozoa.

They differ from the oocytes I in three important respects: (1) they have no protective membrane corresponding with the oolemma of the oocyte; (2) they are not enclosed in follicles; (3) the spermatocytes are not surrounded by definite encircling layers of cells similar to the cells of the stratum granulosum.

As the spermatocytes lie in the walls of the tubules of the testes they are intermingled with other cells, the supporting and nurse cells, amidst which they undergo their maturation divisions, and their descendants become embedded in the nurse cells, where they are converted into spermatozoa. To a certain extent, therefore, the nurse cells may be looked upon as corresponding with the cells of the ovular cumulus which surround the growing oocyte.

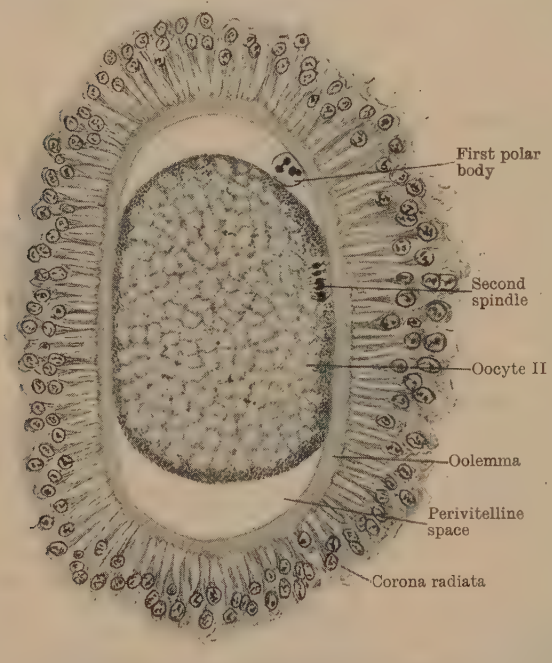

Fig. 24.—Oocyte of a Ferret after Separation of the First Polar Body. Diameters of oocyte exclusive of oolemma, 110 $\mu \times 110\ \mu \times 41\ \mu$.

After it has reached its full growth each spermatocyte I, like each oocyte I, can produce only four descendants, and the descendants, as in the case of the oocyte I, are formed by two successive mitotic divisions, of which the first is heterotypical and produces reduction of the chromosomes, and the second is homotypical.

The two divisions differ from the corresponding divisions of the oocytes in three important respects: (1) centrosomes are present; (2) the four grand-daughter cells produced are of equal size and presumably of equal value, so far as capability of uniting with a mature ovum to form a zygote is concerned; (3) each of the four grand-daughter cells possesses two centrosomes.

In the prophase of the first or heterotype division the nucleus and nucleolus disappear in the ordinary way. The centrosome divides, and an achromatic spindle appears, which has the daughter centrosomes at its poles and half the typical number of chromosomes at its equator. The chromosomes are twin chromosomes. During the metaphase the two segments of each twin chromosome separate from each other. In the anaphase they travel to the opposite poles of the achromatic spindle, and consequently, when the cell divides in the telophase, each daughter cell or **spermatocyte** II contains a centrosome and half the typical number of chromosomes (Fig. 10).

The second maturation division, which takes place without the intervention of a resting stage, is of the homotype form. The centrosome divides, a new achromatic spindle appears, and the daughter chromosomes gather at its equator. In the metaphase the chromosomes divide into equal parts, which travel to the opposite poles of the spindle during the anaphase, and when the telophase is completed the grand-daughter cells, which are called **spermatids**, possess a centrosome and half the typical number of chromosomes (Fig. 10). In the resting stage which follows, the

chromatic particles become enclosed in a new-formed nucleus, and the centrosome, if it has not already divided, separates into two parts, one which lies nearer the nucleus and is called the *anterior centrosome*, and another, farther from the nucleus, termed the *posterior centrosome* (Fig. 27). Numerous mitochondria are present, and an indefinite structure, called the accessory body, is also found in the cell protoplasm. A spermatid, therefore, differs from a typical animal cell not only because it possesses the chromatic substance of only half the typical number of chromosomes, but also because it possesses an accessory body and two centrosomes.

From Spermatid to Spermatozoon.—The reader will have noted that the female gametes become mature and ready for conjugation with male gametes directly after the second maturation division is completed. In the case of the male germ cells, however, the spermatids which result from the second maturation division have still to undergo a complicated process of transformation before they become converted to spermatozoa or mature male gametes. The process of transformation takes place in association with the nurse cells in which the developing spermatozoa become embedded.

The details of the process of transformation are difficult to follow, and the knowledge regarding them is still to some extent indefinite. Certain points, however, are well established; but before they are considered it is necessary that the reader should be acquainted with the anatomy of an adult spermatozoon.

THE SPERMATOZOON.

A spermatozoon is a minute organism consisting of a head, a neck, a body, a tail, and an end-piece. Its total length is about 50 μ, that is, its length is about the same as the diameter of the nucleus of the ovum.

The **head** has the form of a laterally compressed ovoid. It is separable into anterior and posterior portions, and the anterior portion is more or less completely covered by a head-cap, which culminates in a sharp ridge. The length of the head is about 4·5 μ.

The **neck** is an extremely short constricted region which intervenes between the head and the body. At its anterior end, where it joins the head, there is a deeply staining **anterior centrosome**, and at its posterior end a similarly deep-staining **posterior centrosome**, from which a deep-staining **axial filament** extends posteriorly through the body and tail into the end-piece (Fig. 26).

The Body.—The body is a little longer than the head, and its constituent parts are: (1) a portion of the axial filament; (2) a portion of the axial sheath; (3) the spiral sheath; (4) the mitochondrial sheath; (5) the end-ring.

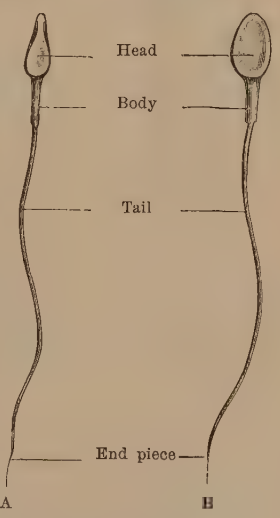

Fig. 25.—Human Spermatozoa (after Retzius).
A, Side view; B, Front view.

The **axial sheath** is a thin layer of protoplasm immediately surrounding the **axial filament**.

The **spiral sheath** consists of a **spiral fibril** embedded in indifferent protoplasm, and the **mitochondrial sheath**, which surrounds the spiral sheath, is formed by protoplasm containing numerous mitochondria.

The **end-ring** closes the posterior ends of the spiral and mitochondrial sheaths, and it is perforated by the axial filament and its sheath as they pass from the body into the tail.

The **tail** is 28-29 μ long. It consists of prolongations of the axial filament and its sheath, and it ends in the short thin *end-piece*.

The Transformation of the Spermatid into the Spermatozoon.—As the transformation progresses the nucleus of the spermatid becomes the head of the spermatozoon. The axial filament grows out from the posterior centrosome of the spermatid, which divides into two parts, one of which becomes the posterior

centrosome of the neck of the spermatozoon, whilst the other becomes the end-ring of the body of the spermatozoon.

The anterior centrosome of the spermatid becomes the anterior centrosome of the neck of the spermatozoon. The cytoplasm of the spermatid forms the axial sheath, the indifferent protoplasm of the spiral sheath and mitochondrial sheath. The origin of the spiral filament and the origin of the head-cap are uncertain, but it is stated that, in some animals, the head-cap is formed from the accessory body, which is not shown in Fig. 27.

The Object of the Reduction of the Chromosomes.—The most striking phenomenon of the process of the maturation of the gametes is the reduction of the chromosomes. The constancy of the reduction tends to emphasise its importance, but, as we have no definite knowledge of the functions of the chromatic substance, the object of the reduction can only be surmised. The evidence which has been accumulated tends to the conclusion that the particles of the chromatic substance are the bearers of hereditary tendencies and capabilities.[1] If this is the case, then they are the means by which ancestral possessions, in the morphological sense, are transmitted

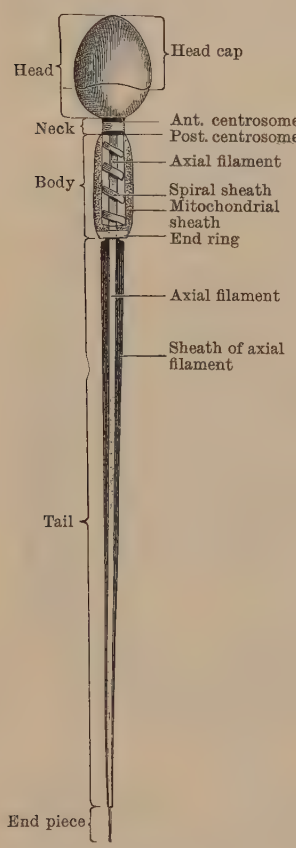

Fig. 26.—Structure of a Human Spermatozoon (after Meeves).

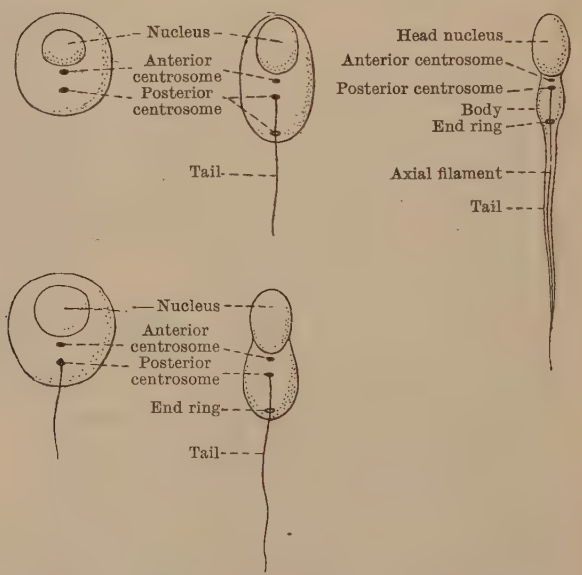

Fig. 27.—Schema of Transformation of Spermatid into Spermatozoon (after Meeves, modified).

from generation to generation. There is evidence also, first ascertained by Mendel and substantiated and increased in recent years by his followers, which lends probability to the belief that the tendency carriers form two main groups: (1) those which carry certain tendencies; (2) those which carry opposite tendencies. The bearers of tendencies and the bearers of their opposites are allelomorphic or alternative to each other, and are called *allelomorphs*. Thus the particles which bear tallness and dwarfness respectively are allelomorphs, that is, they are alternative to each other.

Further, the facts which are known suggest the idea that in the primitive germ cells, and their descendants which contain the typical number of chromosomes, the character-bearing particles are arranged in pairs of which both elements may bear the same tendencies, or one may bear one tendency and the other the opposite.

[1] It must be understood that this function, if it exists, does not prevent the chromatic particles possessing other functions, and that there is no evidence that the potency of a tendency depends upon amount of chromatic substance.

For example, if red and blue be supposed to be opposite tendencies carried by different particles or allelomorphs, then the germ cells of any given animal, male or female, may contain either a pair of red-bearing particles, a pair of blue-bearing particles, or a red- and a blue-bearing particle associated together as a pair.

The reduction of the chromosomes during the maturation divisions of the germ cells is an admitted fact, and it is believed that the reduction is a necessary preliminary to the union of a male and a female gamete to form a zygote from which a new individual may arise. It is assumed that the purpose of the reduction is the segregation of the different tendency bearers from each other in order that they may enter into new combinations. If this assumption is correct, then every mature germ element or gamete contains only one element of any given pair of tendency bearers—in the supposititious case under consideration, either the red or the blue bearer—but not both; and the object of the reducing division is the segregation of the allelomorphs in order that they may enter into new and possibly into different combinations, producing new and possibly varied results.

If, in the case of any given group of animals, the mature germ cells of some of both sexes contain the blue-bearing particles and others the red-bearing particles, it necessarily follows that three possible results may ensue when impregnation occurs, that is when two mature germ cells unite to form a zygote.

(1) A female gamete bearing red tendency particles may fuse with a male gamete bearing red tendency particles; (2) a female gamete bearing blue tendency particles may meet and fuse with a male gamete bearing blue tendency particles; (3) a female gamete bearing red tendency particles may meet and fuse with a male gamete bearing blue tendency particles. The constitution of the zygotes formed may be stated as follows:—

RR BB RB,

and the character of the individual developed from the zygote will vary according to the combination. If two red tendency bearing gametes meet, the individual will be red; if two blue tendency bearing gametes meet, the individual produced will be blue; but when a gamete bearing red tendency particles unites with a gamete bearing blue tendency particles the individual will be either red or blue or a combination of the two, the result depending upon the relative potency or dominance of the two tendencies.

Further exposition of this interesting subject would be out of place in a text-book of anatomy, but it is of such great importance in association with the transmission of hereditary characteristics and hereditary diseases that every medical student should make himself familiar with its possibilities by consulting the works of Bateson, Punnet, Doncaster, and other writers and observers who are attempting to solve the complicated problems which it presents.

Fertilisation or Syngamy.

The process of union of the male and female gametes to form a zygote is termed fertilisation or syngamy. It commences when a spermatozoon enters an oocyte II but it is not completed until the nuclear elements of the two have united.

The process has not been seen in the human subject but it may be assumed that all its essential features are the same as those which have been found to occur in other mammals. This assumption is the more justifiable because the phenomena of the maturation of the oocyte and fertilisation have been found to take place in the same manner, and to be essentially similar in detail, in several very different groups of mammals.

It has already been pointed out that, after the spermatozoon enters oocyte II the latter divides and becomes the second polar body and the mature oocyte in which a female pronucleus is formed. It has also been noted that the female pronucleus contains half the number of haploid chromosomes which was present in oocyte I before the maturation commenced. As the female pronucleus forms, the head and body of the spermatozoon which lies in the mature oocyte are

transformed into two centrosomes and a male pronucleus. The male pronucleus is smaller than the female pronucleus, and it also contains only half the number of haploid chromosomes which was present in the spermatocyte I from which it descended.

As soon as the female and male pronuclei are established they approach each other (Fig. 29), meet, and fuse together to form a single nucleus (Fig. 28), called the *first segmentation nucleus*, which contains the full number of haploid chromosomes, that is, the number which was present in the oocyte I and the spermatocyte I from which the mature oocyte and the spermatozoon were respectively descended.

When fertilisation is completed, therefore, a new structure called a **zygote** is formed. It lies, together with the polar bodies, inside the oolemma, and it consists of a cell body which contains a nucleus, the first segmentation nucleus, and two centrosomes, which lie at opposite poles of the nucleus.

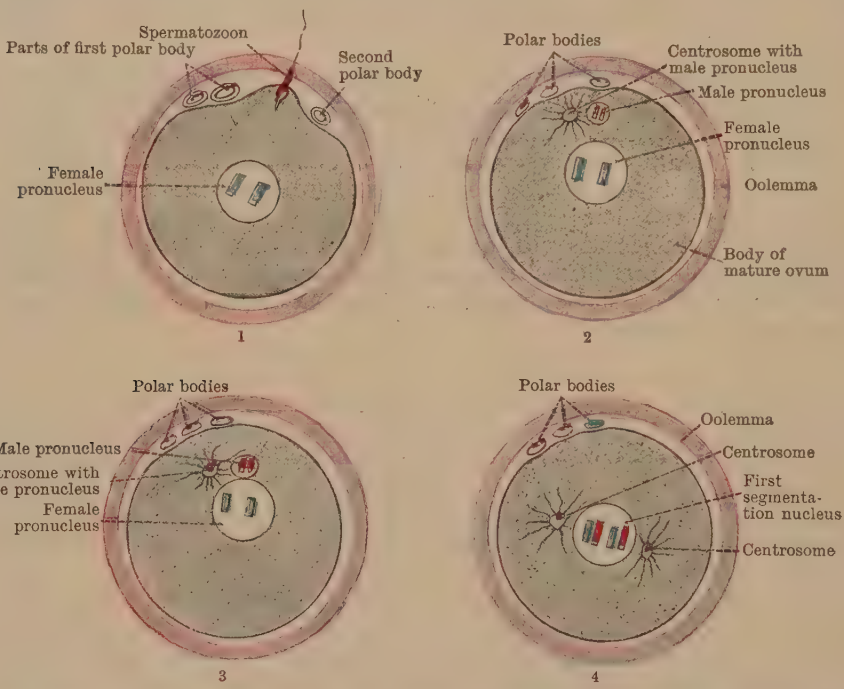

FIG. 28.—SCHEMA OF THE FERTILISATION OF THE MATURE OVUM AND THE FORMATION OF THE ZYGOTE.

The number of chromosomes in the first segmentation nucleus is that typical for the cells of the group of animals to which the zygote belongs, half of them being derived from the female and half from the male ancestor of the zygote.

The only essential difference in appearance between an oocyte I and a zygote is the presence of two centrosomes in the zygote, but oocyte I is a cell almost at the end of its life period, and with the hope of producing only one capable descendant whose chances of life are small, whilst the zygote is a rejuvenated cell with great possibilities, for it is endowed with the potentialities of its parents and is capable of producing a new individual.

THE DETERMINATION OF SEX.

Sex is determined at the time of the union of the gametes and it is dependent upon the absence or presence of a special chromosome or group of chromosomes called sex chromosomes.

The evidence upon which the above assertion rests is quite definite in the cases of many invertebrates, but it is less certain in the case of some vertebrates. Moreover, it is known that, in the cases of certain animals, sex can be controlled by external factors acting upon the oocyte and upon the zygote, and by alterations

of the environment of the zygote; nevertheless, when a sex chromosome is present, it is the dominant factor in the production of sex.

In some forms the presence of a sex chromosome in the zygote results in the production of a male offspring, in others in the production of a female offspring. In the human subject it is believed that it determines the female sex and that it passes into the zygote with the spermatozoon.

According to Winiwarter, each human oocyte I has 48 chromosomes and each spermatocyte I 47 chromosomes, therefore each mature oocyte has 24 chromosomes, but some spermatozoa have 24 and others 23 chromosomes. The 24th chromosome of a spermatozoon is the sex chromosome, and when a spermatozoon carrying 24 chromosomes unites with a mature oocyte the zygote formed will possess 48 chromosomes, and the offspring developed from it will be a female, whilst the zygote formed by the union of a mature oocyte and a spermatozoon carrying only 23 chromosomes will only possess 47 chromosomes and the offspring which arises from it will be a male.

In the earliest periods of its life the sex of the offspring cannot be told, but whilst it is still an embryo (see p. 7) it becomes quite evidently either a male or a female.

Segmentation.

Immediately after its formation the zygote is separated, by a series of consecutive mitotic divisions, into a large number of cells which are grouped together in the form of a solid spherical mass, called a **morula** on account of the mulberry-like appearance of its surface. This period of division is called the period of segmentation (Figs. 30-33).

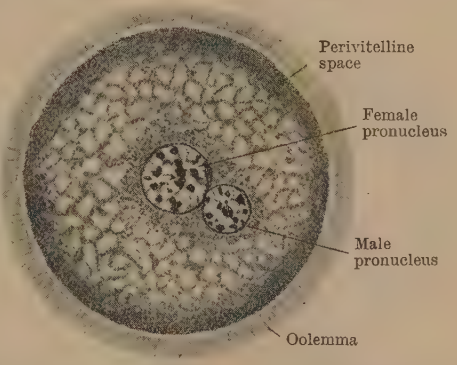

Fig. 29.—Zygote of a Ferret just before the Fusion of the Pronuclei. Diameters of zygote exclusive of oolemma, 100 $\mu \times 93\ \mu \times 90\ \mu$.

The segmentation divisions are of the homotype form, and there is evidence which tends to the conclusion that the earliest divisions, by which the zygote is divided first into two and then into four parts, are quantitatively and qualitatively equal. After a time, however, the divisions result in the formation of cells of different sizes and different capabilities, definite and circumscribed functions being allocated to certain groups of cells and their descendants. It is probable that at this time cells are set apart which are the progenitors of the germ cells of the next generation, and which therefore retain all the capabilities of their ancestors. These cells are the means by which the species is reproduced and the hereditary tendencies are transmitted from generation to generation. At the same time other cells are set apart for the production of the tissues and organs of the individual which will be produced from the zygote, and in which the germ cells and their descendants will be lodged and protected till they attain their maturity.

The morula is formed inside the oolemma and as the cell divisions which produce it proceed, but before they are completed, the polar bodies disappear.

After the morula is established one of the first definite changes which occur in its constitution is the differentiation of its cells into an outer layer and an inner mass (Fig. 32).

In the human subject, as in many other mammals, the cells of the outer layer constitute the **trophoblast** or trophoblastic ectoderm, which plays a most important part in the nutrition of the embryo and fœtus. It enters into the formation of the **chorion**, or outermost envelope of the growing zygote, which is subsequently differentiated into a placental and a non-placental portion and which serves, in the first instance, as both a protective and a nutritive covering.

In many mammals the cells of the inner mass soon separate into two main

groups, the ecto-mesoderm and the entoderm; but it appears probable that, in the human subject, they differentiate into three groups, **ecto-mesoderm, primary mesoderm**, and **entoderm**.

In the majority of mammals, immediately before, or as the differentiation of the inner mass occurs, a cavity appears in the zygote. The cavity is called the **segmentation cavity**, and as soon as it appears the morula is converted into a **blastula**. The segmentation cavity enlarges until it separates the inner mass from the outer layer, except at one pole of the zygote, where the inner mass and the outer layer remain in contact. It appears, however, from the evidence available, that a segmentation cavity is not formed in the human zygote. Instead the primary mesoderm proliferates and extends until it separates the remainder of the inner mass, that is the amniotic ectoderm, the ecto-mesoderm, and the entoderm from the outer layer or trophoblast, and, simultaneously, cavities appear in the ectodermal and entodermal masses of cells. Thus the human morula becomes a blastula (Fig. 35).

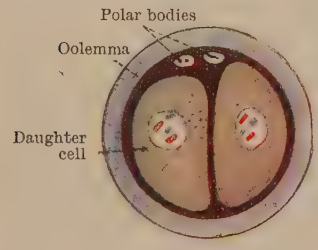

FIG. 30.—SEGMENTATION OF ZYGOTE. 2-Cell Stage.

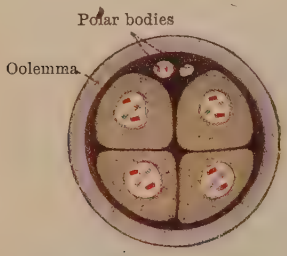

FIG. 31.—SEGMENTATION OF ZYGOTE. 4-Cell Stage.

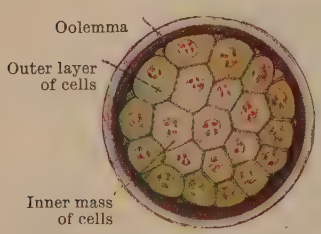

FIG. 32.—SEGMENTATION OF ZYGOTE. Morula Stage.

When the above-mentioned changes have occurred the zygote consists of three spheres, one large and two small. The large sphere is bounded by the trophoblast; it contains the two small spheres and the jelly-like mass of primary mesoderm derived from the primary mesoderm segment of the inner mass (Fig. 35).

The two small vesicles lie ex-centrically in the interior of the larger vesicle. The larger and more external of the two is the ecto-mesodermal vesicle. It is separated from the trophoblast, peripherally, and the entodermal vesicle, centrally, by the surrounding primary mesoderm.

The early appearance of the mesoderm in the zygote and its insinuation at so early a period between the ectoderm and the entoderm are peculiarities limited to the human subject. In most mammals the mesoderm does not appear until the embryonic area and its primitive streak are defined.

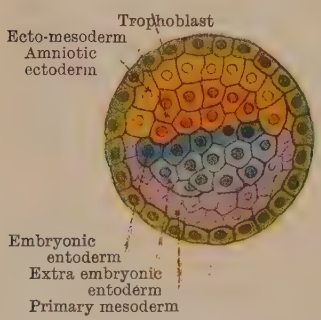

FIG. 33.—DIFFERENTIATION OF ZYGOTE AND CELLS (Hypothetical).

The Embryonic Area.—The area where the two inner vesicles lie in apposition with each other is the region of the zygote from which the embryo will be formed; it is called, therefore, the **embryonic area**, and at the time of its definition it consists of three layers, ectoderm, primary mesoderm, and entoderm.

The remainder of the zygote is utilised for the formation of membranes and appendages necessary for the protection, nutrition, respiration, and excretion of the offspring during the period of intrauterine life.

It is uncertain whether the mesoderm which is present in the area at this period takes part in the formation of the embryo or is replaced at a later period by mesoderm derived from the cells of the ecto-mesodermal vesicle; the latter certainly forms a large part of the mesoderm of the embryo.

The Extra-Embryonic Cœlom.—The extra-embryonic cœlom is a space which appears as two clefts, one on each side of the embryonic area, in the primary mesoderm (Fig. 36). The clefts fuse together round the periphery of the embryonic area, and the single space so formed expands rapidly until the mesoderm which

originally filled the greater part of the larger vesicle becomes converted into a thin layer which lines the inner surface of the trophoblast and covers the outer surfaces of the epithelial walls of the extra-embryonic parts of the two inner vesicles (Fig. 38).

The extra-embryonic cœlom does not extend into the embryonic area, and it never completely separates the ecto-mesodermal vesicle from the inner surface of the trophoblast; on the contrary, the primary mesoderm on the outer surface of the ecto-mesodermal vesicle retains its continuity with the mesoderm on the inner surface of the trophoblast until the termination of intrauterine life, and it takes part, as will be seen later, in the formation of the umbilical cord, which connects the fœtus with the placenta (p. 60).

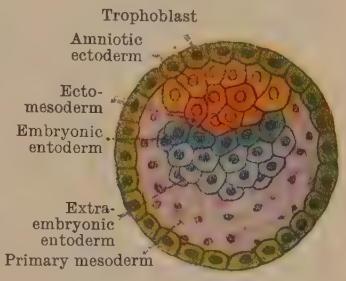

FIG. 34.—FURTHER DIFFERENTIATION OF ZYGOTE (Hypothetical).

The Differentiation of the Embryonic Area.—As the embryonic area is the area of contact between the ecto-mesodermal and the entodermal vesicles it is, at first, circular in outline. As growth continues the area becomes oval, and a linear streak, the **primitive streak**, appears in that part of the oval which becomes the posterior part of the area (Fig. 37).

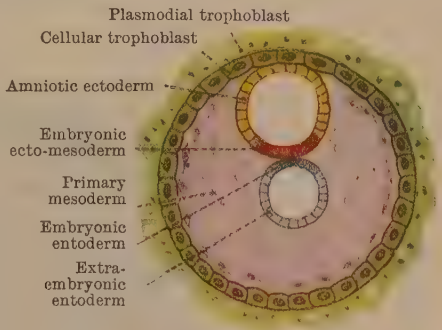

FIG. 35.—SCHEMA OF DIFFERENTIATION OF ZYGOTE (Bryce's Ovum).

At the same time the position of the mesodermal elements of the wall of the ecto-mesodermal vesicle is revealed, for the primitive streak is a thickened ridge of cells which grows from the ecto-mesoderm and projects against the entoderm in the posterior part of the embryonic area, pushing aside the primitive mesoderm which intervened between the adjacent parts of the walls of the ecto-mesodermal and the entodermal vesicles. The deeper cells of the ridge, those next the entoderm, are the mesodermal elements of the primitive ecto-mesoderm, and, by proliferation, they form the larger part, if not the whole, of the embryonic mesoderm and also an organ, called the **notochord**. The mesoderm produced from the primitive streak may be termed the **secondary mesoderm**.

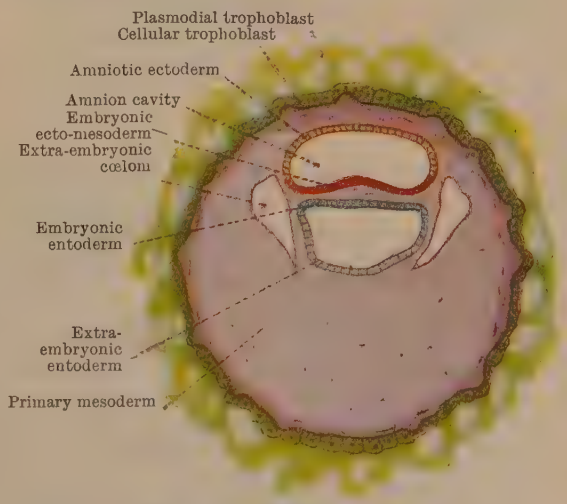

FIG. 36.—SCHEMA OF DIFFERENTIATION OF ZYGOTE (Peter's Ovum).

Immediately after the formation of the primitive streak a groove, the **neural groove**, appears in the anterior part of the embryonic area. It is formed by the longitudinal folding of a thickened plate of ectoderm, the **neural plate**, which is the rudiment of the whole of the central and peripheral portions of the nervous system, except perhaps the olfactory nerves, and the end organs of the sensory nerves. From it also are derived the cells of the primitive sheaths of the nerve-fibres and the chromaffin cells of the supra-renal glands and other chromaffin bodies.

The lateral walls of the neural groove are called the **neural folds**.

Almost from the first the anterior ends of the neural folds are united together a short distance posterior to the anterior end of the embryonic area. Their posterior ends, which remain separate for a time, embrace the anterior part of the primitive streak. In the meantime, however, a groove, the **primitive groove**, has appeared on the surface of the primitive streak. The anterior end of the primitive groove deepens, until it forms a perforation which passes, through the anterior end of the streak and the subjacent entoderm, into the cavity of the entodermal vesicle. As this perforation passes from the floor of the posterior part of the neural groove into that part of the entodermal vesicle which afterwards becomes the primitive enteron or alimentary canal, it is called the **neurenteric canal**. The neurenteric canal is but a transitory passage, and it disappears in man and other mammals before the neural groove is converted into a closed neural tube.

After the appearance of the primitive groove and the neurenteric canal the posterior ends of the neural folds converge, across the anterior part of the primitive streak and groove, and fuse together posterior to the neurenteric canal. The primitive streak is thus divided into two portions. (1) An anterior portion, which lies at first in the floor of the neural groove, and, later, in the floor or ventral wall of the posterior end of the spinal medulla; and (2) a posterior portion, which remains on the surface and takes part in the formation of the median portion of the posterior end of the body, forming the perineum, and the median part of the ventral wall of the body, from the perineum to the umbilicus. It is through the perineal section of the posterior part of the primitive streak that, at a later period of embryonic life, the anal and urogenital orifices of the body are formed.

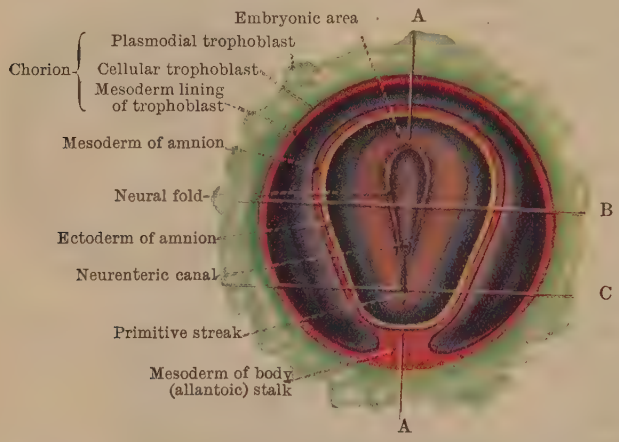

FIG. 37.—SCHEMA OF DORSAL SURFACE OF EMBRYONIC AREA OF ZYGOTE AFTER THE REMOVAL OF PART OF THE CHORION AND PART OF THE AMNION.

The Formation of the Notochord and the Secondary Mesoderm.—The notochord and the secondary mesoderm are formed from the primitive streak; the notochord from its anterior extremity, and the secondary mesoderm from its lateral margins and posterior end.

As soon as the primitive streak is established its anterior end becomes a node or centre of growth by means of which the length and, to a certain extent, the breadth of the body are increased. The portion of the body formed by the activity of the anterior end of the streak is the dorsal portion, from the back part of the roof of the nose, anteriorly, to the posterior end of the trunk. The perineum and the ventral wall of the body, from the perineum to the umbilicus, are formed from the posterior part of the primitive streak. Nevertheless, the primitive streak undergoes little or no increase in length; indeed, as growth continues, it becomes relatively shorter as contrasted with the total length of the embryonic region, for the new material, formed by its borders and its anterior extremity, is transformed into the tissues of the embryo as rapidly as it is created.

The Notochord.—The notochord, or primitive skeletal axis, is formed by the proliferation of cells from the anterior end of the primitive streak. On its first appearance it is a narrow process of cells, the **head process**, which projects forwards from the anterior boundary of the neurenteric canal, between the ectoderm and the entoderm. Shortly after its appearance the head process wedges its way between the entoderm cells, and from that period onwards, as the posterior parts are formed, by continued proliferation from the front end of the primitive streak, they are at once intercalated in the dorsal wall of the entodermal sac,

where they remain, forming a part of the dorsal wall of the entodermal cavity (Fig. 39), for a considerable time. At a later period the notochordal cells are excalated from the entoderm, and then they form a cylindrical rod of cells which occupies the median plane, lying between the floor of the ectodermal neural groove and the entodermal roof of the primitive alimentary canal, which, in the meantime, has been more or less moulded off from the dorsal part of the entodermal sac (Fig. 43). For a still longer time the caudal end of the notochord remains connected with the anterior end of the primitive streak, and its cephalic end is continuous with the entoderm of a small portion of the embryonic area, which lies immediately in front of the anterior end of the neural groove and which becomes bilaminar by the disappearance of the primary mesoderm. This region, because it afterwards forms the boundary membrane between the anterior end of the primitive entodermal canal and the primitive buccal cavity or stomatodæum, is called the **bucco-pharyngeal membrane** (Fig. 61, p. 47). It disappears about the third week of embryonic life, and immediately afterwards the anterior end of the notochord separates from the entoderm, but the posterior end remains continuous with the primitive streak, until the formation of the neural tube is completed.

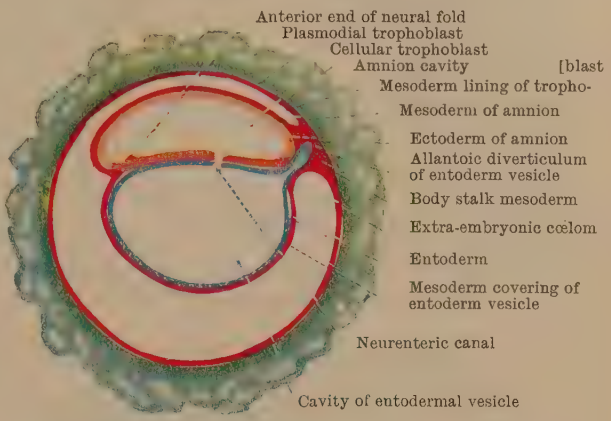

FIG. 38.—SCHEMA OF SAGITTAL SECTION OF ZYGOTE ALONG LINE A IN FIG. 37.

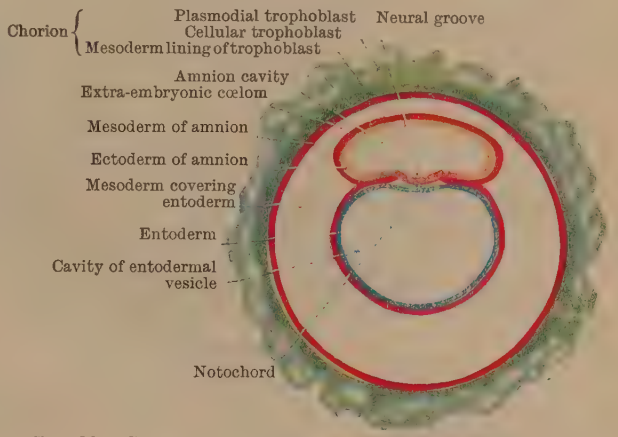

FIG. 39.—SCHEMA OF TRANSVERSE SECTION OF ZYGOTE ALONG LINE B IN FIG. 37.

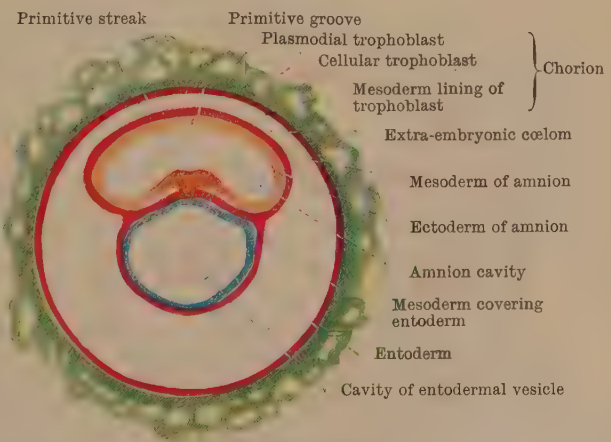

FIG. 40.—SCHEMA OF TRANSVERSE SECTION OF ZYGOTE ALONG LINE C IN FIG. 37.

In the very early stage of its development the caudal end of the notochord is traversed by the neurenteric canal, which, therefore, is frequently spoken of as the notochordal canal.

After a time the cylindrical notochordal rod is surrounded by secondary mesoderm which becomes converted into the vertebral column of the adult. As the vertebral column is formed the notochord is enlarged in the regions of the inter-vertebral fibro-cartilages and for a time assumes a nodulated appearance (Fig. 60).

Ultimately the notochord disappears, as a distinct structure, but remnants of

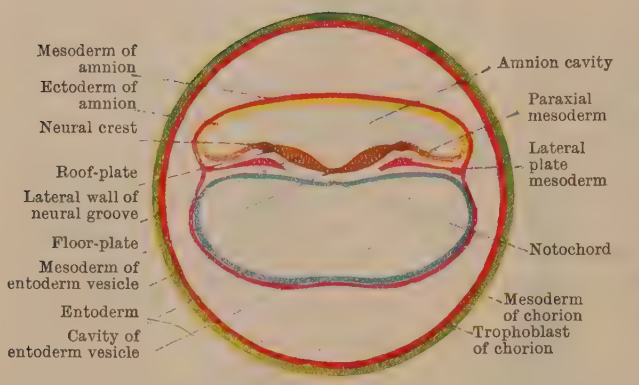

FIG. 41.—TRANSVERSE SECTION OF A ZYGOTE, showing early stage of embryonic secondary mesoderm before the appearance of the embryonic parts of cœlom.

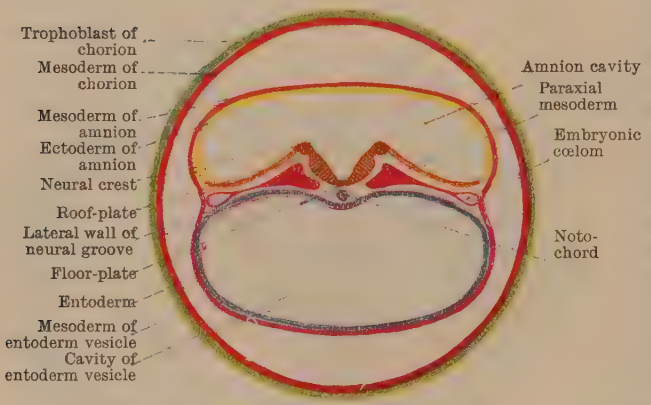

FIG. 42.—TRANSVERSE SECTION OF A ZYGOTE, showing early stage of development of embryonic cœlom and differentiation of mesoderm.

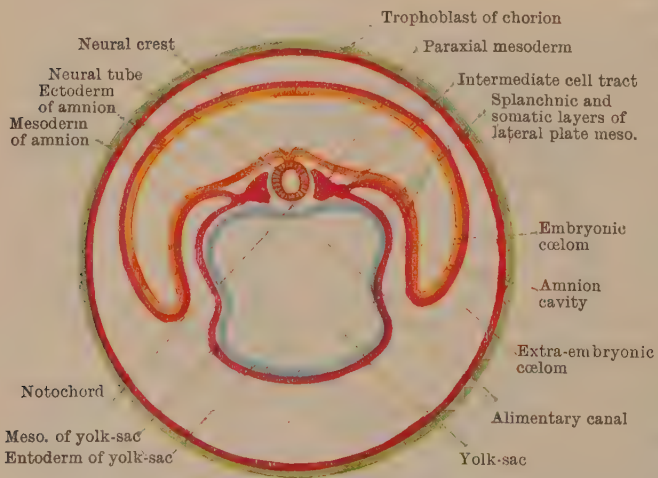

FIG. 43.—TRANSVERSE SECTION OF A ZYGOTE, showing union of intra- and extra-embryonic parts of cœlom and separation of embryonic mesoderm into paraxial bars, intermediate tracts, and lateral plates, with separation of lateral plates into somatic and splanchnic layers by the intra-embryonic part of the cœlom.

it are believed to persist as the pulpy centres of the intervertebral fibro-cartilages. The extension of the notochord into the region of the head is of interest from a morphological, and possibly also from a practical point of view. It extends through the base of the cranium from the anterior border of the foramen magnum into the posterior part of the body of the sphenoid bone. Its presence in the posterior part of the skull suggests that that region was, primitively, of vertebral nature. As the notochord passes through the occipital portion of the skull it pierces the basilar portion of the occipital region first from within outwards and then in the reverse direction. It lies, therefore, for a short distance, on the ventral surface of the rudiment of the occipital bone, in the dorsal wall of the pharynx, and it is possible that some of the tumours which form in the dorsal wall of the pharynx are due to the proliferation of remnants of its pharyngeal portion.

The Differentiation of the Secondary Mesoderm.—It has already been noted that a portion of the inner mass of the human zygote becomes converted directly into mesoderm which may be called, for convenience, *primary mesoderm.* It was stated also that the wall of the larger of the two inner vesicles of the zygote consists of ecto-mesoderm, that term being intended to convey the idea that the cells of the wall of the larger inner vesicle were the progenitors of both ectodermal and mesodermal cells.

As soon as the larger of the two inner vesicles is formed two areas of its wall are defined: (1) the part in

contact with the smaller inner or entodermal vesicle and (2) the remainder. As future events prove, the cells of the larger area, which is not in contact with the entodermal vesicle, simply produce ectodermal descendants which line the inner surface of a sac-like covering of the embryo termed the amnion; they are, therefore, the predecessors of the *amniotic ectoderm*.

The cells of the larger inner vesicle, which lie adjacent to the smaller entoderm vesicle, and are merely separated from the entoderm by a thin layer of primary mesoderm, take part in the formation of the embryo; forming, with the entoderm, the embryonic area from which the embryo is evolved. These cells are the forerunners of both ectoderm and mesoderm, and as the mesoderm developed from them is differentiated after the formation of the primary mesoderm it may be termed **secondary mesoderm** or **primitive streak mesoderm**; the latter term being applied because it is differentiated in a linear region called the primitive streak (p. 27). It is the formation and fate of this primitive streak mesoderm which is now to be considered.

At first the embryonic area is circular in outline, at a later period it becomes ovoid, and in the narrower or caudal portion of the ovoid area a linear thickening appears; this is the **primitive streak** (Figs. 37, 40). It is formed by the proliferation of the ecto-mesodermal cells of the wall of the larger inner vesicle. The deeper cells of the streak, which displace the primary mesoderm from the median plane, and thus come into contact with the entoderm, are the rudiments of the secondary or primitive streak mesoderm (Fig. 40). The superficial cells form part of the surface ectoderm of the embryo.

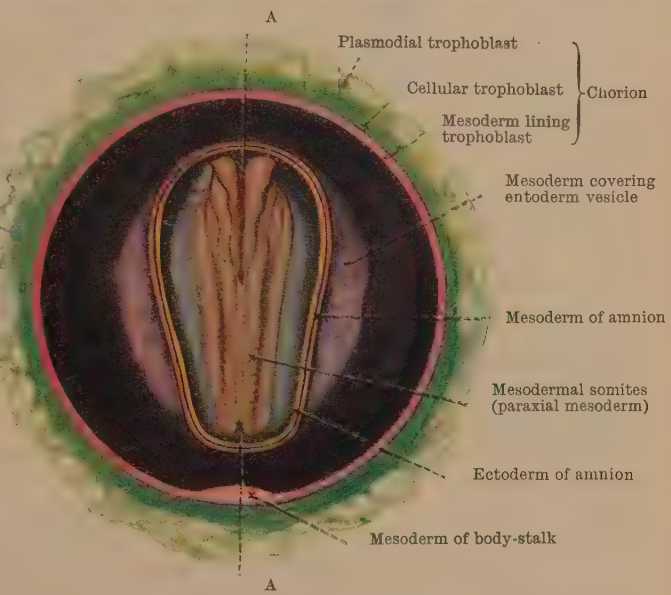

FIG. 44.—SCHEMA OF DORSAL ASPECT OF EMBRYO, showing partial closure of neural groove.

Portions of the chorion and amnion have been removed.
The neural folds have fused, except in the cephalic and caudal regions, both the cephalic and the caudal ends of the embryo have been bent ventrically and thirteen mesodermal somites have been formed.

At the anterior end of the primitive streak the mesodermal elements of the streak fuse with the subjacent entoderm and through the fused mass a perforation, the neurenteric canal (p. 28), is formed (Fig. 38).

The canal itself soon disappears, but the cells of its walls form a nodal growing point, and by their proliferation the length and breadth of the embryonic area are increased. The mesoderm cells proliferated from the cephalic border of the nodal point are the rudiments of the notochord, which has already been considered (p. 28).

It is uncertain whether or not the mesodermal cells budded off from the nodal point blend with the cells of the primary mesoderm, but there can be little doubt that they form by far the greater part, if not the whole, of the permanent mesoderm of the embryo.

Either by displacement or by union with the primary mesoderm the secondary mesoderm forms a continuous sheet of cells, in the embryonic area, on each side of the median plane.

Each of the lateral sheets is thickest where it abuts against the notochord and the wall of the neural groove, and thinnest at its peripheral margin, where it is continuous with the primary mesoderm of the extra-embryonic area (Fig. 41).

At the cephalic end of the embryonic area the medial margins of the mesodermal sheets fuse together across the median plane, forming a transverse bar of mesodermal cells which may be called the **pericardial mesoderm** (Fig. 54), because the pericardial sac, which envelops the heart, is afterwards developed from it. The area in which this mesoderm lies may be named the pericardial region of the embryonic area (Fig. 54).

Between the bar of pericardial mesoderm, the cephalic end of the neural groove, and the medial margins of the mesodermal plates lies a small segment of the embryonic area from which the primary mesoderm entirely disappears, leaving the ectoderm and entoderm in contact. This is the **bucco-pharyngeal area.** It afterwards becomes the **bucco-pharyngeal membrane** (Figs. 56, 61), which separates the primitive mouth or stomatodæum from the cephalic end of the primitive entodermal alimentary canal. As already stated, the bucco-pharyngeal membrane disappears during the third week, when the stomatodæum and the primitive alimentary canal become continuous with each other.

Between the bucco-pharyngeal area and the cephalic end of the primitive streak the medial margins of the mesodermal plates are separated from one another by the notochord and the neural groove (Fig. 42), and still more caudally they are united with the sides of the streak (Fig. 40).

After the permanent mesodermal plates are definitely established a series of clefts appear in their peripheral margins. The clefts, on each side, soon fuse together to form the bilateral rudiments of the **embryonic cœlom** (Fig. 42).

The septum of cells at the lateral border of the embryonic area on each side, which, for a time, separates the embryonic from the extra-embryonic cœlom, soon disappears, and the cœlom then forms a continuous cavity (Fig. 43).

The embryonic cœlom also extends medially, but the medial extension ceases whilst the cavity is still at some distance from the median plane, except at the cephalic end of the embryonic area, where the two lateral halves of the embryonic cœlom become continuous with one another through the interior of the pericardial mesodermal bar (Figs. 55, 61).

As the embryonic cœlom is forming and extending, a longitudinal constriction appears in each lateral half of the mesoderm, a short distance from its medial border. This constriction separates each plate into three parts: (1) a medial bar, the **paraxial mesoderm**, which lies at the side of the neural groove and the notochord (Fig. 43); (2) the constricted portion, which is called the **intermediate cell tract**; and (3) the part lateral to the constriction, which is called the **lateral plate** (Fig. 43).

The embryonic cœlom is confined, as a rule, in the human subject, to the lateral plate, which it divides into a superficial layer, next the ectoderm, the **somatic mesoderm**, and a deeper layer, next the entoderm, the **splanchnic mesoderm.**

The medial borders of the somatic and splanchnic mesoderm are continuous with one another round the medial border of the cœlom. The lateral border of the somatic mesoderm is continuous, at the margin of the embryonic area, with the mesoderm which covers the outer surface of the amnion, and the lateral border of the splanchnic layer is continuous with the mesoderm on the wall of the extra-embryonic or yolk-sac portion of the entodermal sac.

The Paraxial Mesoderm.—Each paraxial mesodermal bar soon assumes the form of a triangular prism with the apex directed ventro-medially, towards the notochord, and the base dorso-laterally, towards the surface ectoderm.

The cephalic portion of each paraxial bar, as far caudalwards as the middle of the hind-brain (see p. 38), remains unsegmented, but the remainder is cut into a number of segments, the **mesodermal somites**, by a series of transverse clefts (Fig. 44). The first cleft appears in the region of the hind-brain, and the others are formed successively, each caudal to its predecessor. Only three or four somites lie in the region of the head; the remainder are in the body area of the embryonic region. The segmentation of the paraxial bars commences before their elongation is completed, and the posterior somites are separated off as the paraxial bars are extended by the continued proliferation from the nodal point at the anterior end of the primitive streak.

When they are first defined the somites are solid masses of cells, but in

a short time a cavity—the cœlom of the somite or **myocœle**—is developed in each mass.

In many animals the myocœle is continuous through the intermediate cell tract with the more lateral parts of the cœlom, but that is not usually the case in human embryos.

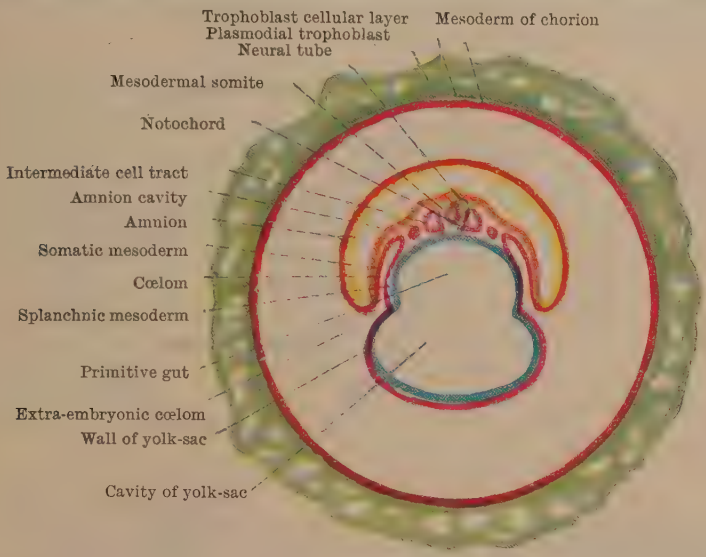

FIG. 45.—TRANSVERSE SECTION OF THE ZYGOTE SHOWN IN FIG. 44, showing the differentiation of the mesoderm.

The apical portion of the hollow mesodermal somite is its **scleratogenous segment.** The cells of the scleratogenous section of the somite undergo rapid proliferation. Some of the newly formed scleratogenous cells invade the myocœle; others migrate towards the notochord; finally, the scleratogenous cells separate from the remainder

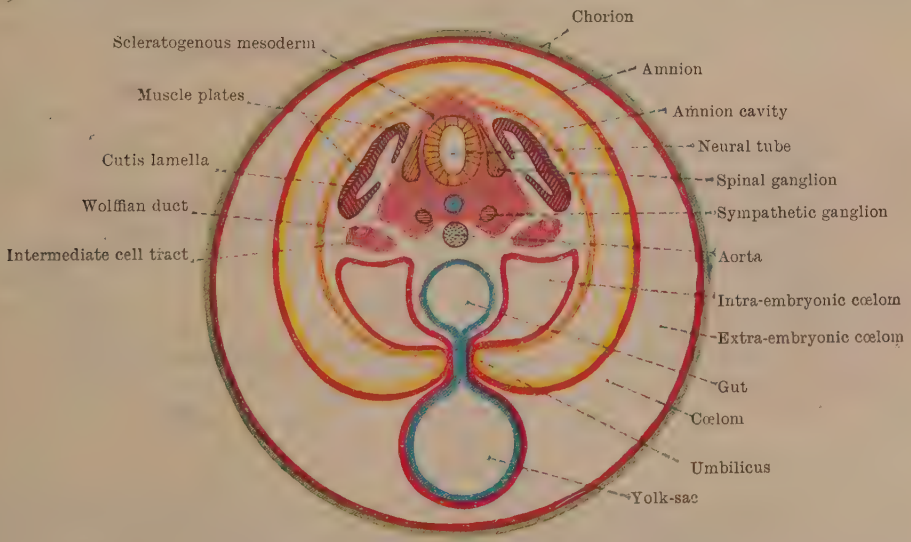

FIG. 46.—SCHEMA OF A TRANSVERSE SECTION OF A ZYGOTE, showing differentiation of mesoderm and extension of amnion.

of the somite, and as they increase in number they migrate along the sides of the notochord and the neural tube, which has been formed in the meantime from the neural groove, and join with their fellows of the opposite side, and with their cephalic and caudal neighbours. In this way is formed, around the neural tube and the notochord, a continuous sheath of mesoderm, the **membranous vertebral**

column, from which are differentiated, in later stages, the vertebral column and its ligaments, and the membranes of the brain and the spinal medulla.

After the separation of the scleratogenous segments of the mesodermal somites, the remainders of the somites, each of which consists of a flat plate with incurved dorsal and ventral margins, constitute the **muscle plates** from which the striped muscle fibres are derived.

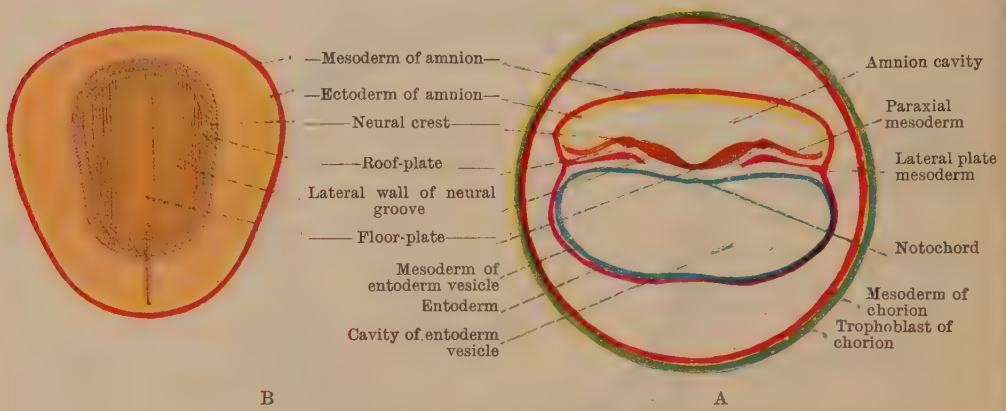

FIG. 47.

A. Transverse section of a zygote, showing the constituent parts.
B. Diagram of embryonic area showing parts of neural plate and primitive streak.

In the opinion of some observers the outermost portion of each of the above-described plates is developed into subcutaneous connective tissue cells; consequently it is spoken of as the *cutis lamella*. According to this view the muscle cells are formed from the innermost cells and the incurved margins of the plates.

The Intermediate Cell Tracts.—The intermediate cell tracts are the rudiments of the internal organs of the genital system and the temporary and permanent urinary system, with the exception of the urinary bladder and the urethra.

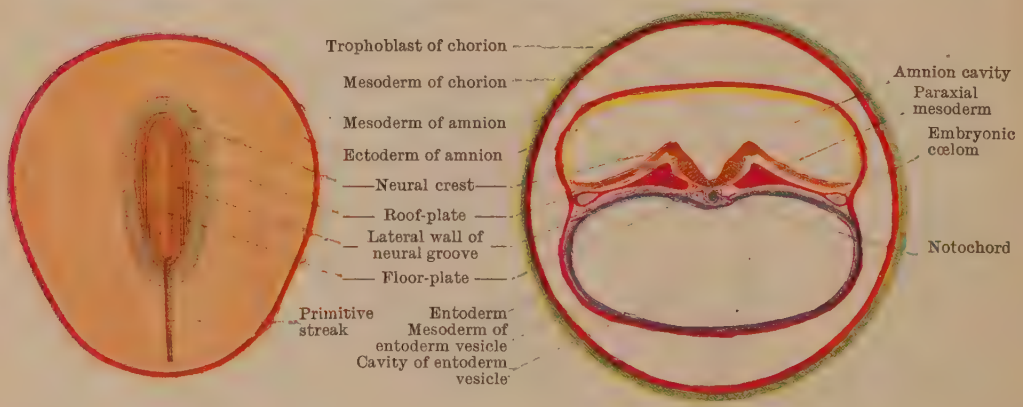

FIG. 48.

A. Diagram of a transverse section of a zygote, showing the formation of a neural groove in the embryonic area
B. Diagram of a surface view of the embryonic area of the same zygote.

The Lateral Plates.—From the cells of the lateral plates are formed the lining endothelial cells of the great serous cavities of the body—the pleuræ, the pericardium, and the peritoneum; the majority of the connective tissues, with the exception of those of the vertebral column and the head, the greater part or all the mesoderm of the limbs, and, probably, the unstriped muscle fibres of the walls of the alimentary canal and the blood-vessels.

The Cephalic Mesoderm.—It has already been noted that the mesoderm of the

head becomes segmented only in the region of the caudal part of the hind-brain, where four cephalic mesodermal somites are formed on each side. From the scleratogenous portions of these somites are developed the occipital part of the skull and the corresponding portions of the membranes of the brain, and from their muscle plates the intrinsic muscles of the tongue.

The unsegmented part of the cephalic mesoderm gives rise to the remaining muscles and connective tissues of the head region.

The Mesenchyme.—Before the embryonic area becomes an embryo, there appear, between the more definite layers of mesoderm and the adjacent entoderm and ectoderm, a number of cells of irregular form and wandering habits, but which are undoubtedly of mesodermal nature that constitute the **mesenchyme.**

Early Stages of the Development of the Nervous System.—No definite trace of the nervous system is present until the primitive streak has formed and the embryonic area has passed from a circular to a pear-shaped form. Then an area of thickened ectoderm, the **neural plate**, appears in the anterior part of the embryonic area. It commences a short distance posterior to the anterior end of the area,

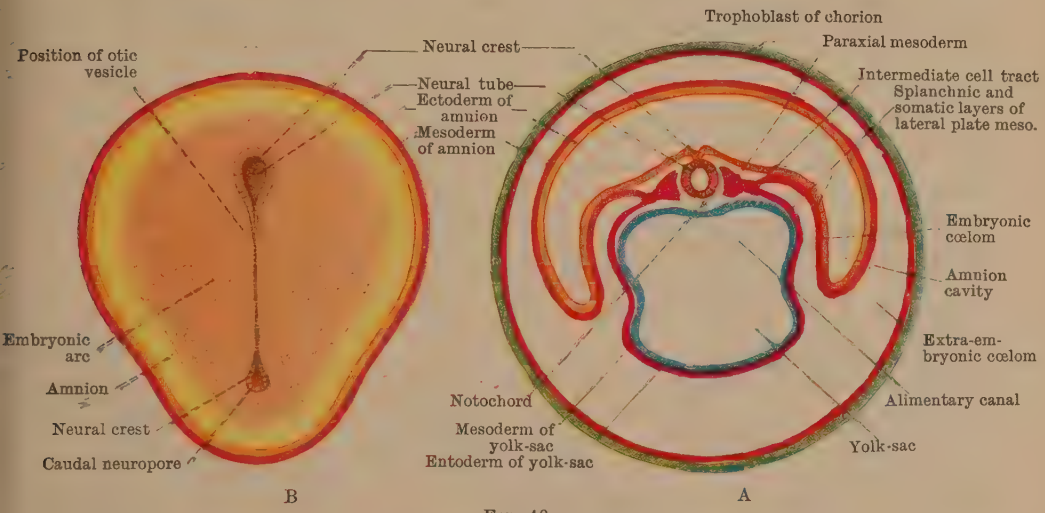

FIG. 49.

A. Diagram of a transverse section of a zygote, in which the neural tube has formed but has not separated from the surface ectoderm.

B. Diagram of embryonic area of same zygote. Compare with surface view of embryo in Fig. 44.

and its posterior extremity embraces the anterior end of the primitive streak. Its lateral margins fade into the surrounding ectoderm, and, at first, cannot be definitely defined; but, as the elongation of the plate continues, coincidently with the elongation of the embryonic area, the lateral margins of the plate are elevated, as the mesoderm beneath them thickens, and so they become distinct. As the lateral margins of the neural plate are raised the plate is necessarily folded longitudinally, and the sulcus so formed is called the **neural groove.** Each side wall of the neural groove, formed by the corresponding half of the neural plate, is a **neural fold.** At a very early period the neural folds unite anteriorly to form the anterior boundary of the neural groove, and, somewhat later, they unite posteriorly, posterior to the neurenteric canal and across the anterior end of the primitive streak. After the lateral boundaries and the anterior and posterior extremities of the neural groove are defined, the lateral margins of the neural folds converge until they meet and fuse in the median plane, and the neural groove is thus converted into the **neural tube**, which possesses a floor or ventral wall, formed by the central part of the original neural plate and called the **basal plate** or floor-plate; a dorsal wall or **roof-plate**, and two lateral walls formed by the lateral parts of the neural plate.

The fusion of the lateral margins of the neural plate to form the roof-plate of the neural tube commences in the cervical region, and from there extends

cranialwards and caudalwards, therefore the last parts of the roof-plate which are formed are its anterior and its posterior extremities; consequently, for a time, the **neural canal**, which is the cavity of the tube, opens on the surface at its anterior and posterior ends; the anterior opening being called the **anterior neuropore**, whilst the open part at the posterior end is termed the **posterior neuropore** (Fig. 49). Eventually, however, about the third week of embryonic life, both apertures are closed and, for a time, the neural canal becomes a completely closed cavity.

As the margins of the neural groove rise and converge they carry with them the adjacent ectoderm to which they are attached, and which forms part of the

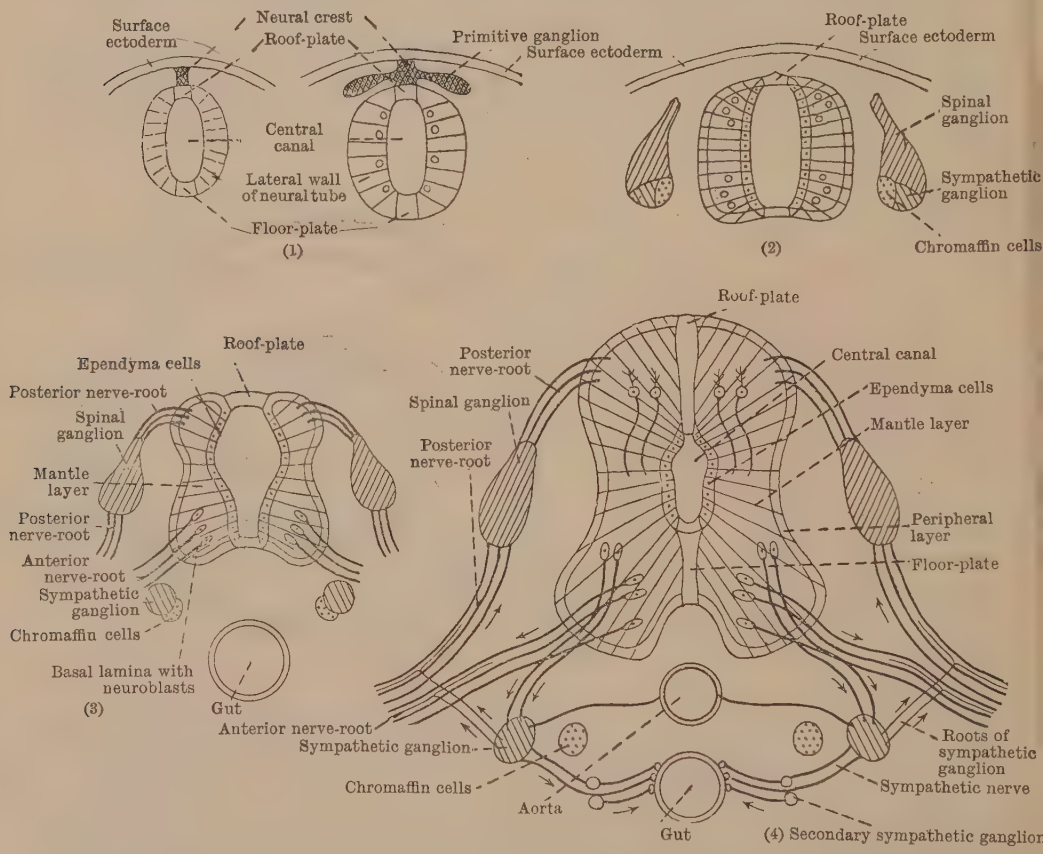

FIG. 50.—DIAGRAMS illustrating the formation of (1) the rudiments of the primitive ganglion from the neural crest. (2) The differentiation of different parts of the primitive ganglion into permanent ganglion root, sympathetic ganglion, and masses of chromaffin cells. (3) The formation of the anterior and posterior nerve-roots. (4) The differentiation of the walls of the neural tube into ependymal matter and peripheral layers.

The cells of the primitive ganglion which form the primitive sheaths of the nerves are not shown in the diagrams.

surface covering of the embryo; consequently, when the lateral margins of the folds meet and unite, the tube, which is completed by their fusion, is embedded in the body of the embryo, but, for a time, its dorsal wall is attached to the surface ectoderm by a ridge of cells, formed by the fused lateral margins of the neural plate. This ridge is called the **neural crest** (Figs. 47-50).

The neural crest is the rudiment of the cerebral and spinal nerve ganglia, the sympathetic ganglia, the chromaffin cells of the chromaffin organs, and the cellular sheaths of the peripheral nerves; whilst the walls of the neural tube become transformed into the various constituent parts of the central nervous system, the brain and spinal medulla, the retinæ of the eye-balls, and the optic nerves.[1]

[1] It is stated, by some observers, that some of the sympathetic nerve cells are derived from the ventral parts of the lateral walls of the neural tube.

The Formation of the Nerve Ganglia, the Chromaffin Tissues, and the Primitive Nerve Sheaths.—The **primitive ganglia** grow as cell buds from the neural crest which, for a time, connects the dorsal wall of the neural tube with the surface ectoderm. In the body region they correspond in number with the spinal nerves and with the primitive segments into which the mesoderm becomes divided, but in the cephalic region their arrangement is more irregular, and some of the ganglia of the cerebral nerves receive additional cell elements from the surface ectoderm or the entoderm.

Simultaneously with the appearance of the cell buds which form the primitive ganglia, the neural crest disappears, and directly after the ganglia are formed they lose their connexion with both the neural tube and the surface ectoderm and become isolated cell clumps. At this period, therefore, the nervous system consists of the neural tube and the primitive ganglia.

After the primitive ganglia have lost their connexion with the neural tube they increase in size by the proliferation of their constituent cells, and they migrate ventrally along the sides of the neural tube, but the migration ceases before the ventral ends of the ganglia reach the level of the ventral wall of the tube. As the migration proceeds clumps of cells are budded off from the ventral ends of the ganglia. These secondary cell buds are the rudiments of the sympathetic ganglion cells and of the chromaffin tissue which is found in the sympathetic nerve plexuses, the medulla of the suprarenal glands, and in the carotid glands. In the first instance the secondary cell buds which form the sympathetic ganglia wander ventrally and medially, from the ventral ends of the primitive ganglia, until they attain the positions, afterwards occupied by the ganglia of the sympathetic trunks, on the ventro-lateral aspects of the vertebral column. From the primary sympathetic ganglia buds of cells are given off; these buds wander still further ventrally to become the cells of the ganglia of the cardiac, cœliac, and other great ganglionic nerve plexuses, as well as to form the chromaffin cells of the chromaffin organs.

The exact manner in which the cells of the primitive sheaths of the nerves originate from the primitive ganglia is not known, but it has been shown by Harrison, in the case of the frog, that if the primitive ganglia are destroyed, the primitive sheaths of the nerves are not formed. Presumably, therefore, in the frog the cellular sheaths of the nerves are derived from cells produced by the primitive ganglia, and it may be assumed that they have a similar origin in the human subject.

After the rudiments of the sympathetic system, the chromaffin cells, and the cellular sheaths of the nerves have separated, the remains of the primitive ganglia become the permanent spinal and cerebral nerve ganglia.

In the early stages these ganglia are completely isolated structures which lie along the sides of the neural tube between the lateral walls of the tube medially, and the mesoderm somites laterally.

Some time after the ganglia of the cerebral and spinal nerves become isolated their cells give off processes which become nerve-fibres. These fibres grow out both from the dorsal and the ventral ends of the ganglia, and, together with the ganglia, they form, in the cranial region, certain of the cerebral nerves, and, in the spinal region, the posterior roots of the spinal nerves.

The fibres which grow out of the dorsal ends of the ganglia enter the walls of the neural tube, and by their means the ganglia regain connexion with the tube.

The fibres which grow out from the ventral end of each spinal ganglion unite with the fibres of the corresponding anterior nerve-root, which, in the meantime, has grown out from the cells of the ventral part of the lateral wall of the spinal portion of the neural tube, and form with them a spinal nerve-trunk.

The Differentiation of the Neural Tube.—Before the neural groove is converted into a closed tube, an expansion of its anterior part indicates the separation of the neural rudiment into cerebral and spinal sections, the dilated portion being the rudiment of the **brain** and undilated part the rudiment of the **spinal medulla.**

Whilst the cerebral portion is still unclosed, three secondary dilatations of its

walls indicate its separation into three sections, the primitive **fore-brain**, the **mid-brain**, and the **hind-brain**; the primitive fore-brain being the most cephalward or anterior and the hind-brain the most caudal or posterior of the three (Fig. 44).

Shortly after the three segments of the brain are defined, and before it becomes a closed tube, a vesicular evagination forms at the cephalic end of each lateral wall of the primitive fore-brain region. These evaginations are the **primary optic vesicles**, and they are the rudiments of the **optic nerves**, the **retinæ**, and the **posterior epithelium of the ciliary body** and the **iris** of the eye-ball.

When the cerebral portions of the neural folds meet and fuse dorsally the cerebral dilatations become the primitive brain vesicles, each vesicle possessing its own cavity and walls, but the cavities of the three vesicles are continuous with one another, and the cavity of the hind-brain vesicle is continuous, caudally, with the central canal of the spinal part of the neural tube.

After the primitive brain vesicles are formed, a diverticulum grows out from the cephalic end of the primitive fore-brain vesicle. This is the rudiment of the **secondary fore-brain**. Its cephalic end soon divides into two lateral halves, which are the rudiments of the **cerebral hemispheres** of the adult brain (Fig. 51).

After their formation the cerebral hemispheres expand rapidly in all directions. They soon overlap the primitive fore-brain and mid-brain (Fig. 69), and, eventually, the hind-brain also, and each gives off from the cephalic end of its ventral wall a secondary diverticulum, the **olfactory diverticulum**, which becomes converted, later, into the olfactory bulb and olfactory tract.

When they first appear the rudiments of the cerebral hemispheres are connected together, across the median plane, by a part of the cephalic end of the wall of the **secondary fore-brain dilatation**, which is called the **lamina terminalis**. This primitive connexion between the two cerebral hemispheres persists throughout the whole of life, and it is supplemented, at a later period, by the formation of three secondary commissures, the corpus callosum and the fornix, which grow through the upper part of the lamina terminalis, and the anterior commissure which grows through its lower part.

The Fate of the Walls of the Primitive Brain Vesicles.—The primitive hind-brain, which is also called the rhombencephalon, is separated in the later stages of development into two parts. (1) A caudal portion which is connected with the medulla spinalis, and which becomes the **medulla oblongata** or myelencephalon of the adult brain. (2) A cephalic portion which is continuous at one end with the medulla oblongata and at the other with the mid-brain. The ventral wall of the cephalic portion of the primitive hind-brain is ultimately converted into the **pons**, and its dorsal wall differentiates into two parts—a caudal part which becomes the **cerebellum**; and a cephalic part which is converted into the **anterior medullary velum** and the **brachia conjunctiva**. The brachia conjunctiva connect the cerebellum with the ventral part of the mid-brain. The pons and cerebellum form the metencephalon of the adult, whilst the brachia conjunctiva and the anterior medullary velum constitute parts of the isthmus rhombencephali (Figs. 51, 69).

The ventral portion of the primitive mid-brain is converted into the two **peduncles of the cerebrum** of the adult brain, and the dorsal portion is transformed into four rounded elevations, the colliculi or **corpora quadrigemina**.

The transformations which take place in the region of the primitive fore-brain or prosencephalon are numerous and complicated; therefore its ventral, lateral, and dorsal walls require separate consideration.

By the expansion of its cephalic (anterior) extremity is formed the **secondary fore-brain**, which becomes divided, as already explained, into the two secondary vesicles which are the rudiments of the **cerebral hemispheres** of the completed brain.

After the formation of the rudiments of the cerebral hemispheres, which constitute the **telencephalon** of the adult, the primitive fore-brain and the undivided stalk of the secondary fore-brain diverticulum become the **diencephalon**.

The cephalic or anterior end of the diencephalon is closed by the lamina terminalis (see above), in association with which are subsequently developed two columns which run dorso-ventrally, the **columns of the fornix**, and three transverse

commissures, two of which connect the cerebral hemispheres, the corpus callosum, and the **anterior commissure**, whilst the third is the **optic chiasma** in which the medial fibres of the optic nerves decussate.

From the cephalic or anterior end of the ventral wall of the diencephalon a diverticulum is projected ventrally towards the dorsal wall of the primitive mouth. The ventral end of this diverticulum becomes the posterior lobe of the **hypophysis** (O.T. **pituitary body**) of the adult, the dorsal end becomes the *tuber cinereum*, and the intermediate part is the *infundibulum* which connects the *tuber cinereum* of the adult brain with the posterior lobe of the hypophysis.

Caudal to the hypophyseal diverticulum a single elevation appears in the ventral wall of the diencephalon. It is the **corpus mamillare**, which afterwards separates into the paired **corpora mamillaria** of the adult brain.

Still more caudally the ventral wall of the diencephalon takes part in the formation of the **substantia perforata posterior**, which lies between the two peduncles of the cerebrum and is partly developed from the cephalic or anterior end of the ventral wall of the primitive mid-brain.

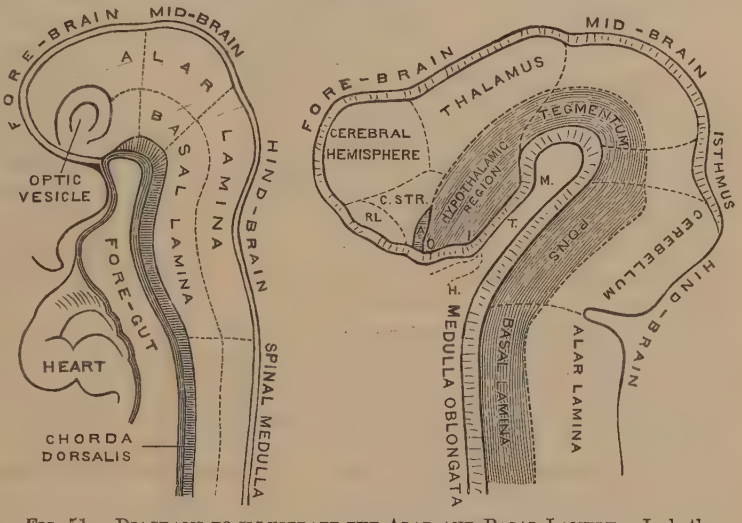

FIG. 51.—DIAGRAMS TO ILLUSTRATE THE ALAR AND BASAL LAMINÆ. In both cases the embryonic brain is represented in mesial section (His).

A. The different subdivisions of the brain are marked off from each other by dotted lines, and the dotted line running in the long axis of the neural tube indicates the separation of the alar from the basal lamina of the lateral wall.

B. Medial section through the brain of a human embryo at the end of the first month. Dotted lines mark off the different regions and also the alar and basal laminæ from each other.

H, Buccal part of hypophysis cerebri; RL, Olfactory lobe; C.STR, Corpus striatum; A, Entrance to optic stalk; O, Optic recess; I, Infundibular recess; T, Tuber cinereum; M, Mamillary eminence.

The greater part of the **dorsal** wall of the diencephalon is ultimately reduced to a single layer of epithelial cells, but near its caudal end a diverticulum is projected dorsally. This is the **epiphysis** or **pineal body**, which remains quite rudimentary in man as contrasted with many other animals. At a later period two transverse bands of fibres appear in the dorsal wall of the diencephalon, one in front of and the other immediately behind the root of the epiphyseal recess. The anterior band is the **dorsal** or **habenular commissure**, and the posterior is the **posterior commissure** of the adult brain.

These structures, collectively, together with a small diverticulum of the epithelial roof, which appears anterior to the dorsal commissure, and is called the supra-pineal recess, constitute the so-called **epithalamus**.

Each lateral wall of the diencephalon is differentiated into a dorsal and a ventral part. The dorsal part forms a large gray mass called the **thalamus**, and on the posterior end of the thalamus are developed two rounded elevations, the **medial** and the **lateral geniculate bodies**, which constitute the **metathalamus** of the adult brain.

The ventral or basal portion of the lateral wall of the diencephalon, together with the adjacent part of the ventral wall, forms the **hypothalamus** of the fully developed brain.

The Fate of the Spinal Portion of the Primitive Neural Tube.—The

spinal portion of the neural tube, during the first three months of intra-uterine life, develops equally in its whole extent, but after that period a longer cephalic (superior in the erect posture) and a shorter caudal portion are recognisable. The cephalic portion undergoes still further development and is converted into the spinal medulla of the adult, but in the smaller caudal portion retrogressive changes occur, and it is transformed into the non-functional **filum terminale** of the completed medulla spinalis.

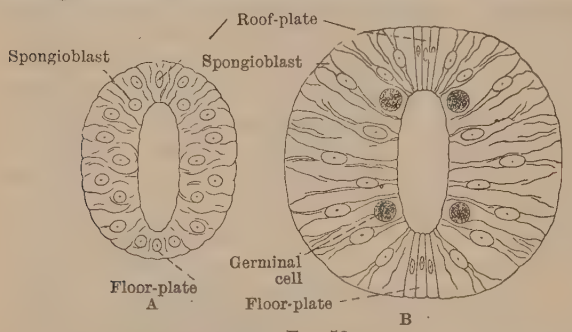

FIG. 52.

A. Diagram of a transverse section of a spinal medulla which has not differentiated into groups of cells.

B. Diagram of a transverse section of a spinal medulla showing positions of germinal cells.

Histological Differentiation of the Walls of the Neural Tube. — In the earliest stages of its development the walls of the neural tube consist of a mass of nucleated protoplasm, more or less distinctly differentiated into cell areas, of columnar form, which extend between and are connected with an **internal limiting membrane**, bounding the neural canal, and an **external limiting membrane**, which surrounds the whole tube. At this time the outline of a transverse section of the primitive neural tube is somewhat ovoid (Fig. 52). The cavity of the tube is compressed laterally into a dorso-ventral cleft, which is bounded by dorsal, ventral, and lateral walls. In the dorsal and ventral walls, called respectively the roof- and floor-plates, the columnar character of the primitive epithelial elements of the medulla spinalis is retained throughout the whole of life, but the peripheral parts of some of the cells are converted into fibrils.

In the lateral walls of the embryonic medulla spinalis some of the cells soon assume a spherical form. These spherical cells have large deeply staining nuclei, and they are termed **germinal cells**.

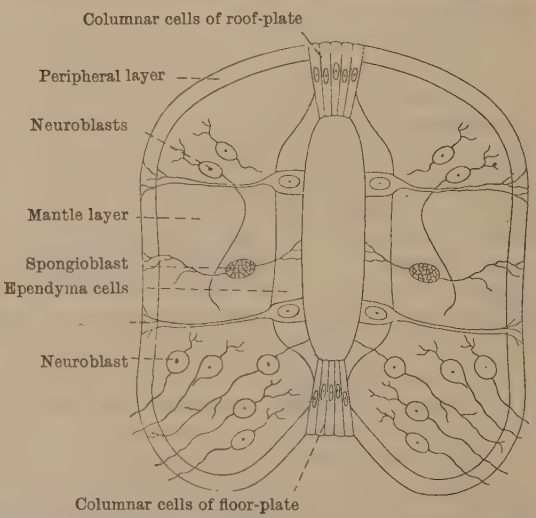

FIG. 53.—SHOWING ELEMENTS OF CENTRAL NERVOUS SYSTEM.

For many years it was believed that the germinal cells were the predecessors of the primitive nerve elements or **neuroblasts**, and that the remaining cells, called **spongioblasts**, became transformed into the reticular sustentacular tissue of the central nervous system. It appears, however, from the results of more recent researches, that some of the descendants of the germinal cells become spongioblasts whilst others become neuroblasts or primitive nerve-cells. Moreover, there appear to be two groups of germinal cells; the descendants of one group are directly transformed into the ependymal or lining cells of the central canal, whilst those of the other group form in the first instance **indifferent cells**, some of whose descendants become neuroblasts and others spongioblasts. The fate of the cells present before the germinal cells appear, and which do not become germinal cells, is uncertain, but they probably take part in the formation of the spongioblastic tissue.

It is believed, therefore, that all the nerve-cells are the descendants of the germinal cells, and that the spongioblasts which become developed into the cells

of the neuroglia or sustentacular reticulum are derived partly from the non-germinal cells of the primitive neural tube and, partly, they are descendants of the germinal cells.

As differentiation proceeds three layers and two membranes are gradually defined in the walls of the neural tube: (1) a central layer of columnar ependyma cells immediately surrounding the central canal; (2) an intermediate or mantle layer consisting of neuroblasts, and their processes the nerve-fibres, intermingled with spongioblasts; (3) a peripheral reticular layer consisting, at first, of processes of the bodies of the spongioblasts. The membranes are an external limiting membrane, surrounding the exterior of the tube, formed by the fused outer ends of the spongioblastic cells, and an internal limiting membrane bounding the central canal and continuous with the inner ends of the ependyma cells. Throughout the whole of the spinal medulla and the brain, the ependyma cells become transformed into the columnar ciliated cells which line the cavities of the adult brain and spinal medulla. The mantle layer becomes converted into the central gray matter of the adult central nervous system.

The peripheral reticular layer, in the spinal region, becomes permeated by nerve-fibres, which are merely processes of the nerve-cells, and it is thus converted into the white matter of the adult spinal medulla. In the brain region it is either transformed in the same way into white matter, or it remains in a more rudimentary condition as a thin peripheral layer of neuroglia on the surface of the gray matter. On the other hand, in the brain region white matter is formed internal to the gray matter by the growth of nerve-fibres which insinuate themselves between the mantle layer externally and the bodies of the ependyma cells internally.

As the histological differentiation of the walls of the neural tube is proceeding each lateral wall is divided into a dorsal part, the **alar lamina**, and a ventral part, the **basal lamina**, by a sulcus-like dilatation of the central canal called the *sulcus limitans*. After the limiting sulci are formed the parts of the walls of the neural tube are a roof-plate, a floor-plate, and two lateral walls, each of which consists of an alar lamina, essentially sensory in function, and a basal lamina, essentially motor in function (Fig. 50).

The Fate of the Cavities of the Primitive Brain.—The cavity of the spinal portion of the primitive neural tube becomes the central canal of the spinal medulla of the adult. The cavities of the primitive brain vesicles are transformed into the ventricles, foramina, and aqueduct of the adult brain. The cavities of the telencephalic divisions of the secondary fore-brain become the **right** and **left lateral ventricles** of the adult brain. The cavity of the undivided portion of the secondary fore-brain vesicle, together with the cavity of the primary fore-brain, become the **third ventricle** or cavity of the diencephalon, and the apertures of communication between the third ventricle and the cerebral hemispheres are the **interventricular foramina** (O.T. **foramina of Monro**).

The cavity of the hind-brain vesicle becomes the **fourth ventricle**, and the cavity of the primitive mid-brain is converted into the **aqueductus cerebri**, which connects the third with the fourth ventricle.

After the anterior and posterior neuropores (p. 36) are closed, the cavity of the neural tube is, for a time, a completely enclosed space. Subsequently the mesoderm, which in the meantime has surrounded the tube, becomes differentiated, in its immediate neighbourhood, into three membranes. The innermost of the three is closely connected with the walls of the neural tube and is called the **pia mater**. The outermost, known as the **dura mater**, is dense and resistant, and the intermediate membrane is a thin lamella called the **arachnoid**.

As the membranes are formed, spaces are differentiated between them. The space between the dura mater and the arachnoid is the **subdural space**, and that between the arachnoid and the pia mater is the **subarachnoid space**.

After a time a median perforation, the **median aperture of the fourth ventricle**, and two lateral perforations pierce the dorsal wall of the fourth ventricle and the pia mater which covers it, and thus the fourth ventricle becomes connected with the subarachnoid space.

THE FORMATION OF THE EMBRYO.

The transformation of the relatively flat embryonic area into the form of the embryo is due, in the first instance, to the rapid extension of the median part of the area, as contrasted with the slower growth of its margins, and the later modelling of the various parts of the embryo is due to different rates of growth in different parts of the embryonic region.

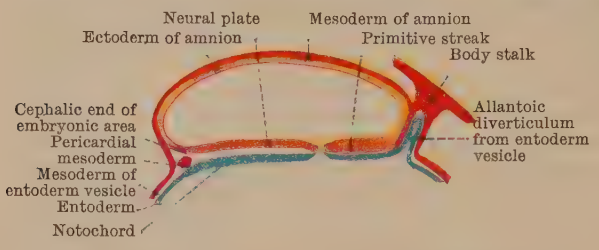

FIG. 54.—SCHEMA OF SAGITTAL SECTION OF EMBRYONIC AREA AND AMNION BEFORE THE FOLDING OF THE AREA HAS COMMENCED.

By the rapid proliferation of cells from the nodal growing point, at the cephalic end of the primitive streak, the cephalo-caudal length of the area is increased, whilst the cephalic and caudal ends of the area remain relatively fixed, consequently the area becomes folded longitudinally. At the same time, the cephalic end of the neural groove is pushed away from the nodal point, until it lies at first dorsal and then cephalad to the cephalic border of the area. As a result of this movement the bucco-pharyngeal and the pericardial areas become reversed in position, and a **cephalic** or **head fold** is formed. This fold is bounded, dorsally, by what is now the cephalic portion of the embryo, ventrally, by the reversed pericardial region, and its cephalic end is formed by the extremity of the head region and the bucco-pharyngeal membrane.

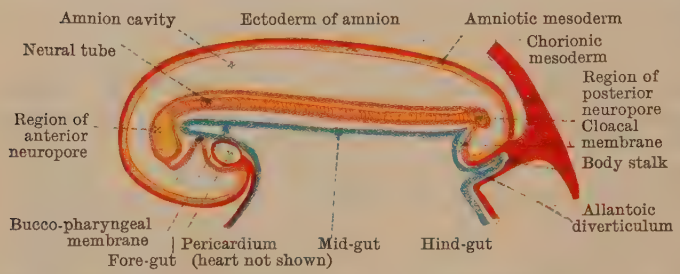

FIG. 55.—SCHEMA OF SAGITTAL SECTION OF EMBRYONIC AREA SHORTLY AFTER THE FOLDING HAS COMMENCED. The pericardial mesoderm is carried into the ventral wall of the fore-gut and the cœlom has extended through it. The cephalic end of the neural tube and the caudal part of the primitive streak are bent ventrally, and the latter now forms the cloacal membrane.

The growth at the nodal point not only produces a head fold, but at the same time it forces the cephalic end of the primitive streak caudally over the caudal end of the embryonic area, thus forming a **tail fold.**

As the head and tail folds of the embryo are produced by the longitudinal increase of the embryonic area, transverse growth of the area results in the formation of right and left **lateral folds** (Figs. 43, 46), and as the various folds are formed the embryo rises, like a mushroom, into the interior of the amnion cavity.

The portion of the entodermal sac which is enclosed within the hollow embryo, formed by the folding of the embryonic area, is the **primitive entodermal alimentary canal.** The part which remains outside the embryo is the **yolk-sac**, and the passage of communication between the two is the **vitello-intestinal duct.**

That portion of the primitive entodermal alimentary canal which lies in the head fold is termed the **fore-gut**, the part in the tail fold is the **hind-gut**, and the intermediate portion which is in free communication with the yolk-sac is the **mid-gut.**

As the extension of the embryonic area and its folding proceed the margin of the area, which remains relatively stationary, becomes the margin of an orifice, on the ventral aspect of the embryo, through which the primitive alimentary canal of the embryo and the intra-embryonic part of the cœlom communicate, respectively, with the yolk-sac and the extra-embryonic portion of the cœlom. This orifice is the **primitive umbilical orifice.**

Not only does the primitive alimentary canal communicate with the yolk-

sac, and the intra-embryonic with the extra-embryonic cœlom, at the margin of the umbilical orifice, but also the body walls of the embryo, formed by the somatopleure, become continuous, at the same margin, with the wall of the amnion.

The young embryo is connected also with the inner surface of the chorion by a band of tissue which is part of the median portion of the caudal part of the wall of the amnion sac. The mesoderm in this region is thickened, and contains in its interior a diverticulum, **allantoic diverticulum**, which is primarily derived from the entodermal sac, but is afterwards connected with the hind-gut. This strand consists of ectoderm and mesoderm, and it contains not only the allantoic diverticulum but also the blood-vessels passing between the embryo and the chorion. It was called, by His, the **body stalk**, but the term is not fortunate, for it takes no part in the formation in the body of the embryo. On the other hand, its mesodermal and entodermal constituents represent a diverticulum from the wall of the hind-gut, present in many mammals and known as the **allantois**; it might with advantage, therefore, be termed the **allantoic stalk**.

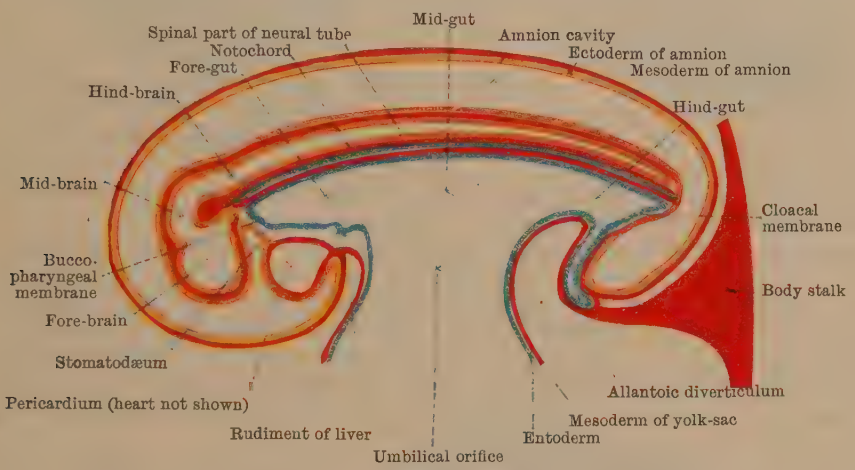

FIG. 56.—SCHEMA OF SAGITTAL SECTION OF EMBRYO AFTER THE FOLDING HAS DEFINED BOTH THE FORE-GUT AND HIND-GUT AREAS.

At first the umbilical orifice is relatively large as contrasted with the total size of the embryo, but as the embryo rapidly extends, in all directions, from the margin of the orifice, the latter soon becomes relatively small. Ultimately the various parts of the margin of the orifice are approximated until they fuse together, closing the opening and forming a cicatrix on the ventral wall of the abdomen which is known as the **umbilicus** or **navel**.

THE EMBRYO.

Whilst the embryonic area is being folded into the form of the embryo, the neural groove on the surface of the area is being converted into the neural tube. After the neural tube is completely closed and separated from the surface, during the third week, the embryo is an elongated organism possessing a larger cephalic end, a smaller caudal end, attached by the body stalk to the chorion (Fig. 55), a continuous and unbroken dorsal surface, a ventral surface separated into cephalic and caudal portions by the umbilical orifice, two lateral surfaces right and left, and it contains within its interior three cavities: (1) The cavity of the neural tube, which becomes the cavities of the brain and the spinal medulla (Fig. 56); (2) the primitive alimentary canal, which is a portion of the entodermal vesicle constricted off during the folding of the embryonic area (Figs. 43, 46); (3) the embryonic cœlom.

The embryonic cœlom consists of a pericardial portion, which lies cranial to

the umbilicus and ventral to the fore-gut, and right and left lateral portions, which lie at the sides of the fore-gut, the mid-gut, and the hind-gut.

The right and left portions communicate with one another, ventral to the fore-gut, through the pericardial portion, and ventral to the hind-gut, they also communicate with the extra-embryonic cœlom at the lateral and caudal margins of the umbilical orifice.

At this period the embryo is easily distinguished from the remainder of the zygote, and it is so far developed that indications of its general plan of organisation are discernible.

It has, as yet, no limbs, but the general contour of the head and body are defined. It possesses a notochord or primitive skeletal axis, afterwards replaced by the permanent vertebral column. On the dorsal aspect of the notochord lies the neural tube, which is the rudiment of the future brain and the spinal medulla.

At the sides of the neural tube and the notochord are the mesodermal somites and the nerve ganglia (Figs. 46, 49).

Ventral to the notochord is the primitive alimentary canal (Fig. 56), closed at its cephalic end by the bucco-pharyngeal membrane, and at its caudal end by what was originally the caudal portion of the primitive streak, but which is now called the **cloacal membrane** because it separates the caudal end of the hind-gut, which becomes the **entodermal cloaca**, from the amniotic cavity (Fig. 56).

At the sides of the primitive alimentary canal are the right and left lateral parts of the cœlom, and between the dorsal angle of each half of the cœlom and the mesodermal somites of the same side lies the intermediate cell tract which is the rudiment of the greater part of the genito-urinary system (Figs. 45, 46).

Ventral to the fore-gut is the pericardial mesoderm, traversed by the pericardial portion of the cœlom, which is connected dorsally, on each side, with the corresponding lateral portions of the cœlom; and ventral to the hind-gut is the cloacal membrane. Between the pericardial region at the one end and the cloacal membrane at the other lies the umbilical orifice, through which the mid-gut communicates with the yolk sac, the intra-embryonic part of the cœlom with the extra-embryonic cœlom, and the allantoic diverticulum with the cloaca (Figs. 45, 56).

THE LIMBS.

When it is first defined the embryo is entirely devoid of limbs (Fig. 57). During the third week a superficial ridge appears on each side, along the line of the intermediate cell tract in the interior. This is the **Wolffian ridge**, and upon it the **limb buds**, which are the rudiments of the fore and hind limbs, are formed, as secondary elevations; the fore-limb buds preceding the hind-limb buds in time of appearance (Fig. 58).

Shortly after it has appeared, each limb bud assumes a semilunar outline; it projects at right angles from the surface of the body, and it possesses dorsal and ventral surfaces, and cephalic or preaxial, and caudal or postaxial borders. The bud is the rudiment of the distal segment of the future limb, the hand in the case of the fore-limb, and the foot in the case of the hind-limb.

As the limb-rudiment increases in length the more proximal segments of the limb are differentiated, the forearm and arm in the case of the fore-limb, and the leg and the thigh in the case of the hind-limb. At the same time the limbs are folded ventrally, so that their original ventral surfaces become medial and their original dorsal surfaces lateral, and the convexities of the elbows and knees are directed laterally. At a later period, on account of a rotation which takes place in opposite directions in the fore- as contrasted with the hind-limbs, the convexity of the elbow is turned towards the caudal end of the body and that of the knee towards the cephalic end. It is only at much later periods of development, as the erect posture is assumed, that the convexity of the elbow is directed dorsally and the convexity of the knee ventrally.

The terminal or distal segment of each limb is, at first, a flat plate with a rounded margin, but it soon differentiates into a proximal or basal part and a

more flattened marginal portion. It is along the line where these two parts are continuous that the rudiments of the **digits** appear. They become evident as small elevations on the dorsal surface of the limb bud about the fifth week; they extend

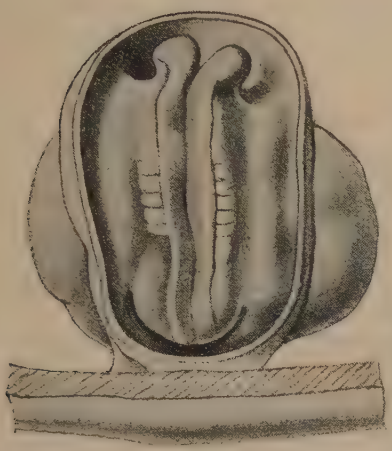

FIG. 57.—VIEW OF DORSAL ASPECT OF A HUMAN EMBRYO—1·38 mm. long, before the appearance of the limbs. (From Keibel and Elze, *Normaltafeln.*)

FIG. 58.—DORSAL LATERAL VIEW OF A HUMAN EMBRYO — 2·4 mm. long. The Wolffian ridge is seen at the lateral border of the mesodermal somites. (Keibel and Elze, *Normaltafeln.*)

peripherally, and by the sixth week the fingers project beyond the margins of the hand segment, but the toes do not attain to a corresponding stage of development until the early part of the seventh week.

The **nails** are later developments. They appear at the third month and reach the ends of the digits at the sixth month.

Each limb bud is essentially an extension from a definite number of segments of the body. It consists, at first, of a core of mesoderm covered by ectoderm. As it grows the anterior branches of the spinal nerves of the corresponding segments are prolonged into it, together with a number of blood-vessels. The nerves remain as the nerves of the fully developed limb, but the blood-vessels are reduced in number and are modified to form the permanent main trunks.

FIG. 59.—LATERAL VIEW OF A HUMAN EMBRYO—2·1 mm. greatest length, showing limb buds projecting from the Wolffian ridge. (Keibel and Elze, *Normaltafeln.*)

The greater part, if not the whole, of the mesodermal core of the primitive limb-rudiment is derived from somatic mesoderm of the lateral plate. As the development proceeds it is differentiated into the cartilaginous, muscular, and other connective tissue elements which are the rudiments of the skeletal framework and the muscles and fasciæ of the adult limb.

It is uncertain whether or not the muscle elements of the mesodermal core are derived from the lateral plate mesoderm, or from muscle cells which have migrated into the limb, from the muscle plates of the segments from which the limb is formed and from which muscles of the body wall are developed; and

although it is generally believed that the bone which replaces the cartilaginous skeletal rudiments is produced by mesodermal cells, it has been asserted that the bone-producing cells originate in the ectoderm and migrate from the surface into the interior.

THE EARLIER MODIFICATIONS OF THE PRIMITIVE ENTODERMAL ALIMENTARY CANAL AND THE FORMATION OF THE STOMATODÆUM AND PROCTODÆUM.

The greater part of the permanent alimentary canal is derived from the entodermal sac and is therefore lined by entoderm cells. This part is enclosed in the embryo as the latter is folded off from the remainder of the zygote (Fig. 56), but the cephalic and caudal portions of the alimentary canal are formed by the enclosure of part of the external space and are, therefore, lined by ectoderm.

Fig. 60.—Lateral View of a Human Embryo—9·5 mm. long. (Keibel and Elze, *Normaltafeln.*)

Note that the limb rudiments no longer project at right angles from the side of the body but that they are bent ventrally.

The cephalic part is a portion of a space called the **stomatodæum** which lies, at first, between the ventrally bent extremity of the head and the bulging pericardial region (Fig. 56). At a later period it is enclosed laterally by the rudiments of the maxillæ or upper jaws, and caudally by the mandibular rudiments.

When it first appears the stomatodæum is separated from the cephalic end of the entodermal portion of the primitive canal by the bucco-pharyngeal membrane, but when that septum disappears, during the third week, the stomatodæum communicates with the fore-gut. Subsequently, it is separated into nasal and oral portions, and the oral portion forms that part of the mouth in which the gums and the teeth are developed.

The caudal part of the permanent canal is formed by the elevation of a surface fold round a pit-like hollow called the **proctodæum** (Fig. 66), which is separated from the caudal part of the entodermal portion of the alimentary canal, until about the fourth week, by a membrane called the **anal membrane**, a portion of the more extensive cloacal membrane mentioned on p. 44.

Differentiation of the Fore-gut.

Derivatives of the Lateral Wall.—Shortly after the fore-gut is enclosed, and whilst it is still separated from the stomatodæum by the bucco-pharyngeal membrane, its cephalic extremity dilates to form the primitive pharynx, and thereafter a series of thirteen pouches are formed in its walls, five in each lateral wall; the **pharyngeal** or **branchial pouches**; two in its ventral wall, one near the cephalic extremity, the rudiment of the **thyreoid gland**, and a second situated more caudally, which is the germ of the **respiratory system**, that is, the epithelial lining of the larynx, the trachea, the bronchi, and the lungs. The thirteenth pouch, **Seessel's pouch**, is formed in the dorsal wall, immediately caudal to the dorsal end of the bucco-pharyngeal membrane, and it projects into the floor of the primitive cranium.

Simultaneously with the formation of the pharyngeal pouches internally a series of clefts appear externally. They correspond in position with the first four pharyngeal pouches, and they are called the **pharyngeal** or **branchial clefts.**

By means of the pharyngeal pouches and clefts the lateral boundary of the cephalic part of the fore-gut, on each side, is divided into a series of bars, the **pharyngeal** or **branchial bars**, five in number, but the fifth is distinctly visible only in the inner aspect of the pharynx.

The first of the pharyngeal bars is the rudiment of the maxillary and mandibular regions. It is called the **mandibular arch.** The second is the **hyoid arch**, and the remainder are the branchial arches proper.

When they first appear, the arches extend from the level of the dorsal wall of the fore-gut to the pericardium but, as growth proceeds, and the neck is developed between the head and the pericardium, the ventral ends of the arches of opposite sides meet in the ventral wall of the primitive pharynx. The growth of the mandibular and the hyoid arches soon greatly exceeds that of the branchial arches proper, and the latter gradually recede from the surface until, on each side, they lie at the bottom of a depression, the **precervical sinus**, which is overlapped by the caudal

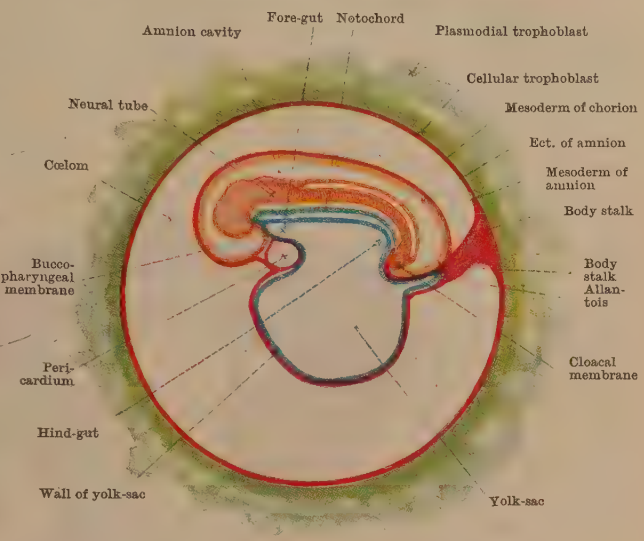

FIG. 61.—SAGITTAL SECTION OF ZYGOTE SHOWN IN FIG. 44.

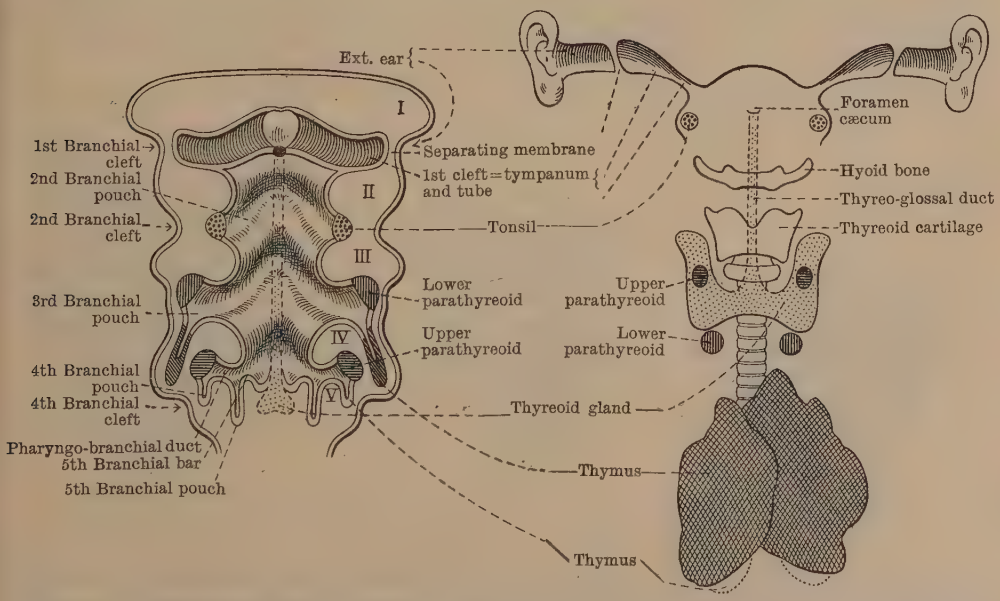

FIG. 62.—SCHEMA showing the branchial pouches, the branchial clefts, the branchial bars, and the thyreo-glossal duct and some of their derivatives. I., II., III., IV., and V., the five branchial bars.

border of the hyoid arch. As the overgrowth of the hyoid arch continues the opening of the precervical sinus to the surface is reduced to a narrow channel, the **precervical duct.** Afterwards this is obliterated, the sinus becomes the **precervical vesicle,**

but the position of the original aperture of the precervical duct is temporarily indicated by a sulcus, the **precervical sulcus,** which soon disappears. The precervical vesicle lies at the side of the third pharyngeal cleft, and it is associated with the second and fourth clefts by narrow canals, the **branchial ducts**, which are the remains of the branchial clefts. Ultimately the precervical vesicle and the branchial ducts disappear, but it has been suggested that before the vesicle disappears a part of the lobe of the thymus of the same side is formed from its wall.

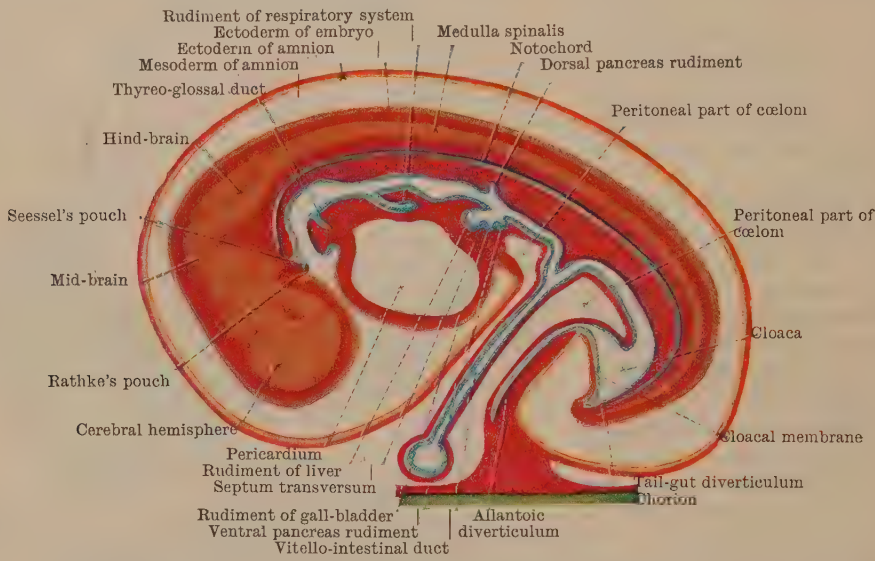

FIG. 63.—SCHEMA OF A LONGITUDINAL SECTION OF AN EMBRYO. (After Mall, modified.) Showing dorsal and ventral diverticula for alimentary canal. The heart is not shown.

The portion of the wall of the primitive pharynx which lies between each pair of visceral arches and separates the clefts externally from the pouches internally is called the **separating membrane**. In the earliest stages it consists of ectoderm, mesoderm, and entoderm; then, for a time, the mesoderm disappears to reappear again between the two epithelial strata at a still later period.

Round the margins of the dorsal part of the first pharyngeal or mandibular

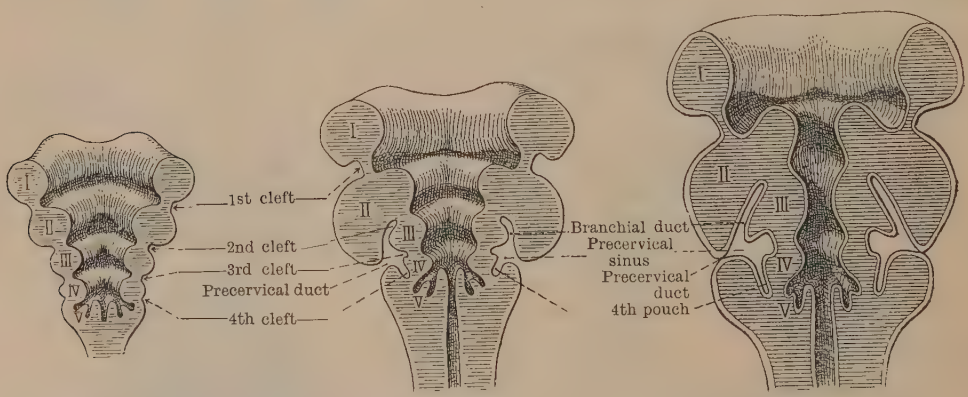

FIG. 64.—SCHEMA showing the formation of the precervical sinus, the branchial ducts, and the precervical sulcus.

cleft are formed a series of tubercles which develop into the **auricle** of the external ear, and the cavity of the cleft becomes the **external acoustic meatus** (see p. 58). The first pharyngeal pouch and the adjacent part of the cavity of the primitive pharynx becomes the **tympanic cavity** and the **auditory** (O.T. **Eustachian**) **tube.** A part of the cavity of the second pharyngeal or hyoid pouch is represented in the adult by the supra-tonsillar recess, which lies in the side wall of the pharynx above the palatine tonsil (Fig. 62).

The third pharyngeal pouch opens like the first and second directly into the cavity of the fore-gut, but the fourth and fifth pouches lie in the lateral wall of a common recess which opens by a single aperture, the **pharyngo-branchial duct**, into the cavity of the primitive pharynx (Fig. 62).

The cavities of the third, fourth, and fifth pouches ultimately disappear, but before the disappearance takes place diverticula which, at first, are hollow but, afterwards, become solid are given off from the ventro-lateral parts of each, and solid epithelial outgrowths, the epithelial bodies, are formed from the dorso-lateral walls of the third and fourth pouches (Fig. 62).

The ventral diverticulum from the third pouch, on each side, forms the main part of the corresponding lobe of the **thymus**, and the ventral diverticulum of the fourth pouch either takes part in the formation of the thymus or it entirely disappears. The rudiment of the thymus is formed in the neck, but as the gland differentiates it extends and it migrates caudally, until its cephalic end lies near the caudal end of the thyreoid gland, at the level of the sixth ring of the trachea, and its caudal end is in the thorax at the level of the fourth costal cartilage.

The epithelial bodies derived from the third and fourth pharyngeal pouches form the structures known in the adult as the **parathyreoid bodies.** That derived from the third pouch migrates caudally more rapidly than its fellow formed from the fourth pouch; consequently the parathyreoid derived from the fourth pharyngeal pouch lies at the middle of the dorsal border of the corresponding lobe of the adult thyreoid gland, and the parathyreoid formed from the third pharyngeal pouch is situated at the caudal end of the corresponding lobe of the thyreoid gland and close to the cephalic end of the thymus.

The diverticulum formed from the ventral part of the fifth pharyngeal pouch is the **ultimo-branchial body.** After it separates from the pouch it becomes solid and is associated with the corresponding lobe of the thyreoid gland, but, apparently, in the human subject, it takes no part in the formation of that gland.

Derivatives of the Ventral Wall.—The diverticulum from the ventral wall of the primitive fore-gut, which is situated nearest the cephalic or anterior end of the gut, is the rudiment of the thyreoid gland. It commences in the median plane, between the ventral ends of the mandibular and hyoid arches, and grows ventrally, into the substance of the neck, then turns caudally, ventral to the cartilages which form in the second, third, and fourth arches, from which the hyoid bone and the cartilages of the larynx are developed. When the caudal end of the diverticulum reaches the region where the cephalic or anterior portion of the trachea will be formed it becomes bilobed, and thus is differentiated into the isthmus and the two lobes of the permanent gland. The stalk of the diverticulum, which extends from what becomes the oral part of the primitive pharynx to the isthmus of the gland, is the **thyreoglossal duct.** Its cephalic end remains as the **foramen cæcum**, which is situated in the dorsum of the tongue, at the junction of the anterior two-thirds with the posterior third. The caudal end sometimes persists and is transformed into the third or pyramidal lobe of the thyreoid gland, which is attached to the dorsal border of the isthmus (Figs. 62, 67).

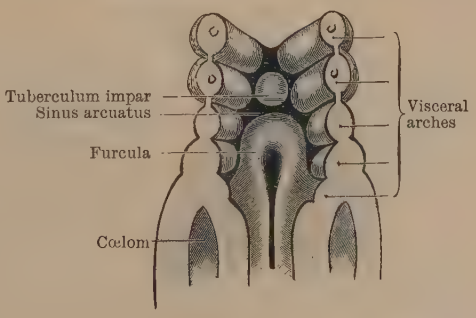

Fig. 65.—View of Floor of Primitive Pharynx, showing the furcula with the groove, from which arise the cavities of the larynx, the trachea, the bronchi, and the alveoli of the lungs.

The more caudally situated diverticulum from the ventral wall of the fore-gut is the **rudiment of the respiratory system** (Figs. 65, 66). When it first appears it has the form of a longitudinal groove bounded at its cranial end and laterally by an elevated ridge, named by His the **furcula** (Fig. 65). The caudal end of the groove soon dilates into a pouch, and then the pouch and groove are separated from the more dorsal part of the fore-gut, which becomes the **œsophagus**, by a constriction,

which passes from the caudal towards the cranial end. The constricting process ceases before the separation reaches the cranial extremity of the respiratory

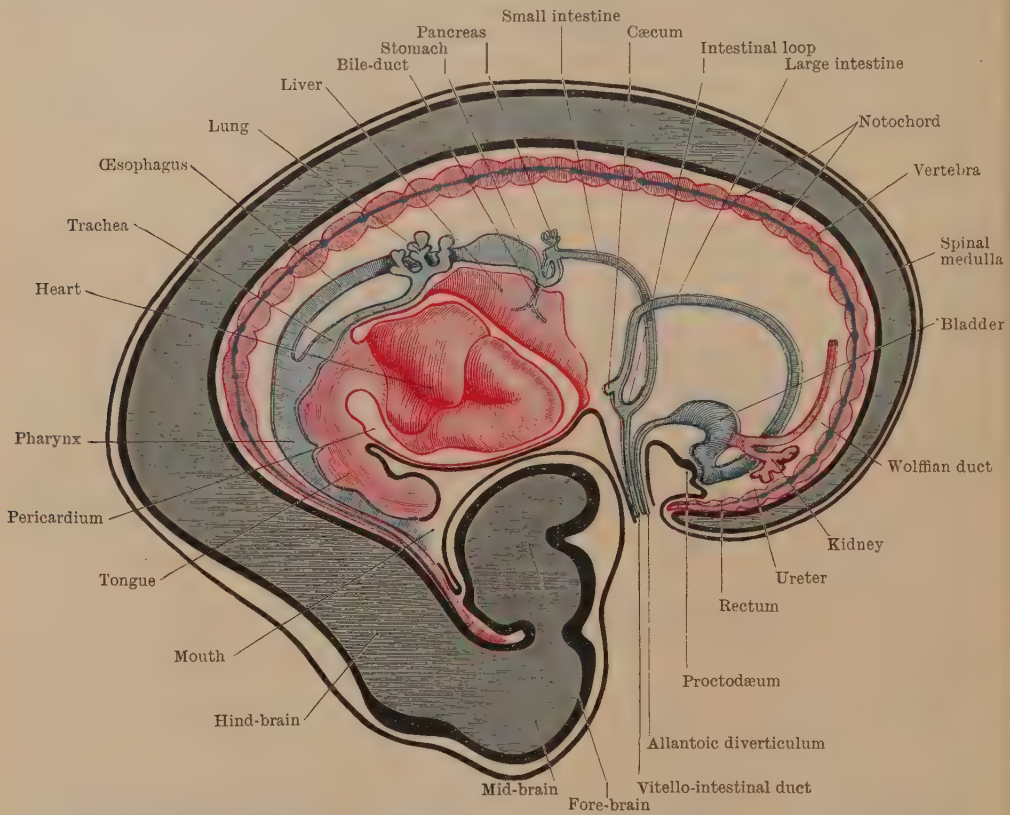

FIG. 66.—FURTHER DEVELOPMENT OF THE ALIMENTARY CANAL, AS SEEN IN A HUMAN EMBRYO ABOUT FIVE WEEKS OLD (Diagrammatic).

The tongue is well formed, the trachea and œsophagus are separated, the bronchi have commenced to branch; the duodenal curve is well formed, and the cæcum has appeared in the loop of the mid-gut. The cloaca is partially separated into genito-urinary and rectal portions.

rudiment, which remains, therefore, in communication with the pharynx and forms the permanent laryngeal aperture. The tube formed by the separation of the groove is differentiated into the larynx and the trachea, and the caudal terminal

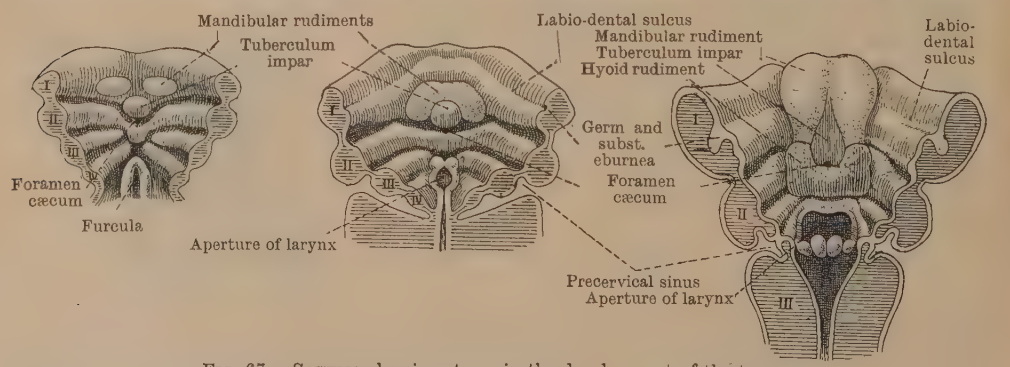

FIG. 67.—SCHEMA showing stages in the development of the tongue.

dilatation soon divides into two lateral lobes, each of which is the rudiment of the epithelium lining the bronchi and the lung of the corresponding side.

The Tongue.—The tongue is formed by *four separate rudiments* which lie in the ventral part of the cranial end of the primitive pharynx. Two of these are eleva-

tions formed on the caudal surfaces of the ventral ends of the mandibular arches, one on each side. The third is a median elevation, the **tuberculum impar**, which is situated immediately caudal to the conjoined ventral ends of the mandibular arches, and the fourth, called the **copula**, formed by the conjoined ventral ends of the second arches, is separated from the tuberculum impar by the orifice of the thyreoid rudiment (Fig. 67).

The two lateral elevations on the mandibular arches unite to form the greater part of the anterior two-thirds of the tongue, upon which all the papillæ are developed. The tuberculum impar either disappears or it forms the median part of the anterior two-thirds of the organ. The posterior third of the tongue, which lies in the ventral or anterior wall of the permanent pharynx, is formed from the copula of the second arches. It follows from what has been said that the commencement of the thyreoid rudiment, which persists in the adult as the

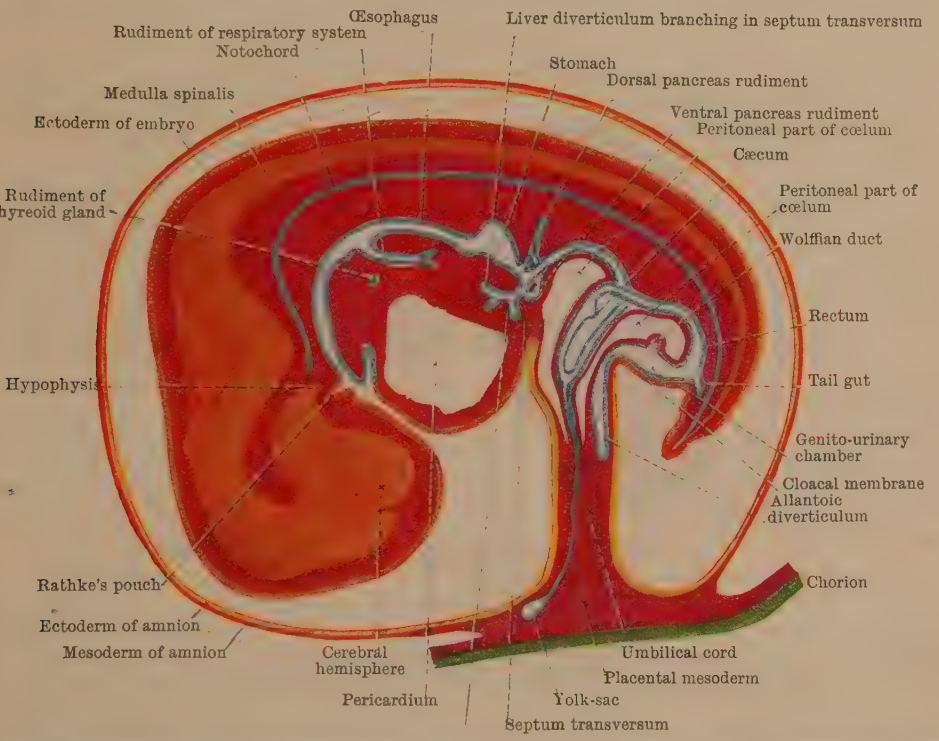

FIG. 68.—SCHEMA showing further stages in the development of the diverticula from the primitive gut and modifications of the mid-gut and the mid-gut regions. The heart is not shown. (After Mall, modified.)

foramen cæcum of the tongue, must lie at the junction of the posterior third with the anterior two-thirds. In many cases it appears to lie in the dorsal end of the anterior two-thirds, a position which may be associated with the fact that, in some cases, the rudiment of the thyreoid passes through the substance of the tuberculum impar and not from between the tuberculum impar and the ventral ends of the hyoid arches.

Derivative of the Dorsal Wall (Seessel's Pouch).—The dorsal diverticulum from the cranial end of the fore-gut, to which the above term is applied, enters the base of the occipital region of the primitive head. The ultimate fate of the pouch is unknown in the human subject, but it has been suggested that it is represented by a depression in the mucous membrane of the cranial part of the pharynx, close to the pharyngeal tonsil, which is known as the pharyngeal bursa.

The reader who has followed this description will have noted that from the cranial portion of the fore-gut are formed the caudal or inferior part of the mouth (with the exception of the lips, teeth, and gums), the pharynx, the thyreoid gland, the thymus, the parathyreoids, the respiratory organs, and the œsophagus. The

more caudally situated portion of the fore-gut is differentiated into the stomach and the first and second parts of the duodenum.

The stomach is formed from the part of the fore-gut immediately adjacent to the œsophagus, and the duodenum from the more caudally placed portion, which is directly continuous with the mid-gut.

The Liver and Pancreas.—When the embryo is about three weeks old and has attained a length of 2·5 mm. a ventral diverticulum appears in the ventral wall of the duodenal part of the fore-gut, and when the age of the embryo is about four weeks and its length increased to about 4 mm. a diverticulum is formed in the dorsal wall a little nearer the cranial end. The ventral pouch is the rudiment of the *liver*, the *gall bladder*, the *bile-ducts*, and a portion of the *pancreas*, and the remainder of the pancreas is formed from the dorsal diverticulum (Figs. 63, 68, 69).

The Derivatives of the Mid-Gut.—The mid-gut is that part of the primitive alimentary tract which lies between the more definitely enclosed fore-gut and

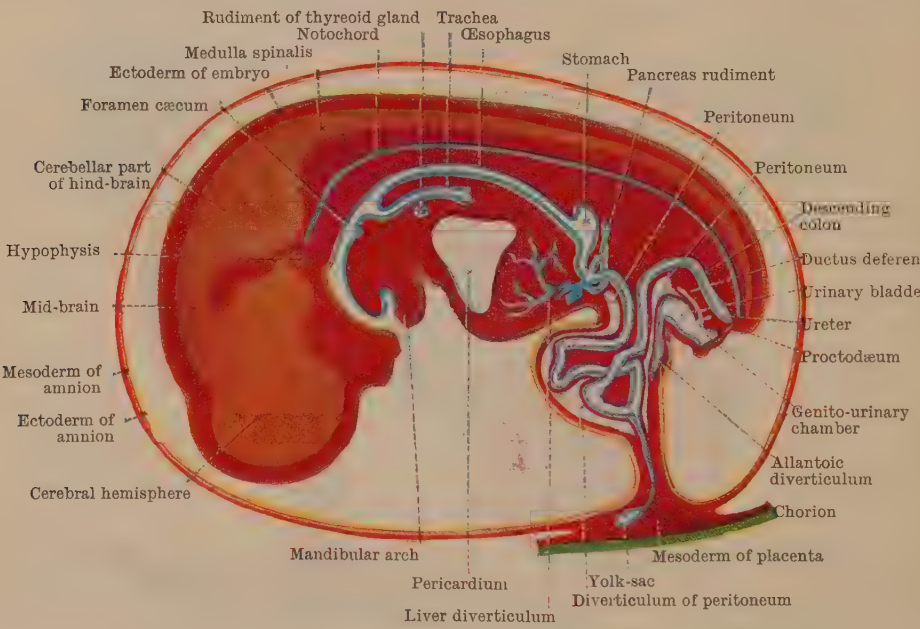

FIG. 69.—SCHEMA showing complete separation of cloaca into dorsal and ventral parts and the temporary ventral hernia of a portion of the gut through the umbilical orifice. The heart is not shown. (After Mall, modified.)

hind-gut, and it is in free communication with the yolk-sac by the vitello-intestinal duct. It is transformed into the greater part of the small intestine.

The Derivatives of the Hind-Gut.—The parts formed from the hind-gut are:—(1) The terminal part of the ileum; (2) the whole of the large intestine, except a small portion of the anal canal; (3) the urachus, the urinary bladder, the urethra in the female, and the greater part of the urethra in the male.[1]

As development proceeds the mid-gut and the cephalic part of the hind-gut form a U-shaped tube which possesses a cranial and a caudal limb, and a ventral extremity which is connected with the yolk-sac by a narrowed and elongated canal, **the vitello-intestinal duct** (Fig. 63).

Upon the caudal limb of the loop, about the middle of its dorso-ventral height, an enlargement appears which is the rudiment of the **cæcum** and **vermiform process** of the adult. After this rudiment has formed the caudal limb of the loop undergoes rotation, being carried first to the left, then cranially, and finally to the right. As it is carried to the right it crosses the cranial (later ventral) aspect of the cranial limb of the loop, and when the rotation is completed the regions of the jejunum and ileum, the cæcum, the ascending and the transverse colon are defined.

[1] T. B. Johnston, *Journ. of Anat.*, Oct. 1913; H. v. Berenberg-Gossler, *Anat.*, Heft. 1913.

After the rotation has occurred the tubular intestine, formed from the mid-gut and the anterior part of the hind-gut, undergoes rapid elongation and is thrown into a number of coils.

When the embryo has attained the length of 10 mm., and is a little over a month old, the greater portion of the coiled gut passes through the umbilical orifice into an expansion of the cœlom formed in the proximal part of the umbilical cord (see p. 52) (Fig. 69), which has replaced the allantoic or body-stalk as the medium by which the embryo is attached to the chorion. The herniated coils remain in the root of the umbilical cord until the embryo is about 40 mm. long, and about ten weeks old, when they return to the abdomen, and the cœlomic space in the umbilical cord disappears.

The Derivatives of the Posterior Part of the Hind-Gut.—When the caudal portion of the hind-gut is first enclosed its terminal extremity and its ventral wall are bounded by the caudal portion of the primitive streak, which is bent ventrally during the folding-off of the embryo.

The terminal part of this portion of the gut becomes expanded, forming a chamber called the **entodermal cloaca**, into the ventral parts of which the ducts of the primitive kidneys, the pronephric or **Wolffian ducts**, open, one on each side.

The ventral part of the cephalic end of the cloaca is continuous with the allantoic diverticulum, and the dorsal part with a tubular portion of gut which forms the descending and probably also the iliac and pelvic portions of the colon.

As the temporary tail is formed and projected first caudally and then ventrally, by the growth energy of the nodal point situated at the caudal end of the neural tube, a diverticulum of the caudal end of the dorsal part of the cloaca is prolonged into it, forming the **tail gut.** This soon becomes shut off from the cloaca. It entirely disappears before the temporary tail is absorbed into the caudal end of the body (Figs. 63, 68, 69).

At a later period the cloaca itself is separated into a dorsal part, the rectum, and a ventral part, the uro-genital chamber, by the formation of a septum, which commences in the angle between the allantoic diverticulum and the ventral wall of the hind-gut, and is prolonged caudally till it reaches and fuses with the internal surface of the cloacal membrane, which thus becomes separated into uro-genital and anal portions, both of which disappear about the eighth week.

In both sexes the uro-genital section of the cloaca is separable into three parts: (1) a cranial part, which is converted into the urachus or middle umbilical ligament; (2) an intermediate part, which becomes the urinary bladder; and (3) a caudal part, which, in the female, is transformed into the urethra and the vestibule of the vagina, whilst in the male it is developed into the urethra.

Derivatives of the Stomatodæum.—When the stomatodæum is first definitely established, it is bounded cranially by the caudal surface of the ventrally bent terminal part of the head, caudally by the conjoined ventral ends of the mandibular arches, and laterally by the dorsal parts of the mandibular arches, and the maxillary processes, which grow ventrally from the dorsal parts of the mandibular arches. The space is open ventrally, and it is closed dorsally by the bucco-pharyngeal membrane, which separates it from the fore-gut (Fig. 61).

The bucco-pharyngeal membrane disappears about the third week, and about the twenty-first day a diverticulum from the stomatodæum is projected into the caudal surface of the head, from the point where that surface originally joined the dorsal end of the external surface of the bucco-pharyngeal membrane. The diverticulum is **Rathke's pouch.** The cranial extremity of the pouch comes into relation with the hypophyseal diverticulum from the floor of the third ventricle, and dilates. The stalk which connects the dilated terminal part of the diverticulum with the stomatodæum disappears, and the terminal vesicle becomes the anterior lobe of the hypophysis (O.T. pituitary body) (Figs. 63, 68, 69). (See Ductless Glands.)

The Separation of the Stomatodæum into Nose and Mouth.—In the cephalic boundary of the stomatodæal space lies the ventral end of the head, which is called the **fronto-nasal process.**

In the fronto-nasal process, on each side of the median plane, is situated a

shallow pit, the **olfactory pit**, and by the pits the process is divided into a median part, the **median nasal process**, and two lateral parts, the **lateral nasal processes.** Further, the margin of the median process is divided by a median cleft into right and left **globular processes** (Fig. 70).

The orifices of the olfactory pits are directed laterally, therefore the lateral nasal processes lie dorsal to the median nasal process in the cranial boundary of the stomatodæal space, and as their margins increase in height the pits deepen.

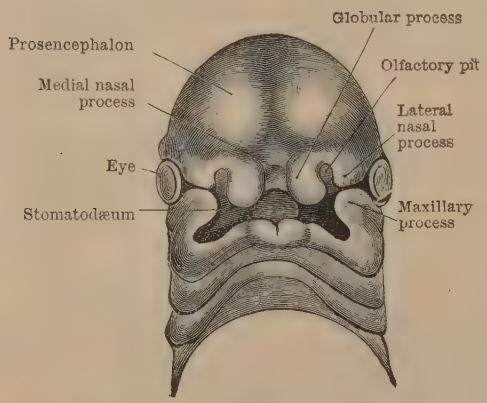

FIG. 70.—ANTERIOR VIEW OF BOUNDARIES OF STOMATODÆUM BEFORE COMPLETION OF PRIMITIVE UPPER LIP.

At this period the cranial boundary of the stomatodæum is divided by the median sulcus and the olfactory pits into four projections—the two globular processes, each of which lies between the median sulcus and an olfactory pit, and the two lateral nasal processes, which form the dorso-lateral borders of the olfactory pits. The lateral boundaries are formed by the maxillary processes and the dorsal parts of the mandibular bars, and the caudal boundary is formed by the medially turned and conjoined ventral parts of the mandibular bars. Immediately cranial to the maxillary process, on each side, is the projecting eye; and leading from it, between the maxillary process and the lateral nasal process, is the **naso-lacrimal sulcus.**

As growth proceeds and each maxillary process grows ventrally, its extremity fuses with the caudal or posterior border of the lateral nasal process, and then, carrying the lateral nasal process with it, it fuses with the globular process of the same side.

After the fusion of the maxillary processes, and the caudal borders of the lateral nasal processes, with the globular processes has occurred, the olfactory pits are completely separated, for a time, from the stomatodæum, and they lie in the ledge which now forms the cranial boundary of the stomatodæal opening. This ledge consists of the two globular processes, fused into a single mass, and the two maxillary processes, the caudal[1] edges of the lateral nasal processes being shut off from the margin of the ledge by the maxillary processes (Fig. 71).

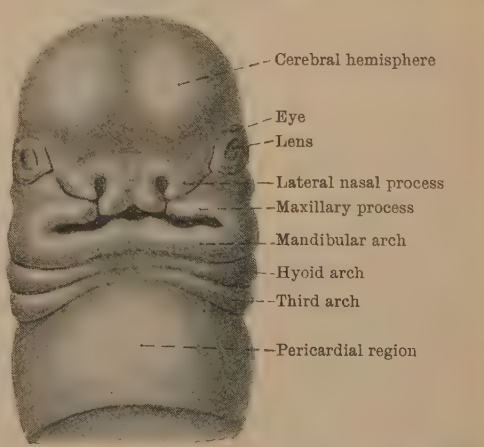

FIG. 71.—SCHEMA OF ANTERIOR VIEW OF THE HEAD OF A HUMAN EMBRYO SHOWING THE COMPLETION OF THE PRIMITIVE UPPER LIP.

After the ledge is completed the dorsal ends of the olfactory pits are separated from the stomatodæal cavity by a thin membrane, but this soon disappears, and the pits open again into the stomatodæal space, through apertures which are called the **primitive choanæ.**

After the formation of the primitive choanæ a ledge grows from the medial surface of each maxillary process towards the median plane, dorsal to the choanæ. These ledges, the **palatine processes**, meet and fuse during the third month of fœtal life, the fusion commencing ventrally and being completed dorsally in the region of the uvula. As the ledges meet and fuse, the stomatodæal cavity is separated into a cranial and a caudal portion. The cranial part is the **nasal cavity**; it is soon divided into two lateral halves by a septum which passes caudally from the base of

[1] Inferior in erect posture.

the cranium. The caudal portion of the stomatodæum blends with the ventral part of the primitive pharynx. Its cavity forms the cavity of the vestibule of the mouth and from its walls the gums and teeth are developed.

The details of the process by which the primitive lips, which form the boundaries of the primitive buccal aperture, are separated into the permanent lips, and the gums are defined, are described in the section dealing with the digestive system.

The Derivative of the Proctodæum.—The proctodæum is a surface depression which owes its origin to the elevation of the surface round the margin of the anal membrane. It forms the lowest portion of the pars analis recti of the adult.

Uro-genital System.—The formation of the internal parts of the uro-genital system from the intermediate cell tract, the uro-genital chamber, and the differentiation of the external genitals in the region of the cloacal membrane are described in the account of the uro-genital system.

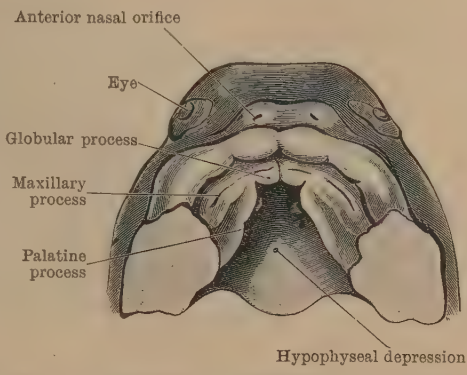

FIG. 72.—PORTION OF THE HEAD OF A HUMAN EMBRYO ABOUT 2½ MONTHS OLD (His). The lips are separated from the gums, and the line of the common dental germ is visible in the latter. The palatine processes are growing inwards from the maxillary processes.

The development of the auditory organ is so intimately associated with the development of the pharyngeal portion of the primitive gut that a short consideration of the chief phenomena may with advantage be introduced here; but for the details of the development of the internal, middle, and external portions of the ear the student must refer to the account of the development given in association with the description of the auditory organ.

THE INTERNAL EAR, THE TYMPANUM AND AUDITORY TUBE, AND THE EXTERNAL EAR.

In the human subject, as in other mammals, the auditory organ consists of the **internal ear** or labyrinth, the middle ear or **tympanum**, with which is associated the **auditory tube** (O.T. **Eustachian**); and the **external ear**, which consists of the **external acoustic meatus** with the **auricle** at its lateral end.

The **internal ear** itself consists of two parts—the **cochlea**, which is the true organ of hearing, and the **vestibule** and the **three semicircular canals** connected with it, which are associated with the recognition of alterations in the position of the head, and, therefore, with the recognition and maintenance of equilibrium.

The whole of the internal ear is lined with ectodermal epithelium, the **auditory epithelium**, which is derived from the surface of the head of the embryo. It is recognisable in embryos of about 2·6 mm. (Fig. 73) as a thickened and slightly depressed plate of ectodermal cells which lies on the surface of the head, in the region of the hind-brain, dorsal to the second branchial cleft. As development proceeds the plate is gradually invaginated into the substance of the head, and is transformed into a pear-shaped vesicle called the **otic vesicle**. For a time the otic vesicle remains in communication with the exterior by a short tubular canal. As the canal disappears a diverticulum is formed from the vesicle immediately to the medial side of the deep end of the canal. The diverticulum grows dorsally as a narrow tube called the *recessus labyrinthi*. It is ultimately transformed into the **ductus** and **saccus endolymphaticus** of the adult ear (see Auditory Organ).

After it is separated from the surface the otic vesicle alters its position, until its ventral end lies in close relation to the dorsal wall of the pharynx, and, at the same time, it undergoes alteration of shape. The ventral part of the vesicle grows towards the median plane, along the ventral wall of the hind-brain. It forms

the cavity and the lining epithelium of the **cochlea**; but it remains in connexion

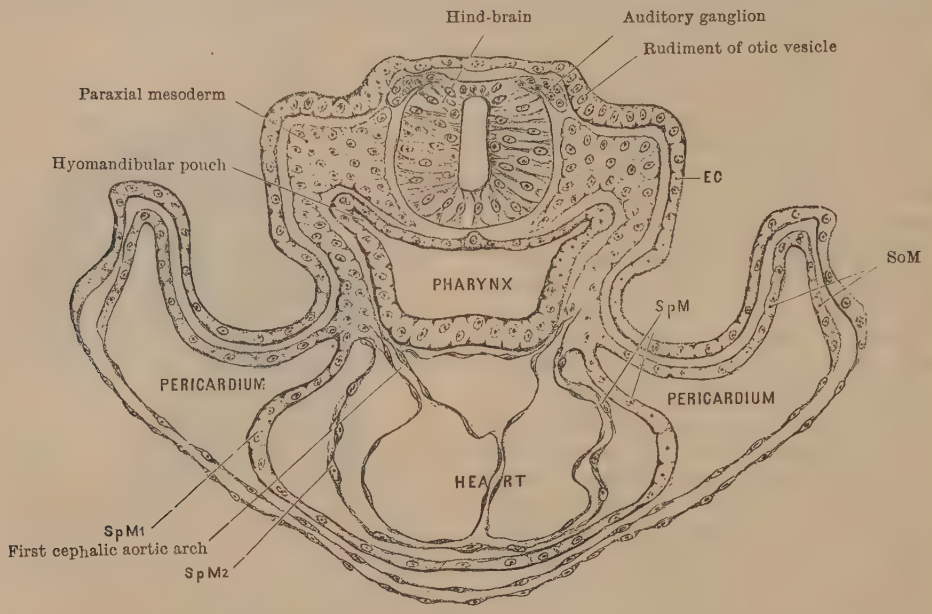

FIG. 73.—TRANSVERSE SECTION OF A RAT EMBRYO.

with the dorsal part by means of a narrow tube, the **canalis reuniens**, and as it grows in length it becomes converted into a spiral tube.

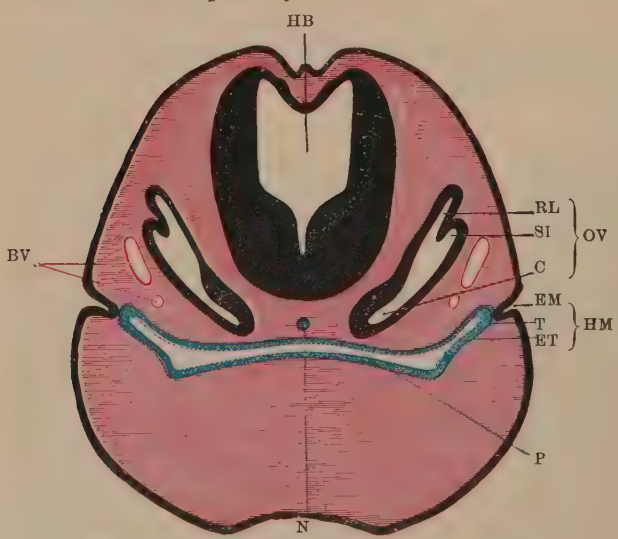

FIG. 74.—TRANSVERSE SECTION THROUGH THE HEAD OF AN EMBRYO.

Showing the rudiments of the three parts of the ear and their relation to the hyomandibular cleft.

ET. Auditory tube.	RL. Recessus labyrinthi.
HB. Hind-brain.	SI. Stalk of invagination.
HM. Hyomandibular cleft.	T. Tympanum.

The portion of the dorsal section of the primitive vesicle, which lies to the lateral side of the **recessus labyrinthi**, first expands and then becomes compressed and constricted into the form of three flat, purse-like diverticula which, by the partial obliteration of their cavities, become converted into the three **semicircular ducts** (see Sense Organs). The more ventral part of the dorsal section of the vesicle is divided, by a constriction of its lateral wall, into a dorsal part, the **utricle**, which remains in connexion with the semicircular ducts, and a ventral part, the **saccule**, which is united to the cochlea by the canalis reuniens. The apex of the constriction which separates the utricle from the saccule passes into the mouth of the ductus endolymphaticus, which is thus transformed into the Y-shaped canal which connects

the utricle with the saccule. At a later period the closed extremity of the ductus endolymphaticus dilates and forms a small saccule, the **saccus endolymphaticus.** In the adult the saccus endolymphaticus lies in the posterior fossa of the skull, in relation with the posterior surface of the petrous part of the temporal bone and external to the dura mater.

When the changes which have been mentioned are completed the primitive otic vesicle is transformed into the epithelial labyrinth.

At a later stage lymph spaces appear in the neighbourhood of the various parts of the epithelial labyrinth, and they become, in the adult temporal bone, the cavities of the semicircular canals which enclose the semicircular ducts, the vestibule, in which lie the utricle and saccule and the adjacent parts of the ductus endolymphaticus, and the scala vestibuli and the scala tympani of the bony cochlea, which lie immediately adjacent to the epithelial ductus cochlearis or scala media (see Auditory Organ).

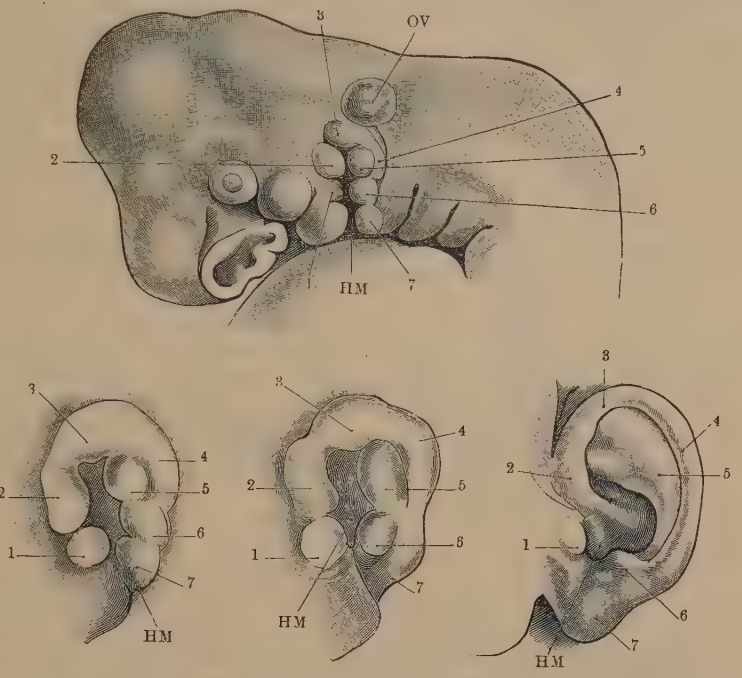

FIG. 75.—FIGURES, MODIFIED FROM HIS, ILLUSTRATING THE FORMATION OF THE PINNA.

5. Tuberculum anthelicis = Antihelix.
6. Tuberculum antitragicum = Antitragus.
7. Tuberculum lobulare = Lobule.

HM. Hyomandibular cleft.
OV. Otic vesicle.

As the lymph spaces appear around the epithelial parts of the labyrinth the mesoderm itself becomes first converted into cartilage and then into the petrous part of the temporal bone, except around the saccus endolymphaticus, which, therefore, in the adult, lies between the dura mater and the posterior surface of the petrous part of the temporal bone.

The **tympanum** and the **auditory tube** (O.T. **Eustachian**) are developed from the first branchial pouch.

The ventral part of the pouch disappears at an early stage. The dorsal extremity expands and is converted into the cavity of the tympanum, whilst the stalk of connexion with the pharynx is gradually constricted off from its lateral towards its medial end, and is converted into the auditory tube. The constriction commences when the embryo has attained a length of about 20 mm., that is about the beginning of the eighth week, and is completed about the end of that week when the embryo is about 25 mm. long.

After the auditory tube is defined it grows rapidly in length, and cartilage appears in its walls during the fourth month.

As the tympanic cavity increases in size the auditory ossicles—*stapes*, *incus*, and *malleus*, which are differentiated from the dorsal ends of the cartilages of the first and second branchial arches, are invaginated into it.

The **membrana tympani**, which separates the tympanum from the external acoustic meatus, is formed from the separating membrane which intervenes

between the first branchial pouch and the first cleft. It consists, therefore, of an external covering of ectoderm, an internal lining of entoderm, and an intervening layer, of fibrous tissue, derived from the mesoderm.

The **external ear** is developed from the cavity and the boundaries of the first branchial cleft. The cavity of the cleft is transformed into the cavity of the external acoustic meatus, and on the mandibular and on the hyoid margins of the cleft three eminences appear. From the eminences on the two arches, and the skin immediately posterior to the eminences on the hyoid arch, are formed the various parts of the auricle, but the exact part played by the individual eminences, in the human subject, is as yet a matter of some doubt.

THE PROTECTION AND NUTRITION OF THE EMBRYO DURING ITS INTRA-UTERINE EXISTENCE.

Whilst it is passing down the uterine tube, and for a brief period after it enters the uterus, the zygote, or impregnated ovum, depends for its nutrition upon the yolk granules (deutoplasm) embedded in its cytoplasm.

As the human ovum is small, and as it contains but little deutoplasm, there is urgent necessity for the formation of adequate arrangements whereby external sources of nutritive supply may be acquired and maintained; that necessity leads to the early establishment of an intimate connexion between the zygote and the mother, which is one of the characteristic features of the development of the human embryo.

During the third week after fertilisation, as the embryo is beginning to be moulded from the embryonic region, and before the paraxial mesoderm commences to separate into mesodermal somites, a primitive heart and the rudiments of some well-defined blood-vessels are distinguishable in the embryo; but the details of the development of the vascular system and the establishment of the embryonic circulation cannot be well understood until the formation and structure of a group of closely associated extra-embryonic organs or appendages, derived from the zygote, and adapted for the nutrition and protection of the embryo, has been considered.

This group includes the chorion, the placenta, the amnion, the umbilical cord, and the yolk-sac.

THE MEMBRANES AND APPENDAGES.

The Chorion.—It has already been noted that when the zygote becomes a blastula it consists of three vesicles, a large vesicle enclosing two smaller vesicles and a mass of primary mesoderm (Fig. 35).

The wall of the large vesicle is composed of trophoblast (trophoblastic ectoderm), and its inner surface is in direct contact with the primary mesoderm.

A little later a cavity, the **extra-embryonic cœlom**, appears in the primary mesoderm, separating it into two layers, one lining the inner surface of the trophoblast and the other covering the outer surfaces of the two inner vesicles (Figs. 76, 77).

As soon as the extra-embryonic cœlom is established the **chorion** is formed; it consists of the trophoblast and its inner covering of mesoderm.

In the meantime the trophoblast has differentiated into two layers, an inner cellular layer, and an outer plasmodial layer. In the plasmodial layer cell territories are not defined, and it consists, therefore, of nucleated protoplasm.

The differentiation of the trophoblast into two layers occurs after the zygote is embedded in the mucous membrane of the uterus which is modified for its reception and which, after the modification has occurred, is called the **decidua**.

As development proceeds the trophoblast increases in thickness and it invades the decidua. As this invasion occurs the plasmodial layer of the trophoblast becomes permeated with spaces which are continuous with the lumina of the maternal blood-vessels in the decidua, and are, therefore, filled with maternal blood.

By means of the spaces the plasmodial trophoblast is separated into branching

processes which intervene between the blood-filled spaces. The processes are the **primary chorionic villi**, and they soon develop cellular interiors (Fig. 78).

After a time the primary villi are invaded by the chorionic mesoderm, and are thus converted into the **secondary chorionic villi**, which become vascularised by the growth of fœtal vessels into the fœtal mesodermal cores. The secondary villi, therefore, consist of a mesodermal core covered by a layer of cellular trophoblast and a layer of plasmodium, the latter lying outside the former. Still later the secondary villi send out numerous branches into the blood spaces, and thus increase greatly in complexity (Figs. 81, 82, 83).

As development progresses still further a part of the chorion is converted into the fœtal portion of an organ called the **placenta**, and thus the chorion is divided into placental and non-placental regions. Upon the placental part the villi continue to increase, but they disappear entirely from the non-placental part, which is then called the **chorion læve** (Fig. 83).

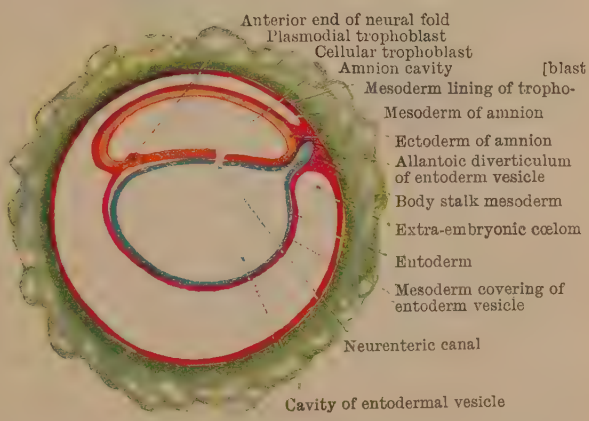

FIG. 76.—SCHEMA OF SAGITTAL SECTION OF ZYGOTE ALONG LINE A.

The Amnion, the Body-Stalk (Allantoic Stalk), and the Umbilical Cord.—The amnion is formed from that portion of the wall of the more peripheral of the two inner vesicles of the zygote — the ecto-mesodermal vesicle — (p. 26), which does not take part in the formation of the embryo. It consists of ectoderm cells covered externally by a layer of extra-embryonic mesoderm, and it is continuous with the margin of the embryonic area (Figs. 76, 77).

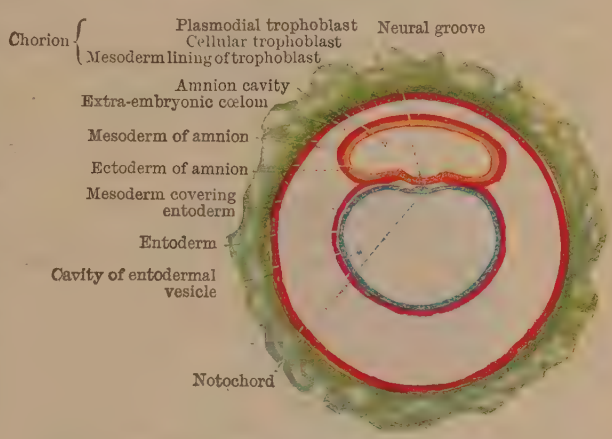

FIG. 77.—SCHEMA OF TRANSVERSE SECTION OF ZYGOTE ALONG LINE B (Fig. 37).

The cavity of the ecto-mesodermal vesicle, enclosed between the amnion and the embryonic area, is the **cavity of the amnion**; it is filled with fluid, which raises the amnion in the form of a cupola over the embryonic region (Fig. 76).

The Body-Stalk (Allantoic Stalk).—It has been noted already that the mesoderm of the median part of the posterior or caudal portion of the amnion becomes thickened. In the thickened strand lies the allantoic diverticulum of the entodermal vesicle (Fig. 76), whilst through it, on either side of the allantoic diverticulum, pass the umbilical arteries and veins, by means of which blood is conveyed between the embryo and the chorion.

This segment of the wall of the amnion vesicle was termed by His the **body-stalk.** It takes no direct part in the formation of the embryo, and as it contains the rudimentary allantoic diverticulum and represents the much more highly developed allantois of other forms, it would, perhaps, be better to term it the **allantoic stalk.** For the present purpose it is important to note that the blood-vessels which pass through the body-stalk enter or leave the body through the umbilical orifice, which is, at first, a relatively large aperture (Fig. 56).

As the embryonic area is folded into the form of the embryo the amnion

increases in extent, filling more and more of the extra-embryonic cœlom, and the embryo rises into the interior of its cavity. In other words, the walls of the amnion bulge ventrally round the cranial and caudal extremities and the lateral borders of the embryo (Figs. 81, 82, 83). As the distension of the amnion still continues, the ventral bulging, round the margin of the umbilical orifice, becomes more pro-

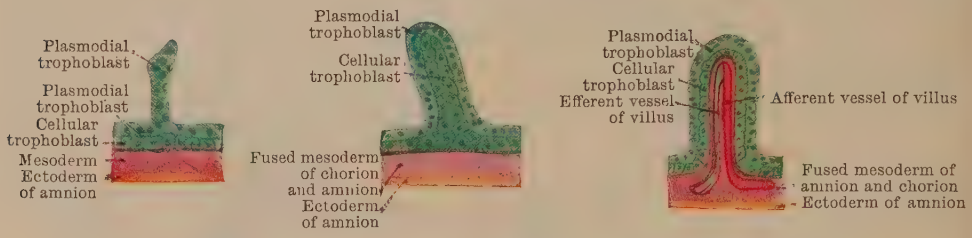

FIG. 78.—SCHEMA OF THREE STAGES IN THE FORMATION OF A CHORIONIC VILLUS.

nounced, the yolk-sac is forced farther and farther away from the embryo, the vitello-intestinal duct is elongated, and it is surrounded by a hollow tube. The cavity of the tube is an elongated part of the extra-embryonic cœlom, and its walls are formed by the amnion (Figs. 63, 68, 69).

The caudal wall of the tube necessarily consists of the elongated body-stalk (allantoic stalk).

As the distension of the amnion still continues, the walls of the tube are forced against the vitello-intestinal duct, and the amniotic mesoderm fuses with the mesoderm of the vitello-intestinal duct. When the fusion is completed, a solid cord, the **umbilical cord**, is formed (Figs. 83, 84, 86). It consists of an external covering of amniotic ectoderm, and a core of mesoderm in which lie the two umbilical arteries of the body-stalk, a single umbilical vein formed by the fusion of the two primitive veins, and the remains of the vitello-intestinal duct and the vitelline vessels. The proximal end of the umbilical cord is connected with the embryo; the distal end is attached to the chorion, and in its neighbourhood lies the now relatively small vesicular yolk-sac (Fig. 68).

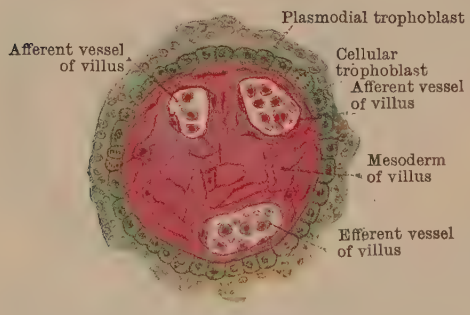

FIG. 79.—SCHEMA OF A TRANSVERSE SECTION OF A SECONDARY CHORIONIC VILLUS. A loop of the afferent vessel has been cut at two points.

As the amnion grows still larger, all that part of its outer surface which does not take part in the formation of the umbilical cord is ultimately pressed into contact with the inner surface of the chorion, with which it fuses, and the cavity of the extra-embryonic part of the cœlom is obliterated (Fig. 84).

The outer wall of the zygote now consists of the fused chorion and amnion, and it contains in its interior the amniotic cavity and the embryo, which is attached to the chorion by the umbilical cord.

When it is first formed the umbilical cord is comparatively short, but, as the amniotic cavity increases, the cord elongates, until it attains a length of from 45 to 50 cm. (18 to 20 inches), a condition which allows the embryo to float freely in the fluid in the amniotic cavity, whilst its nutrition is provided for by the flow and return of blood, through the umbilical cord, to and from the placenta, where interchanges take place between the maternal and the fœtal blood.

The Yolk-Sac or **Umbilical Vesicle.**—When the embryonic area is folded into the form of the embryo, the entodermal vesicle is differentiated into three parts: (1) a part enclosed in the embryo, where it forms the **primitive entodermal alimentary canal**; (2) a part which lies external to the embryo in the extra-embryonic cœlom—this is the **yolk-sac** or **umbilical vesicle**; (3) the third portion is the **vitello-intestinal duct**, which connects the primitive alimentary canal and the yolk-sac together (Figs. 46, 68).

The walls and the cavity of the yolk-sac are, therefore, continuous with the walls of the primitive alimentary canal, and the structural features of the two are identical, each consisting of an internal layer of entodermal cells and an external layer of mesoderm.

Free communication between the yolk-sac and the primitive alimentary canal appears to exist in the human subject till the embryo is three weeks old and about 2·5 mm. long. During the fourth week the vitello-intestinal duct is elongated into a relatively long narrow tube, which is lodged in the umbilical cord, and the yolk-sac, which has become a relatively small vesicle, is placed between the outer surface of the amnion and the inner surface of the chorion, in the region of the placenta (Fig. 68). During the latter part of the fourth or the early part of the fifth week, when the embryo has attained a length of about 5 mm., the vitello-intestinal duct separates from the intestine and commences to undergo atrophy, but remnants of it may be found in the umbilical cord up to the third month.

The yolk-sac itself persists until birth, when it is, relatively, a very minute object which lies either between the amnion and the placenta or between the amnion and the chorion lævе.

At a very early period, before the paraxial mesoderm has commenced to divide into mesodermal somites, a number of arteries, the **primitive vitelline arteries**, are distributed to the yolk-sac from the primitive arterial trunks of the embryo, the primitive aortæ, and the blood is returned from the yolk-sac to the embryo by a pair of **vitelline veins** (Fig. 87).

After a time the arteries are reduced to a single pair, and after the two primitive dorsal aortæ have fused into a single trunk, the pair of vitelline arteries also becomes converted into a single trunk, which passes through the umbilical orifice along the vitello-intestinal duct to the yolk-sac (Fig. 89).

The vitelline veins also pass through the umbilical orifice on their way to the heart of the embryo, and they become connected together, in the interior of the body of the embryo, by transverse anastomoses, which are described in the account of the development of the vascular system (see Vascular System).

After the umbilical cord is formed, the extra-embryonic parts of the vitelline veins disappear, and can no longer be traced in the cord. The same fate overtakes the extra-embryonic and a portion of the intra-embryonic part of the vitelline artery, and the remainder of the artery persists as the superior mesenteric.

THE PLACENTA.

The placenta is an organ developed for the purpose of providing first the embryo and later the fœtus with food and oxygen, and for removing the effete products produced by the metabolic processes which take place in the growing organism. It is formed partly from the zygote and partly from the mucous membrane of the uterus of the mother.

In the placenta the blood-vessels of the embryo of the earlier stages, and the fœtus of the later stages, and the blood of the mother are brought into close relationship with one another, so that free interchanges may readily take place between the two blood streams, but the blood of the embryo and fœtus and the blood of the mother are always separated from one another by two or more layers of fœtal cells. The modifications and transformations of the uterine mucous membrane and the chorion of the zygote, by which this intimate relationship is attained, constitute the phenomena of the development of the placenta.

The details of the development of the human zygote for the first ten or twelve days after the fertilisation of the ovum are not known, but the knowledge of what happens in other mammals justifies the belief that during that time the zygote is formed, in the ovarian, or the middle part of the uterine tube, by the union of a spermatozoon with the mature ovum. During the first ten to fourteen days after its formation it passes along the uterine tube, towards the uterus, whilst, at the same time, it undergoes the divisions which convert it into a morula.[1]

[1] This is an estimate, for there is no certain knowledge, and it is possible that the passage through the uterine tube is completed in seven or eight days or less.

The Formation of the Placenta.—Before the zygote reaches the uterus the mucous membrane which lines the cavity of that organ undergoes changes, in preparation for the reception and retention of the zygote, and when the changes are completed the modified mucous membrane is known as the **uterine decidua.**

The changes which take place are, for the most part, hypertrophic in character; the vascularity of the mucous membrane is increased, mainly by the dilatation of its capillaries; the tubular glands of the membrane are elongated, they become tortuous, and dilatations form in their walls a short distance from their outer closed extremities. At the same time the interglandular tissue increases in amount, and as a result of the various processes the decidua is thicker, softer, more spongy, and more vascular than the mucous membrane from which it was evolved.

Partly on account of the dilatation of the deep part of the glands and partly on account of differences in texture of the internal as contrasted with the external part of the decidua, the membrane may be looked upon as consisting of three layers. (1) An internal layer, next the cavity, the **stratum compactum.** (2) An intermediate layer, the **stratum spongiosum**, formed largely by the dilated parts of the glands. (3) An external layer, the **unchanged layer,** in which lie the comparatively unaltered outer ends of the glands.

When the zygote, in the morula stage, reaches the uterus, it acts as a parasite, it eats its way through the epithelium on the surface of the decidua, and implants itself in the stratum compactum.

The zygote may penetrate the decidua at any point of the wall of the uterine cavity, but it usually enters at some point of the dorsal or the ventral wall. The entrance generally takes place between the mouths of adjacent glands, which are pushed aside, and the zygote becomes at once surrounded by the interglandular tissue of the stratum compactum of the decidua. The aperture through which it passes may be closed by a fibrinous plug or its margins may converge rapidly and fuse together.

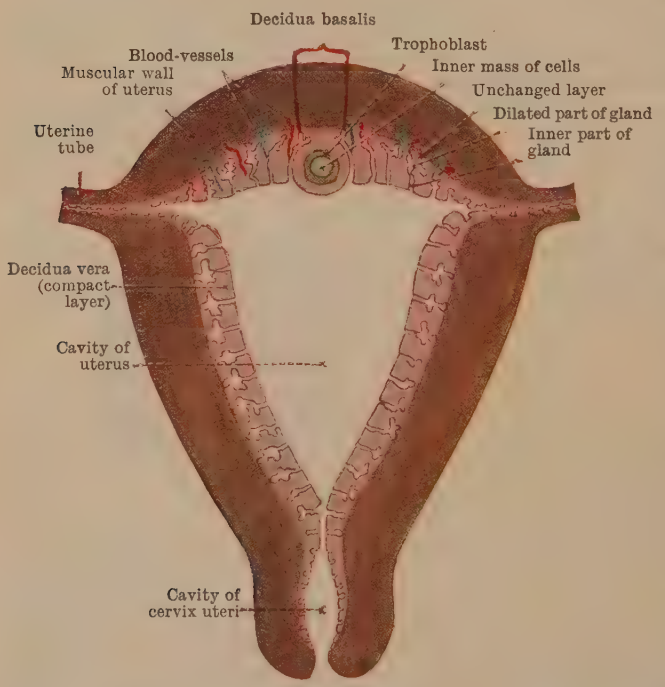

FIG. 80.—SCHEMA OF A FRONTAL SECTION OF THE UTERUS, showing the various parts of the decidua and a zygote embedded in the decidua.

The portion of the decidua in which the zygote is embedded is thicker than the other parts of the membrane, and it is separated by the zygote into an internal part, the **decidua capsularis**, and an external part, the **decidua basalis.** The junction of the decidua capsularis with the decidua basalis is the **decidua marginalis**, and the remainder of the decidua, by far the larger portion, is the **decidua vera.**

As soon as the zygote becomes embedded in the decidua its trophoblast undergoes rapid proliferation. The superficial part of the growing trophoblast becomes converted into a mass of nucleated protoplasm, the plasmodial or syncytial layer, but the inner part remains more or less distinctly cellular.

The plasmodial portion of the trophoblast invades and destroys the surrounding maternal tissue, and at the same time spaces appear in its substance. As the

plasmodium destroys the walls of the dilated maternal blood-vessels, channels are made through which the maternal blood flows into the spaces in the plasmodium, and thus maternal blood begins to circulate in the trophoblast of the zygote.

In the meantime the extra-embryonic cœlom has appeared in the primary mesoderm of the zygote, and the outer layer of the mesoderm has associated itself with the trophoblast to form the chorion (see p. 58).

The spaces in the plasmodium enlarge rapidly after the maternal blood begins to circulate within them, and the plasmodium becomes divided into three series of parts. (1) The parts which lie between adjacent blood spaces, the **primary chorionic villi**. (2) The parts which lie in contact with the mesoderm of the chorion, and which form with the mesoderm the **chorion plate**. (3) The parts which cover the maternal tissues and form the outer boundaries of the blood spaces, the **basal layer**. The blood spaces themselves are called the **intervillous spaces** (Figs. 82, 85).

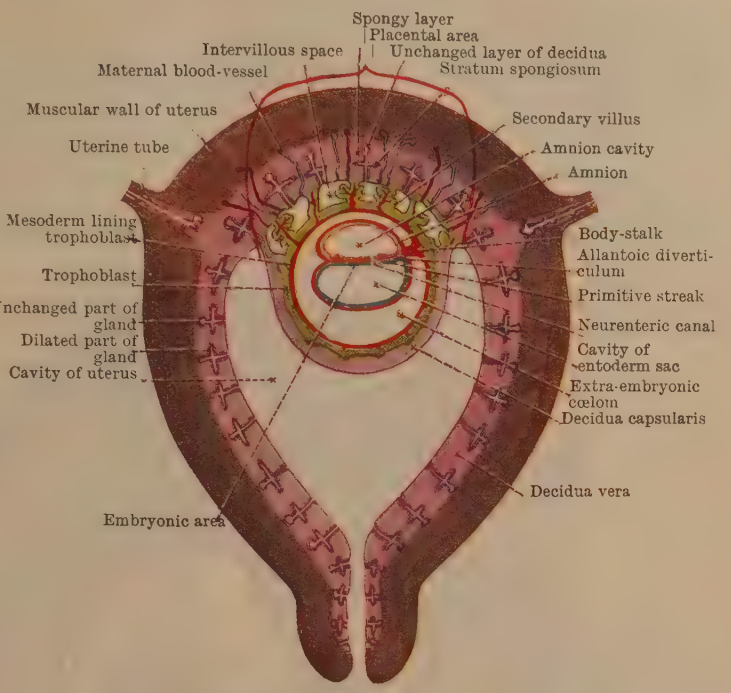

FIG. 81.—SCHEMA OF A SECTION OF A PREGNANT UTERUS AFTER THE FORMATION OF THE INTERVILLOUS SPACES.

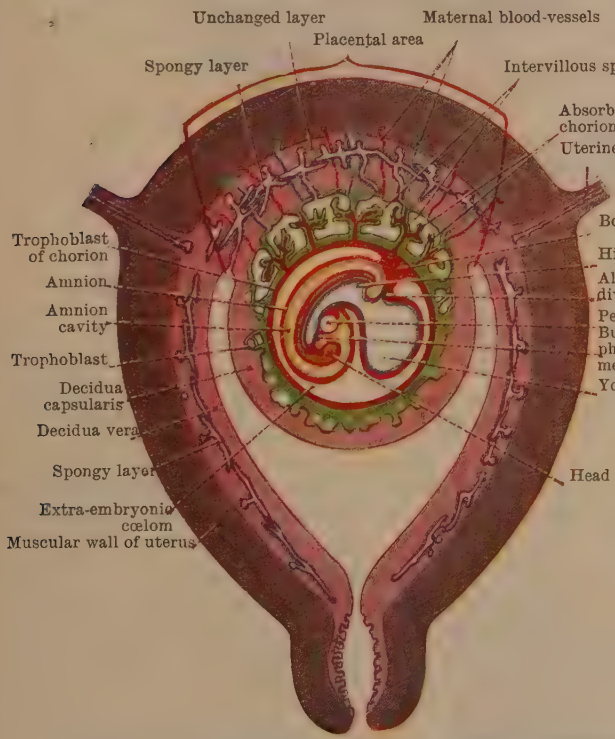

FIG. 82.—SCHEMA OF A FRONTAL SECTION OF A PREGNANT UTERUS AT THE PERIOD OF THE FORMATION OF THE EMBRYO. Note extension of amnion as contrasted with stage shown in Fig. 81.

After a time each primary villus differentiates into a cellular core and plasmodial periphery, and thereafter the villi are invaded by the

mesoderm of the chorion and are thus converted into **secondary villi** (Fig. 82).

The first-formed villi are non-vascular, but by the time the secondary villi have developed the umbilical arteries have grown through the body-stalk (allantoic stalk) into the mesoderm of the chorion, and branches from them enter the mesodermal cores of the villi, which thus become vascular.

When the secondary villi are fully developed each consists of a vascular mesodermal core continuous with the mesoderm of the chorion. The mesodermal core is covered by a layer of cellular trophoblast, *Langhan's layer*, which lies next the mesoderm, and a layer of plasmodium external to the cellular layer. The

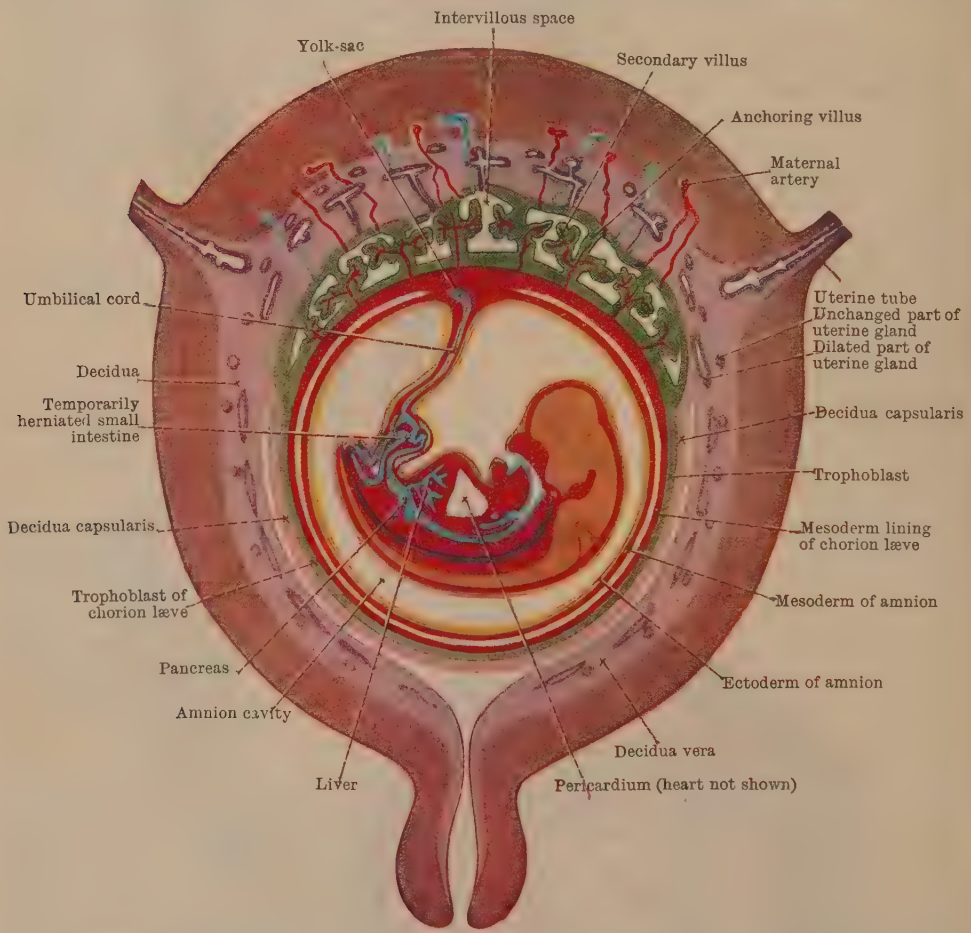

FIG. 83.—SCHEMA OF A SECTION OF A PREGNANT UTERUS AFTER THE FORMATION OF THE UMBILICAL CORD. Note that the expanding amnion has almost obliterated the extra-embryonic cœlom which lies between it and the chorion.

proximal end of each villus is continuous with the chorion plate of the intervillous spaces, formed by the chorion, and the distal extremity is connected with the plasmodial basal layer of the trophoblast, which forms the outer boundary of the intervillous spaces and which is fused with the maternal decidual tissue.

After a time branches are projected from the sides of the secondary villi into the intervillous spaces. In this way two sets of secondary villi are differentiated, (1) the **anchoring villi** (Fig. 85), which cross from the chorion to the basal layer of trophoblast and are attached to the latter by cell columns, which are the remains of the primary villi which have not been penetrated by the fœtal mesoderm, and (2) **free** or **absorbing villi** (Fig. 82), which extend from the sides of the original secondary villi into the blood, in the intervillous spaces.

Whilst the trophoblastic invasion of the compact layer of the decidua is

proceeding, not only are the interglandular elements of the decidua destroyed, but the walls of the glands also, and, as a consequence, some of the glands in the decidua basalis open for a time into the intervillous spaces, and become filled with blood which passes from the spaces into the gland cavities. In many cases, however, before the glands are destroyed their walls are converted into solid strands of cells, and thus the cavities of their more external undestroyed portions are converted into closed spaces.

In the early stages the trophoblast is differentiated in a similar manner over the whole of the surface of the zygote, and thus, for a time, the whole of the surface of the chorion is covered with villi. As the embryo grows, and the amnion and the extra-embryonic cœlom are distended, the zygote increases in size, and the capsular portion of the decidua is stretched till its vascular supply is interfered with and the villi associated with it undergo atrophy and disappear.

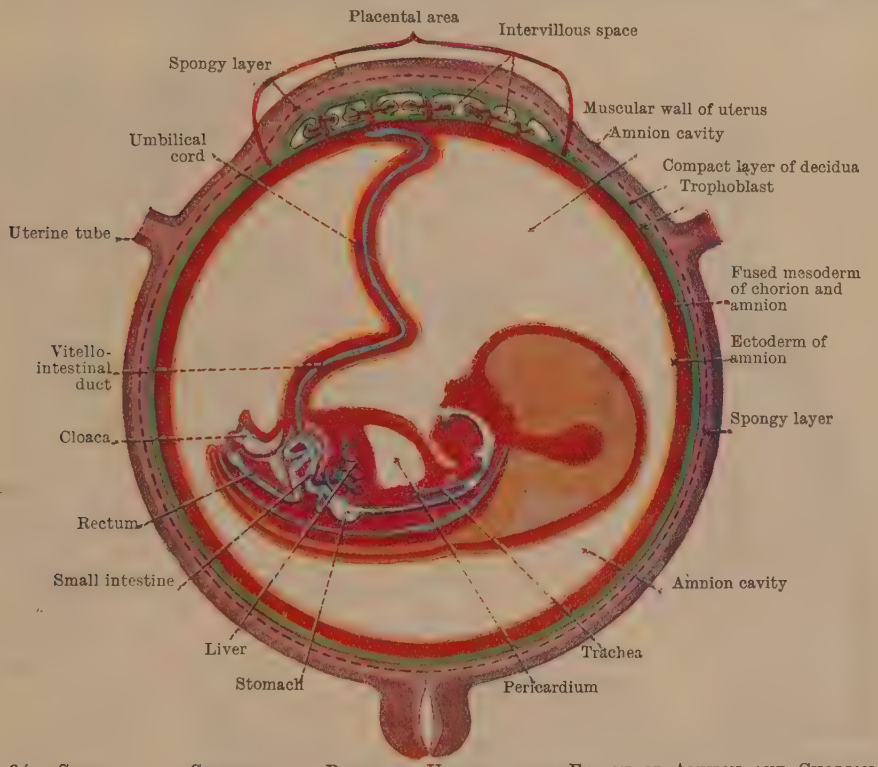

Fig. 84.—Schema of a Section of a Pregnant Uterus after Fusion of Amnion and Chorion.

When these degenerative changes have occurred, the portion of the chorion in association with the thinned decidua capsularis presents a relatively smooth surface, and is known as the **chorion læve**. Whilst the decidua capsularis is being stretched and thinned, and the associated portion of the chorion is being reduced to the condition of a non-villous region, the decidua basalis increases in thickness; at the same time the villi associated with it increase in size and in the complexity of their branches. The portion of the chorion from which these large villi spring is termed the **chorion frondosum**. It is this portion of the chorion which takes part in the formation of the so-called **fœtal portion** of the placenta, the **maternal part** of that organ being formed by the decidua basalis.

The placenta, therefore, is formed partly by the zygote and partly by maternal tissues, but the interchanges between the fœtal and the maternal blood take place in the substance of the zygote through the trophoblast which covers the surfaces of the villi.

As the growth of the embryo and the distension of the amnion continue, the outer surface of the amnion is gradually forced against the inner surface of the chorion, with which it fuses. When this fusion is completed the extra-

embryonic cœlom is obliterated and the zygote contains only one extra-embryonic cavity, the amniotic cavity, in which the fœtus floats in the amnion fluid (Fig. 84).

At this period the amnion cavity is bounded by a wall formed by the fused amnion chorion and decidua. In the meantime the chorion has differentiated into the chorion læve, fused with the decidua capsularis, and the chorion frondosum, fused with the decidua basalis. As the distension of the amnion proceeds to a still greater extent, the part of the wall of the cavity formed by the fused amnion chorion læve and the decidua capsularis projects more and more into the cavity of the uterus, until it is forced against the surrounding wall of the uterine cavity, where it fuses with the decidua vera, and thus the cavity of the uterus is obliterated. This fusion takes place towards the end of the second month, and as soon as it has occurred the discoid mass of placental tissue is continuous at its margin with the fused amnion, chorion, and decidua vera (Fig. 84).

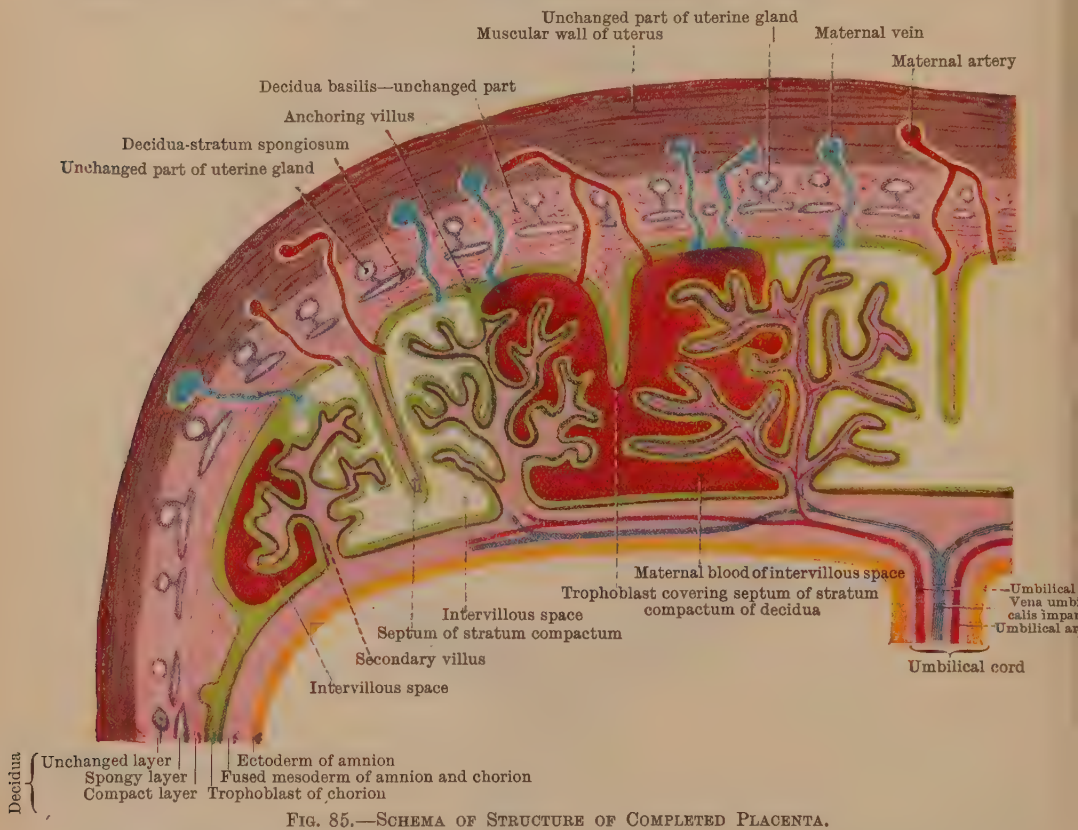

FIG. 85.—SCHEMA OF STRUCTURE OF COMPLETED PLACENTA.

After the second month the fœtus lies in the amnion cavity, which is bounded by the fused chorion and uterine wall, except at the lower end of the uterus, over the orificium internum, where the cavity of the body of the uterus communicates with the cavity of the neck of the uterus; there the amniotic cavity is bounded by a membrane formed by the fused amnion chorion læve and the decidua capsularis only.

And at the end of pregnancy that portion of the membrane is ruptured by the increased pressure of the amnion fluid produced by the contraction of the muscular wall of the uterus (Fig. 86).

Completion of the Placenta.—It has already been stated that each absorbing villus consists of a vascular mesodermal core covered by a cellular and a plasmodial layer of trophoblast, the latter lying next the maternal blood in the intervillous spaces. As development proceeds and the intervillous spaces become larger, the villi become longer and more complicated, and at the same time the cellular layer of the trophoblast largely disappears, until in the majority of the villi the plasmodial layer alone covers the vascular mesodermal core.

In still later stages, degenerative changes occur not only in the villi, but also in the chorionic plate of the intervillous spaces and in the basal trophoblast which closes the spaces externally. One of the results of the degenerative processes is the deposit of fibrinoid material in the place originally occupied by the trophoblast—the object of this process is still unknown; another is the adhesion of the fibrinous layers on the surfaces of adjacent villi, and the fusion of the villi thus connected into masses of intermingled fibrinous and vascular tissue.

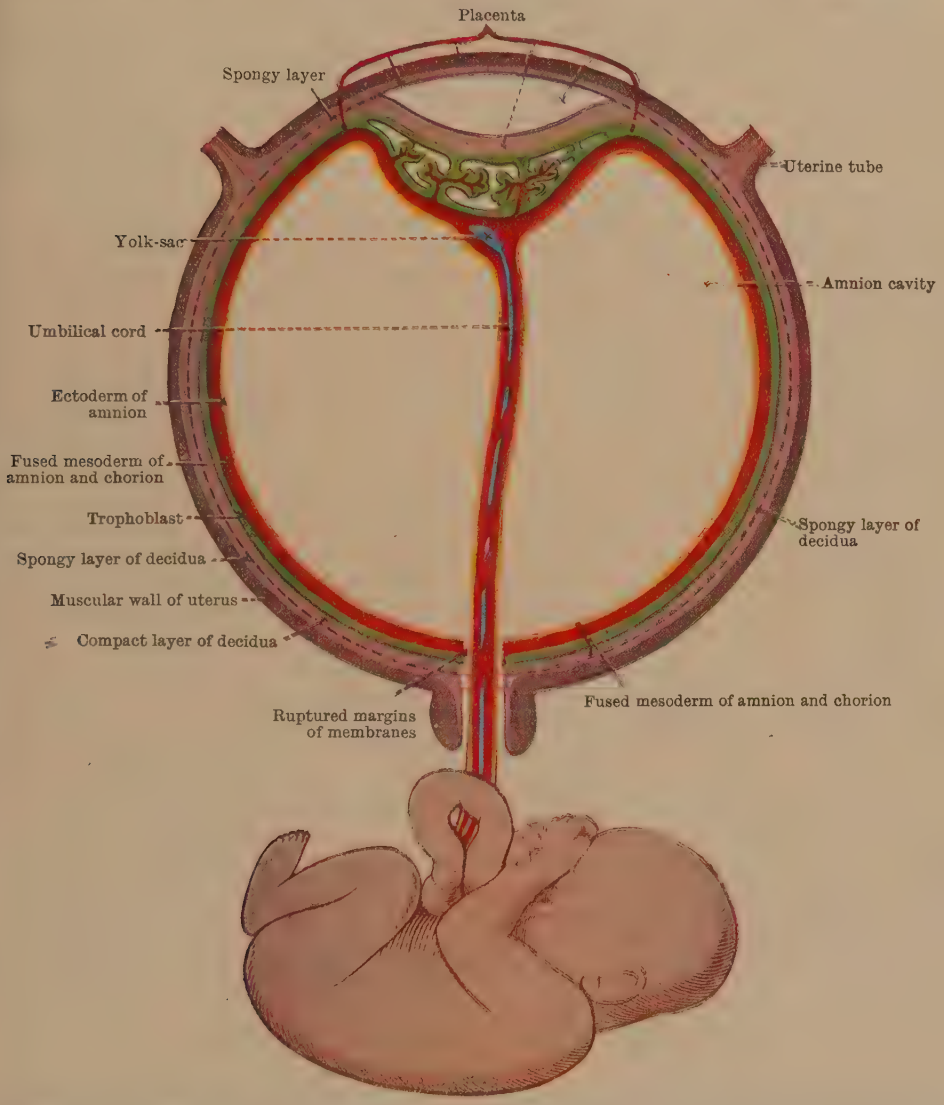

FIG. 86.—SCHEMA OF PREGNANT UTERUS IMMEDIATELY AFTER BIRTH OF THE CHILD, showing commencing separation of the placenta.' Part of the umbilical cord is shown in section and part in surface view. The blue streaks in the former part indicate the position occupied by the vitello-intestinal duct in earlier stages.

When the chorionic part of the placenta is completed it consists of (1) the chorion plate closing the intervillous spaces internally; (2) the villi; (3) the intervillous spaces; and (4) the basal layer of the trophoblast, which closes the intervillous spaces externally, and is perforated by the maternal vessels passing to and from the spaces.

The maternal portion of the completed placenta consists from within outwards of (1) the basal layer of the decidua; (2) the remains of the spongy layer of the decidua; and (3) the unchanged layer.

The basal layer of the decidua is the remains of the compact part of the decidua basalis of earlier stages. It is fused internally with the basal plate of the trophoblast, and is continuous externally with the spongy layer. The spongy layer consists of a series of cleft-like spaces. These spaces are the compressed remains of the earlier dilated portions of the glands of the stratum spongiosum, from which the epithelial lining has, to a great extent, disappeared. The spongy layer is continuous externally with the unchanged layer, in which lie the unaltered outer parts of the glands and the intervening interglandular tissue.

The maternal blood-vessels pass from the muscular wall of the uterus into the submucous tissue, and thence into the placenta, where they traverse the maternal portion and the basal plate of the trophoblast and open into the intervillous spaces. The arteries usually open on or near the septa and the veins in the intermediate areas.

In addition, however, to the constituent parts already described, the chorionic part of the placenta contains some strands of maternal tissue, and in the maternal part there are portions of trophoblast.

The parts of the decidua found in the chorionic part of the placenta are a series of fibrous strands, the remains of parts of the stratum compactum which were not destroyed by the trophoblastic invasion. They are continuous externally with fibrous strands of the maternal part of the placenta, and serve to separate the placenta into a series of lobes, from 15 to 20 in number.

The portions of trophoblast met with in the maternal part of the placenta are variable pieces of plasmodium which appear to have wandered from the general mass. They may be found in any of the strata of the maternal part, and even in the submucous tissue.

At the end of pregnancy, when intra-uterine life terminates, the fused amnion chorion and decidua capsularis are ruptured, in the region of the internal orifice of the uterus, and the amniotic fluid is expelled through the vagina. Next the fœtus is extruded, and as soon as it is born it becomes a child. After the child is born it remains attached to the placenta by the umbilical cord (Fig. 86), which is usually ligatured in two places and then divided, between the ligatures, by a medical man or an attendant. Afterwards the placenta is expelled from the uterus.

Detachment of the placenta is probably caused by contraction of the muscular substance of the uterus, and it takes place by rupture of the strands of the spongy layer of the decidua (Fig. 86). As the detached placenta is expelled the decidua vera is torn through along the line of the spongy layer, and the fused amnion and chorion læve and the inner part of the decidua vera, which are attached to the margin of the placenta and which constitute the membranes, are expelled with it.

At birth the placenta weighs about 500 grm., it has a diameter of about 16 to 20 cm., and is about 3 cm. thick. Its inner surface is covered with the amnion which fused with the chorion towards the end of the second month of pregnancy. Its outer surface is rough, it is formed by the remains of the spongy layer of the decidua, and is divided into a number of areas by a series of fissures which correspond in position with the septa by which the organ is divided into lobes.

THE PRIMITIVE VASCULAR SYSTEM.

As the zygote travels along the uterine tube, from the ovarian towards the uterine end, it exists upon the yolk granules derived from the oocyte. After it enters the uterus it must depend, for a time, upon the same source of nutriment, but as it penetrates the decidua it is probable that the cells of the trophoblast actually devour the cells of the decidua which they invade. This source of food is only sufficient for a short period, whilst the zygote remains relatively small, and substances absorbed by its surface cells can be transmitted easily to all parts.

Whilst the period exists, however, not only are the decidual tissues utilised as a food-supply, but fluids are absorbed from them and transmitted into the interior of the zygote to fill the expanding cavities of the amnion and the cœlom.

In all probability the fluids passed into the zygote contain nutritive materials which suffice for the requirements of the embryonic and non-embryonic parts of the zygote so long as both consist of comparatively thin layers of cells, but when

the embryonic area increases in thickness, and begins to be moulded into the embryo, its association with adjacent fluids becomes less intimate, and as the development of its various parts progresses, a supply of food and oxygen is required which is greater than can be provided by osmosis from the adjacent fluid media. Thus an imperative necessity arises for a method of food-supply adequate to the increasing requirements upon which the continued development and growth depend.

To meet this necessity the **blood vascular system** is formed. The system is essentially an irrigation system. In its earliest stages it consists of a series of vessels, the blood-vessels, all of which contain a corpuscle-laden fluid, called blood. The blood is kept circulating, in the early stages, by the rhythmical contraction of the walls of the vessels, but, after a short time, parts of the vessels are developed into a muscular organ called the heart. After the heart is established the continuance of the circulation of the blood depends upon the regular contractions of the muscular substance of its walls.

The corpuscular portions of the blood and the walls of the blood-vessels are formed from the cells of the zygote, but it is obvious, in the early stages at all events, that the fluid portion of the blood must be obtained from the mother. It is necessary, therefore, both for this purpose and for the facilitation of interchanges between the fœtal and maternal blood streams, that the fœtal blood-vessels should be brought into close association with the maternal blood at an early period. It is for this purpose, among others, that large spaces appear in the trophoblast (p. 25); that the spaces become filled with blood from maternal vessels which have been opened up by the destructive action of the trophoblast cells; and that the spaces are afterwards invaded by the chorionic villi, which carry in their interiors branches of the blood-vessels of the embryo (Fig. 82). As soon as the intimate relationship between the chorionic villi and the maternal blood is established fluids can readily pass from the maternal to the fœtal vessels, and there can be no doubt that both food and oxygen pass from the maternal to the fœtal blood through and by the agency of the trophoblastic epithelium, whilst, at the same time, waste products of fœtal metabolism are passed from the fœtal to the maternal blood.

The Germs of the Vascular System.—In addition to the mesoderm cells which form the paraxial mesoderm and the mesodermal somites into which it divides, the intermediate cell tracts, and the somatic and splanchnic layers of the lateral plates of the embryo, there are certain other cells, of mesodermal nature, called **mesenchyme cells.**

Whether the mesenchyme cells are derived from the primitive streak, like the majority of the embryonic mesoderm cells, or whether they are derivatives of the entoderm cells is uncertain.

The mesenchyme cells are characterised by their irregular and stellate outlines, and by the fact that, speaking generally, they do not form regular layers or masses, but are scattered irregularly between the mesoderm proper on the one hand and the entoderm and ectoderm on the other.

It is from some of the mesenchyme cells that the walls of the primitive blood-vessels and their cellular contents are derived, and the changes by which the transformation is produced become first visible in the walls of the yolk-sac, but they occur later in the embryonic region also.

The mesenchyme cells which are the rudiments of the blood vascular system become definitely spherical and their nuclei become relatively large; at the same time they are aggregated together into more or less round patches which are called **blood islands.** As soon as the cells have attained their distinctive appearance they are known as *hæmohistoblasts* or *angioblasts,* and from them are derived both the endothelial walls of the blood-vessels and the blood corpuscles.

The peripheral hæmohistoblasts become endothelial cells and those more centrally situated become the blood corpuscles.

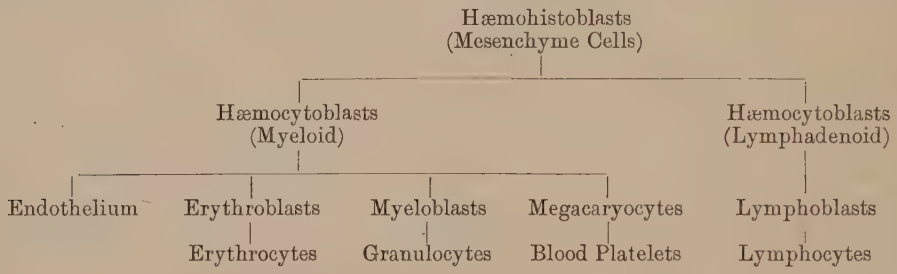
When they first become distinct in the walls of the yolk-sac the blood islands are isolated from one another, but the peripheral hæmohistoblasts soon throw out processes which anastomose with similar processes from other islands and the anastomosing processes develop into endothelial tubes, into which fluid, derived from the maternal blood, is secreted; there is thus established a plexus of

anastomosing tubes filled with blood plasma in which float nucleated cells which are the primitive blood corpuscles.

By similar methods blood-vessels are formed in the embryonic area or they extend into it from the yolk-sac.

In adult animals, however, most of the blood corpuscles are red and non-nucleated, whilst some are white and nucleated. The latter are separable into several groups having distinctive characteristics. The blood-vessels also are different, for the original plexuses are transformed into distinct stems and branches of varying sizes and importance, therefore two groups of events associated with the development of the vascular system still remain to be considered; they are the evolution of the blood corpuscles from the hæmohistoblasts and the development of the main embryonic blood-vessels.

The Development of the Blood Corpuscles.—Numerous researches have been made with the object of discovering the mode of origin of the various groups of blood cells, but there is as yet no general agreement either with regard to the exact genesis or to the terminology to be used in describing the various types of cells which are found at different periods, therefore the schema below, which is modified from Ferrata,[1] must be looked upon merely as a provisional expression of opinion:



As the schema indicates, the general progenitors of the vascular endothelium and the blood cells are certain mesenchyme cells called hæmohistoblasts, and it is those cells which form the blood islands previously mentioned. The descendants of the hæmohistoblasts form two groups, one called *myeloid hæmocytoblasts* and the other *lymphadenoid hæmocytoblasts.*

Some of the descendants of the myeloid hæmocytoblasts form endothelium. Others known as *erythroblasts* become laden with hæmoglobin and after the extrusion of their nuclei they become *erythrocytes* or red blood corpuscles.

The hæmocytoblasts which produce erythroblasts and the erythroblasts themselves increase by mitotic division as they float in the blood stream of the young embryo, so the number of erythrocytes is increased for a time; but, after the liver is differentiated, the number is further increased, for hæmocytoblast cells which have been carried into the liver from the yolk-sac by the blood stream, or which have been developed in it, *in situ*, from hæmohistoblastic mesenchyme cells, produce erythrocytes which pass through the vessel walls and enter the blood stream.

When ossification of bone commences hæmohistoblasts pass into the bones, where their descendants become *erythroblasts, myeloblasts,* and *megacaryocytes.* From the erythroblasts red blood corpuscles are formed, from the myeloblasts granular white blood corpuscles are developed, and the megacaryocytes are the progenitors of blood platelets.

The *lymphocytes* are relatively late in appearing. They are not discoverable until the spleen and other foci of adenoid tissue have been formed, and they are derived from hæmohistoblastic cells which are included in the adenoid masses as they are developed, or which are carried into the adenoid tissue by the blood stream.

In very young embryos both immature and mature blood cells are present in the blood stream, the mature being developed from the immature in the stream, but after bone marrow and lymphoid tissue have been formed it is probable that

[1] *Le Emopatie,* by A. Ferrata, Soc. Editrice Libraria, Rome, 1918.

only mature blood cells pass into the blood stream, entering the stream by piercing the endothelial walls of the capillaries.

The Formation of the Primitive Blood-Vessels.—It has been pointed out that in the yolk-sac area of the entodermal vesicle a plexiform system of tubes, filled with fluid and corpuscular elements, is formed from hæmohistoblastic cells which are called hæmocytoblasts as soon as their destiny becomes evident.

Similar but less easily demonstrated plexuses are formed in the chorionic mesoderm and also in the embryonic area.

It is probable that the various plexuses are directly connected with one another from the period of their initiation, but if that is not the case they soon become connected, and from them are evolved what may be called the primitive stem vessels of the embryo, through which the blood circulates from one area to another.

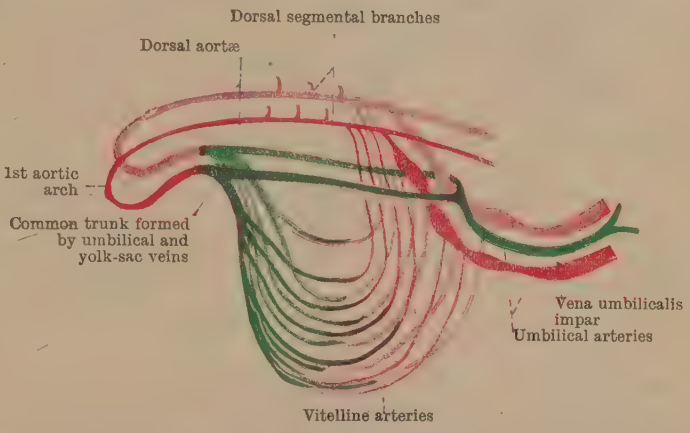


FIG. 87.—SCHEMA OF CIRCULATION OF AN EMBRYO, 1·35 MM. LONG, WITH SIX SOMITES. (After Felix, modified.)

In the embryonic area two main stem vessels are first differentiated; they are the **primitive aortæ.**

The primitive aortæ appear in the splanchnic mesoderm of the pericardial or anterior region of the embryonic area, whence they extend to the caudal or posterior end of the area.

At their anterior ends they are continuous with two stem vessels, right and left, called the **vitelline veins**, which emerge from the vascular plexus in the wall of the yolk-sac.

As the primitive aortæ pass caudalwards in the embryonic area, ventral to the paraxial bars of mesoderm (see p. 32), they give off from their ventral aspects a series of paired branches called **vitelline arteries**, which terminate in the vascular plexus in the yolk-sac wall; and from the caudal and dorsal part of that plexus, represented in Fig. 87 by a series of dilatations, a pair of vessels—the **umbilical arteries**—passes along the body-stalk to the vascular plexus in the chorion, whilst another stem vessel, the **vena umbilicalis impar**, commences in the vascular plexus in the chorion and passes along the body-stalk to the caudal margin of the embryonic area, where it divides into right and left umbilical veins. The latter run along the corresponding margins of the embryonic area and fuse with the corresponding

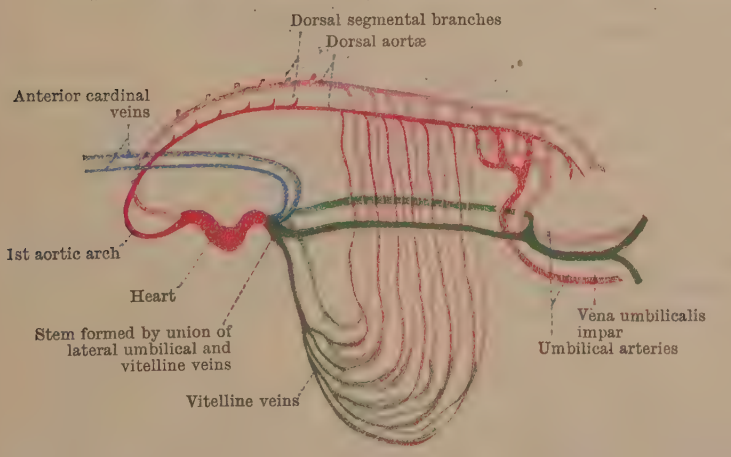

FIG. 88.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO, 2·6 MM. LONG, WITH FOURTEEN SOMITES. (Arteries after Felix, modified.)

vitelline veins at the points where the latter join the primitive aortæ, forming with them vitello-umbilical trunks. Therefore, when the rhythmic contractions commence in the pericardial portions of the primitive aortæ, and pass from the anterior towards the caudal end of the embryonic area, the blood is driven caudalwards, through the primitive aortæ, and passes through their vitelline branches to the yolk-sac and the chorion, whence it is returned to the aortæ by the vitelline and umbilical veins.

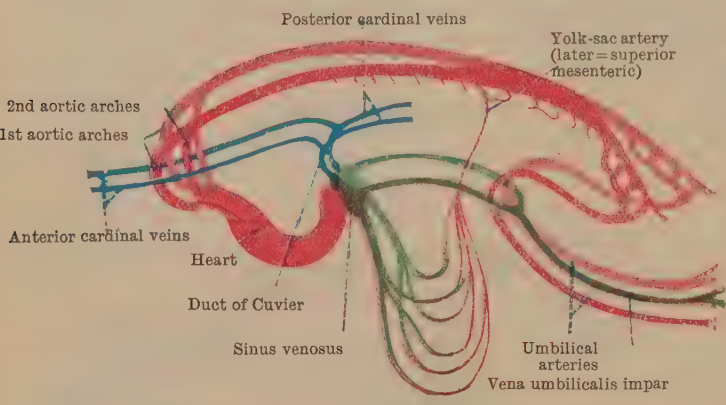

FIG. 89.—SCHEMA OF VASCULAR SYSTEM OF AN EMBRYO WITH TWENTY-THREE SOMITES. (Arteries after Felix, modified.)

In the meantime branches have been given off from the lateral aspects of the primitive aortæ, which in later stages, as the mesodermal somites are defined, become the presegmental and intersegmental arteries, but for a time no purely intra-embryonic veins are distinguishable.

As the head fold is formed and the pericardial region is transposed into the ventral wall of the fore-gut (see pp. 42, 43), the anterior parts of the primitive aortæ are carried ventrally in the fold, and so are bent into the shape of hooks. That condition is well seen in embryos of 1·35 mm. length which possess six mesodermal somites (Fig. 87).

Three parts of each primitive aorta are now defined; the short ventral limb of the hook is the *primitive ventral aorta*, the long dorsal limb is the *primitive dorsal aorta*, and the bend, which connects the two limbs, is the *first aortic arch*. It runs along the side of the buccopharyngeal membrane, in the substance of the mandibular or first branchial arch. What were previously the anterior ends of the primitive aortæ have now become the caudal ends of the primitive ventral aortæ; they lie in the substance of the septum transversum, which is the bar of mesoderm which separates the pericardial cavity from the extra-embryonic cœlom at the cranial margin of the umbilical orifice, and in that situation the common vitello-intestinal venous trunks terminate in them.

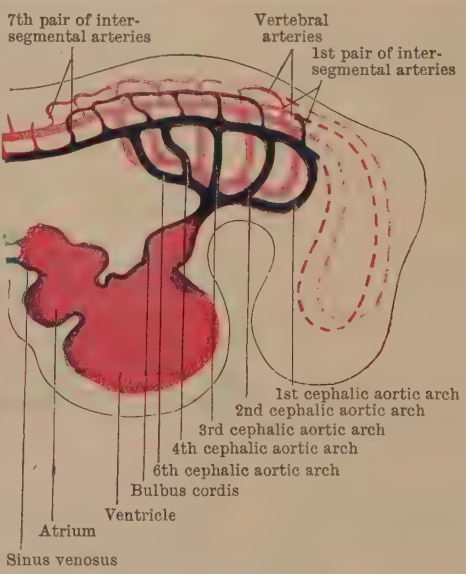

FIG. 90.—DIAGRAM showing 5 mm. stage with five aortic arches.

During the time in which the embryo grows a little more than another millimetre in length, and the tail and lateral folds are formed and the number of its mesodermal somites increases to fourteen pairs, three important changes take place in the vascular system.

(1) The caudal parts of the primitive ventral aortæ fuse together to form a single median tubular heart, which is divided, by dilatations and constrictions, into five parts, named, from the caudal towards the cranial end, the **sinus venosus**, the **atrium**, the **ventricle**, the **bulbus cordis**, and the **arterial trunk**. At the same time the heart increases in length more rapidly than the region in which it lies,

therefore it becomes bent, both in the longitudinal and the transverse direction, and its caudal and cranial ends are relatively approximated (Fig. 88).

(2) The origins of the umbilical arteries are transferred from the vitelline plexus to the primitive dorsal aortæ from which they arise by three roots for each (Fig. 88).

(3) The **precardinal veins**, which are the first pair of purely intra-embryonic veins, are defined. They return blood, which has been distributed to the head, neck, and anterior part of the trunk regions of the embryo by the pre- and inter-segmental arteries, to the sinus venosus of the heart, which they enter, in the septum transversum, close to the terminations of the common vitello-umbilical trunk veins.

As the embryo increases from 2·6 mm. to about 5 mm. in length, by which time it is about five weeks old, its mesodermal somites increase to 38 pairs, and numerous changes take place in the cardiac, the arterial, and the venous parts of the vascular system, and the rudiments of all the main blood-vessels of the adult are defined.

In the case of the heart its various chambers become more definitely demarcated, and the rudiments of the septa which divide its atrial and ventricular portions into right and left parts are formed. (For the further development of the heart see Vascular System.)

The changes in the arterial system consist of fusions, reductions, transpositions, and additions.

Fusions.—The primitive dorsal aortæ fuse, from the region of the tenth mesodermal somite (seventh cervical) caudalwards, to form the permanent descending aorta (Fig. 89) and its caudal continuation the middle sacral artery.

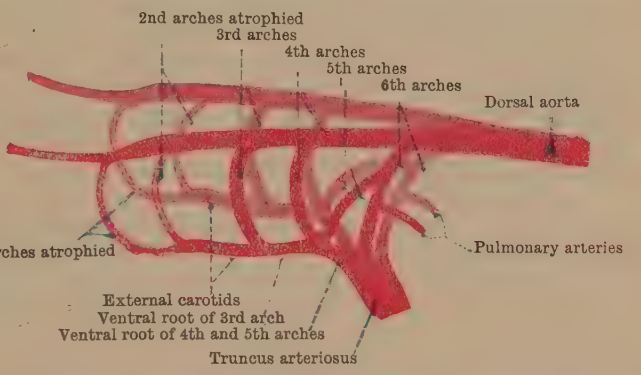

FIG. 91.—SCHEMA OF AORTIC ARCHES OF AN EMBRYO, 9 MM. LONG. (After Tandler, modified.) The second and third arches have atrophied and the transitory fifth has appeared.

At the same time the pairs of ventral branches of the fused portions of the primitive dorsal aortæ fuse to form single trunks, which divide, on the dorsal aspect of the alimentary tube, into right and left branches which reunite on the ventral wall of the tube.

Reductions.—Not only do the paired ventral or vitelline branches of the primitive dorsal fuse to form single trunks, which anastomose with those cranial and caudal to them on the walls of the primitive gut, but they also become reduced in number.

A few remain in the thoracic region and become the bronchial and œsophageal branches of the descending aorta of the adult. In the abdominal region they are reduced to three main vessels, the cœliac artery, the superior mesenteric artery, which for a time passes to the yolk-sac as the vitelline artery (Fig. 89), and the inferior mesenteric artery.

Additions.—Four additional aortic arches, connecting the unfused portions of the primitive ventral and dorsal aortæ, appear in the following sequence, the second, the third, the fourth, and the sixth.

The second pair of arches is found in embryos possessing 23 mesodermal somites (Fig. 89). They spring from the aortic trunk close to the commencements of the primitive ventral aortæ.

Branches are given off from the ventro-lateral aspects of the descending aorta to the rudiments of the nephric or urinary system, which are, in the meantime, developed from the intermediate cell tract, and to the rudiments of the genital glands.

By the time the embryo has fully attained a length of 5 mm. (Fig. 90) all five

pairs of aortic arches are present, but in the meantime, coincidently with the elongation of the neck, the primitive ventral aortæ have also been elongated and the second aortic arches have been transferred to them from the aortic trunk. The remaining three pairs of aortic arches originate from common stems, one on each side, which spring from the aortic trunk close to the origins of the primitive ventral aortæ.

Thus during the period of increase from 2·6 mm. to 5 mm., and by the time the embryo is about five weeks old, the rudiments of all the important arteries of the adult are evolved, and during the same period two additional pairs of intra-embryonic venous trunks are formed. They are called the **postcardinal** and the **subcardinal veins.**

The postcardinal veins (Fig. 89) appear in the thoracic and abdominal regions of the embryo, dorso-lateral to the nephric rudiments.

They drain blood from the body walls and from the nephric rudiments, and their cranial ends join the precardinals, in the thoracic region, at the point where the latter turn ventrally to enter the septum transversum (Fig. 89).

As soon as the union of the pre- and postcardinals is completed the parts of the precardinals ventral to the points of union become the **Ducts of Cuvier.**

In the meantime the common vitello-umbilical venous trunks have been absorbed into the sinus venosus; therefore, at the 5 mm. stage, six veins, three on each side, open into the sinus venosus of the heart. They are the Ducts of Cuvier, the vitelline veins, and the umbilical veins.

The subcardinal veins appear in the abdominal region ventro-medial to the mesonephros, which has been formed from part of the nephric rudiment. They communicate both at their cranial and caudal ends with the postcardinals.

In addition anastomoses are developed, across the median plane, between the pre-, the post-, and the subcardinal veins of opposite sides respectively. Anastomoses also develop between the post- and subcardinal veins of the same side.

At a later period still another pair of intra-embryonic veins is established in the abdominal and thoracic regions. They are called the **supracardinal veins** and they appear dorso-lateral to the descending aorta. They communicate with one another across the median plane, and with the post- and subcardinal veins, and when their formation and anastomoses are completed the rudiments of the main stems of the venous system of the adult are established.

As the changes which have been noted occur in the venous system the third and fourth pairs of aortic arches are transposed from their original positions (Fig. 90) to the primitive ventral aortæ, and the right and left fifth arches which, for a time, connect the ventral aortæ with the dorsal ends of the sixth arches are formed; pulmonary branches are projected from the sixth arches to the rudiments of the lungs, and the first two aortic arches have undergone or have begun to undergo atrophy (Fig. 91).

In order to facilitate the description of the further changes which take place in association with the aortic arches it is customary to speak of the parts of the ventral aortæ which lie caudal to the respective arches as the *ventral roots* of these arches and the corresponding parts of the dorsal aortæ as the *dorsal roots.* (For the further history of the vascular system and the fœtal circulation see Vascular System.)

THE CŒLOM.

It has already been pointed out that there are two parts of the cœlom, the extra-embryonic and the intra-embryonic. Both are clefts separating an outer from an inner layer of mesoderm.

The Extra-embryonic Cœlom.—The extra-embryonic cœlom appears in the primary mesoderm and separates it into a parietal and a visceral layer. The parietal layer covers the inner surface of the trophoblast and forms with it the chorion. It covers also the outer surface of the amnion. The visceral layer covers the outer surface of the extra-embryonic portion of the wall of the entodermal cavity.

The extra-embryonic and intra-embryonic parts of the cœlom are at first

separate from one another (Fig. 42), then they become continuous, for a time, in the region of the umbilical orifice (Fig. 43), but are separated from one another again when the umbilical orifice closes. The extra-embryonic portion is entirely obliterated when the outer surface of the expanding amnion fuses with the inner surface of the chorion (compare Figs. 83 and 84).

The Intra-embryonic Cœlom.—The intra-embryonic cœlom appears as a series of cleft-like spaces in the margin of the embryonic mesoderm. The spaces fuse together to form a ∩-shaped cavity (Fig. 92) which separates the peripheral part of the embryonic mesoderm into a parietal or somatic, and a visceral or splanchnic, layer. The bend of the ∩-shaped cavity lies in the margin of the cephalic part of the embryonic region, and it has no direct communication with the extra-embryonic cœlom, but the greater part of each stem of the cavity, on account of the disappearance of its lateral wall, soon opens, laterally, into the extra-embryonic cœlom.

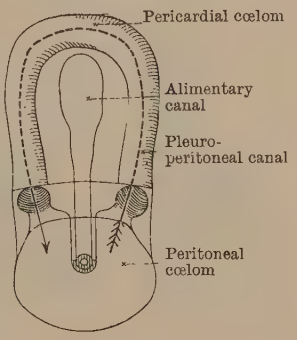

FIG. 92.—SCHEMA OF INTRA-EMBRYONIC CŒLOM SEEN FROM ABOVE BEFORE THE FOLDING OF THE EMBRYONIC AREA.

The transverse portion of the ∩-shaped cavity, which extends across the cephalic end of the embryonic area and connects the two limbs together, is the **pericardial cavity.** The adjacent part of each lateral limb of the cavity is the **pleuro-pericardial canal,** it becomes a *pleural cavity,* and the remaining portions of the two limbs unite ventrally, as the umbilical orifice closes, to form the single **peritoneal cavity.**

As the head fold forms, the pericardial part of the cavity is carried ventrally and caudally into the ventral wall of the fore-gut (Fig. 93). The mesoderm which originally formed its peri-

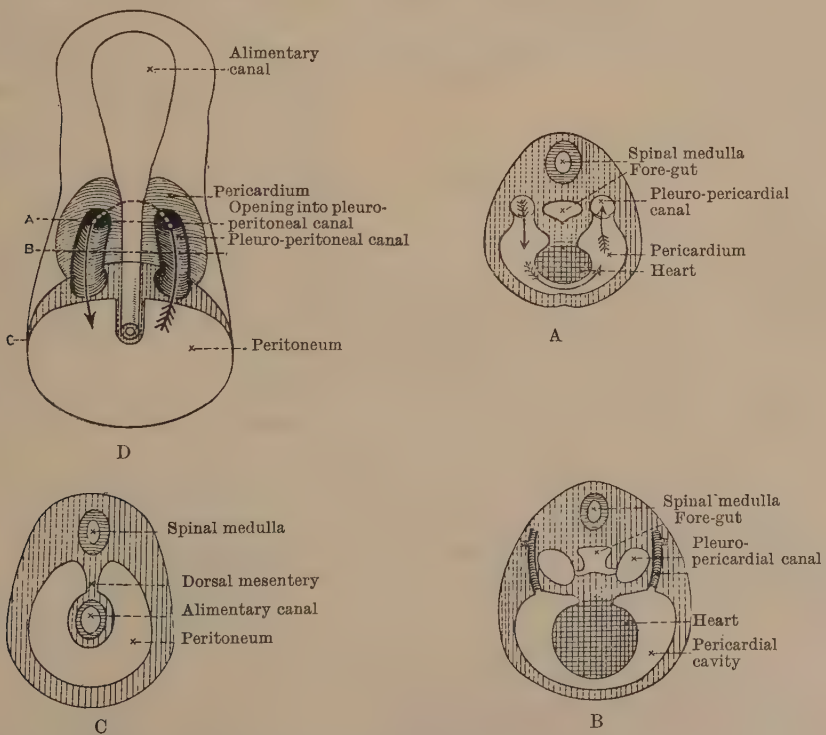

FIG. 93.—SCHEMATA OF EMBRYONIC CŒLOM AFTER FOLDING OF EMBRYONIC AREA BUT BEFORE THE SEPARATION OF THE VARIOUS PARTS. D from above; A, B, and C at levels of line A, B, and C in Fig. D.

pheral boundary, but which now lies in the cephalic boundary of the umbilical orifice, becomes thickened, and forms the *septum transversum* (Figs. 93, 94, 95).

At the cephalic end of its dorsal wall, on each side, the pericardial cavity is still

continuous with the two lateral parts of the cœlom; and each lateral part, which lies dorsal to the pericardium, and between the fore-gut medially and the body wall laterally, is still a pleuro-pericardial canal.

The Separation of the Pericardial, Pleural, and Peritoneal Parts of the Cœlom.—In the lateral wall of each pleuro-pericardial canal, near its cephalic end, lies the duct of Cuvier, passing towards the heart; and a lung bud containing a primitive bronchial tube grows, from the medial wall, into the cavity of each pleuro-pericardial canal (Fig. 94). As the lung buds grow the cavities of the pleuro-pericardial canals increase in size, and each passes ventrally, round the side of the pericardium towards the ventral wall of the body, until it is separated from its fellow of the opposite side only by a median mesoderm-filled interval, which becomes the anterior mediastinum and the anterior part of the superior mediastinum (Fig. 97). At the same time the cavity of each pleuro-pericardial canal, and the growing lung bud in its interior, grow towards the cephalic end of the embryo (Fig. 96).

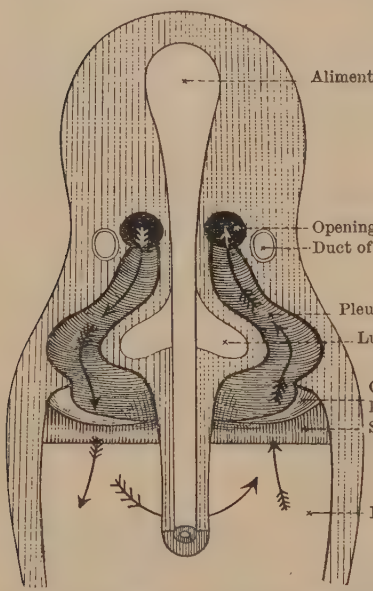

FIG. 94.—SCHEMA OF LATER STAGE OF DIFFERENTIATION OF CŒLOM. A, from above. B, transverse section cut at the level of lung bud in A.

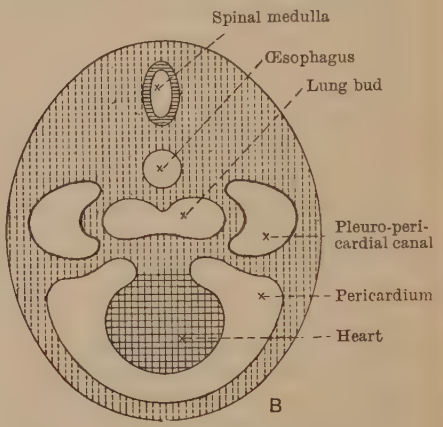

FIG. 95.—SCHEMA OF A TRANSVERSE SECTION AT THE LEVEL OF THE LUNG BUD IN FIG. 94.

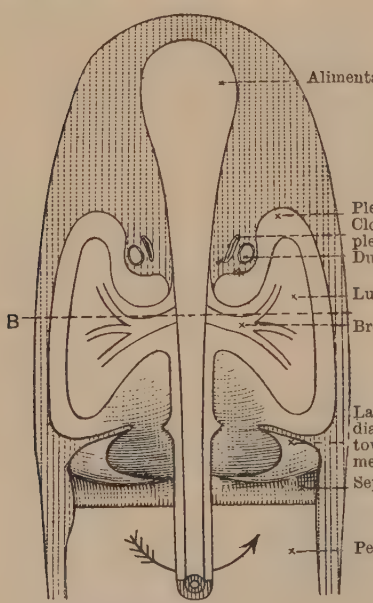

FIG. 96.—SCHEMA OF STILL LATER STAGE OF CŒLOM DIFFERENTIATION. The pleuræ are separated from the pericardia, but still communicate with the peritoneum.

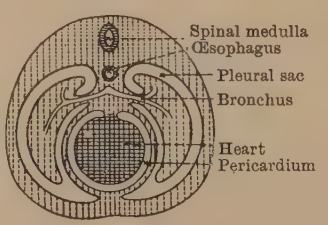

FIG. 97. — SCHEMA OF TRANSVERSE SECTION OF EMBRYO AT LEVEL OF LINE B, Fig. 96, showing ventral extension of the pleuræ.

As it passes cephalwards the growing lung lies to the lateral side of the duct of Cuvier, which is thus forced against the cephalic end of the pleuro-pericardial canal, compressing it towards the median plane, against the sides

of the trachea and the œsophagus, until its cavity is obliterated. When this occurs the pericardial cavity is entirely shut off from the remainder of the cœlom and it becomes a completely closed space (Fig. 96).[1]

As the closure of the pericardial cavity is taking place two wing-like folds of mesoderm, connected ventrally with the septum transversum and laterally with the body walls, appear, caudal to the lungs (Figs. 94, 96). These folds are the rudiments of the lateral parts of the diaphragm, and each passes medially until it fuses with the mesoderm of the side wall of the fore-gut and with the dorsal mesentery. When this fusion is completed the cavity of the portion of the cœlom surrounding the lung, the original pleuro-pericardial canal, is separated from the more caudal part of the cœlom, which now becomes the peritoneal cavity.

Only the broad outlines of the processes by which the pleuro-pericardial canals are separated from the pericardium and the peritoneum and so become the pleural sacs are mentioned in the preceding paragraphs. The details of the processes are too complicated for description in an ordinary text-book of anatomy.

The Formation of the Diaphragm.—There are four main parts of the diaphragm, a ventral, a dorsal, and a right and a left lateral.

The ventral part is formed from the septum transversum, which is gradually differentiated into a caudal, an intermediate, and a cephalic part. The caudal part is transformed into (1) the mesodermal tissue of the liver, which grows towards the abdomen, (2) the falciform and coronary ligaments, and (3) the lesser omentum. The cephalic part becomes the caudal or diaphragmatic wall of the pericardium. The intermediate part is transformed into the ventral portion of the diaphragm.

The dorsal part of the diaphragm is developed from the mesoderm of the dorsal mesentery of the fore-gut. Each lateral part is derived from a lateral ingrowth, which springs ventrally from the septum transversum and laterally from the body wall. The two lateral portions grow towards the median plane till they fuse with the dorsal portion; but in some cases, especially on the left side, the fusion is not completed. In such cases an aperture of communication remains, between the pleural and the peritoneal cavities, through which a portion of the abdominal contents may pass into the pleural sac, constituting a diaphragmatic hernia.

SUMMARY OF THE EXTERNAL FEATURES OF THE HUMAN EMBRYO AND FŒTUS AT DIFFERENT PERIODS OF DEVELOPMENT.

During the first **fourteen** days after the impregnation of the oocyte the human zygote descends through the uterine tube, assumes the morula condition, enters the uterus (see p. 25), penetrates into the decidua compacta, and differentiates into three vesicles and a mass of primitive mesoderm; but, probably, it is not until the beginning of the third week, if Bryce's calculations are correct, that a definite embryonic area is present. By that time the zygote is an ovoid vesicle measuring 2·4 by 1·8 mm. Its wall is formed by the trophoblast, and it contains two inner vesicles, the ecto-mesodermal and the ento-dermal vesicles. The inner vesicles are surrounded by a mass of primary mesoderm in which the extra-embryonic portion of the cœlom is beginning to appear. At that period the embryonic area is the region where the walls of the two inner vesicles lie in relation with one another, and it is ·19 mm. long (Fig. 36).

By the **eighteenth** or **nineteenth** day the area has attained a length of 1·17 mm. and it is ·6 mm. broad. It is pierced, about the centre of its length, by the neurenteric canal; the primitive streak has appeared on the dorsal surface of the area; the primitive groove is distinct, and the neural groove is indicated. The body-stalk is bent dorsally, at right angles with the area, and it contains the allantoic diverticulum, which has already been projected from the wall of the entodermal vesicle (Fig. 98).

During the next twenty-four hours the length of the embryonic area increases to 1·54 mm.; the neurenteric canal is moved caudally, to a point well behind the middle of the length of the area, and the posterior part of the area is bent ventrally, forming the posterior boundary of the hind-gut region and indicating the position of the future cloacal membrane. The head fold has begun to form, and the pericardial region lies in the ventral wall of the rudimentary fore-gut (Fig. 99).

[1] Very rarely, as an abnormal condition the pericardial cavity of the adult communicates on one or other side with a pleural cavity.

By the middle of the **third week** the head and tail folds are distinctly formed and the length of the embryo is 1·9 mm., the neural folds are well developed, the neural groove is still completely open, and six pairs of mesodermal somites are visible (Fig. 100).

In the next few days the length increases to 2·5 mm., the neural groove closes except in the cranial and caudal regions, the number of mesodermal somites is increased to fourteen pairs, and the cranial region begins to bend ventrally as the cervical flexure forms (Fig. 101).

By the end of the **first month** the greatest length of the embryo is about 2·6 mm., the head is bent at right angles to the body, the Wolffian ridges have appeared along the ventral margins of the mesodermal somites and indications of the limb rudiments

Fig. 98.—Frassi's Zygote. Estimated to be 18-19 days old (Bryce). The embryonic area is 1·17 mm. long and ·6 mm. broad. Copied from *Normaltafeln*, Keibel and Elze, representing a reconstruction. The chorion is not shown. The upper part of the amnion is cut away, and the dorsal aspect of the embryonic area is seen from above. In the centre of the area is the neurenteric canal and caudal (inferior in the Fig.) to it is the primitive groove. Cephalwards of the neurenteric canal is the neural groove, in the middle of the neural plate. At the lower (caudal) end of the Fig. is seen a section of the body-stalk containing the allantoic diverticulum, and the nodulated area seen at the upper and right lateral part of the Fig. is a portion of the yolk-sac.

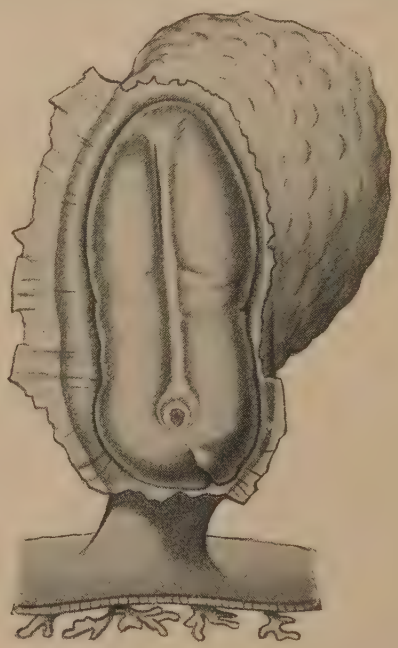

Fig. 99.—Spee's Zygote. (From Keibel and Elze's *Normaltafeln*.) Length of embryonic area 1·54 mm. Estimated age 19-20 days (Bryce). At the lower end of the Fig. (caudal end of the embryo) is seen a portion of the chorion attached to the embryo by the body-stalk. A portion of the amnion is still attached to the margin of the embryonic area, and the dorsal surface of the embryonic area is exposed. In the median plane of the area is the neural groove, and at the caudal end of the groove is the neurenteric canal. The caudal part of the area is bent ventrally, and upon it is the remains of the primitive groove. The yolk-sac is seen at the upper and right part of the Fig.

are present. The rudiments of the otic vesicles have appeared as slight depressions in the region of the hind-brain. The anterior and posterior neuropores are still open (Fig. 102).

In the latter part of the fourth or the beginning of the fifth week the embryo attains a length of about 5 mm., when measured from the vertex of the head to the base of the tail, the mesodermal somites increase to thirty-five; the rudiments of the fore- and hind-limbs become quite distinct; the otic vesicles sink into the interior of the head but remain connected with the surface by a narrow canal, the tail becomes a very definite appendage, and the bulgings caused by the otic vesicles are quite obvious on the surface of the head. The cervical flexure remains acute, and the head bends at right angles upon itself in the region of the mid-brain, forming the cephalic flexure, with the result that the frontal extremity of the head is turned caudally (Fig. 103).

By the end of the **fifth week** the length of the embryo has increased to 11 mm. (CR)[1]

[1] CR indicates the crown-rump or crown-breech measurement which corresponds with the sitting height (Mall).

(Mall). Forty-three mesodermal somites are present, but only about twenty-one are visible on the surface. During the fifth week the lens of the eye appears as a thickening of the surface ectoderm; sinks into the interior of the eyeball; becomes a vesicle and separates from the surface. The three segments of the fore-limb become visible, and the rudiments of the fingers appear. The hind-limb is less advanced; the thigh segment is not distinct, and the rudiments of the toes are not yet visible. The third and fourth visceral arches disappear from the surface and lie in the depths of the **precervical sinus**, a depression between the neck and the anterior part of the body; this is overlapped, superficially, by the caudal margin of the second arch, which grows tailwards and forms the operculum of

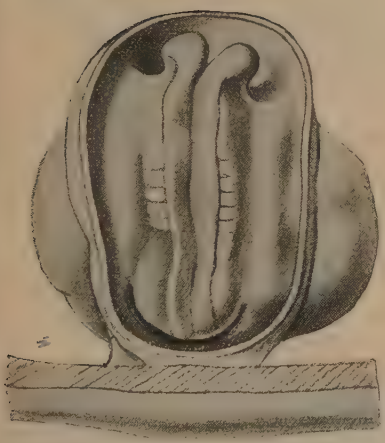

FIG. 100.—KRŒMER-PFANNENSTIEL ZYGOTE. (From Keibel and Elze's *Normaltafeln.*) The embryonic region is folded into the form of an embryo, which is 1·9 mm. long, and it is possibly about three weeks old. At the lower end of the Fig. (the caudal end of the embryo) are seen portions of the chorion and body-stalk. The cerebral portion of the neural rudiment is defined. Six pairs of mesodermal somites are present, but there are no signs of limbs.

FIG. 101.—BALLE'S EMBRYO. (From Keibel and Elze's *Normaltafeln.*) Length after hardening in alcohol 2·5 mm. The neural groove is closed from the sixth somite to within a short distance of the caudal end, but it is open anteriorly. The hind-, mid-, and fore-brain regions and the optic vesicle can be distinguished At the lower end of the Fig. is the body-stalk, and at the right side a part of the yolk-sac.

FIG. 102.—PFANNENSTIEL'S EMBRYO. (From Keibel and Elze's *Normaltafeln.*) Length of embryo about 2·6 mm. The rudiment of the otic vesicle is seen in the Fig. above the second branchial cleft. The heart and pericardium form the bulging eminence below the head, and the Wolffian ridge is seen at the lateral border of the mesodermal somites.

the sinus (see p. 47) (Figs. 104, 105). During the fifth week the head grows rapidly, and becomes relatively very large as contrasted with the body.

During this week also the olfactory pits appear, and grow dorsally in the roof of the stomatodæum, separating the median from the lateral nasal processes; the median process is divided into the two globular processes; and the maxillary processes of the mandibular arches, growing towards the median plane, fuse with the lateral nasal and the globular processes, so completing the lateral parts of the primitive cranial lip (Figs. 70, 71, 72).

The nodular outgrowths which form the rudiments of the auricles appear on the margins of the hyo-mandibular cleft and fuse together, and by the end of the week traces of the tragus, the helix, and the antitragus are visible (Fig. 106).

By the **seventh week** the embryo has attained a length of 17 mm. (CR). The cervical flexure has begun to unfold. The rudiments of the eyelids have appeared. The globular processes have fused together, but there is still a distinct notch in the middle of the upper lip. The margins of the auricles are now well defined; the hands are folded

FIG. 103.—SIDE VIEW OF AN EMBRYO, measuring about 5 mm. from the root of the neck to the base of the tail, and about 47 mm. from the crown or mid-brain region to the base of the tail, that is to the breech or rump. (From Keibel and Elze's *Normaltafeln.*) The neural tube is closed. The limb buds are quite distinct, and the maxillary process of the mandibular bar has grown forward below the eye (dorsal to the eye in the Fig.).

FIG. 104.—EMBRYO OF 7·2 MM., CR MEASUREMENT. 8·5 greatest length. (From Keibel and Elze's *Normaltafeln.*) fore-limb is distinctly in advance of the hind-limb. second branchial arch has begun to overlap the third fourth and to enclose the precervical sinus. The tip of maxillary process is in contact with the lateral and me nasal processes at the margins of the olfactory pit.

FIG. 105.—EMBRYO, 7·2 mm. (CR), and 8 mm. greatest length. (From Keibel and Elze's *Normaltafeln.*) The limbs have begun to fold ventrally. The second arch has completely overlapped the third and fourth, which now lie in the precervical sinus, and the sinus still opens on the surface at the posterior border of the second arch. The lens of the eyeball is very evident, and rudiments of the auricle of the external ear have appeared on the mandibular or first, and the hyoid or second arch.

FIG. 106.—EMBRYO, 10·9 mm. (CR), and 11·5 mm. gre length. (From Keibel and Elze's *Normaltafeln.*) The cervical sinus is closed and additional rudiments o auricle of the external ear are present on the first second arches. The anterior nares are no longer v from the side.

medially; the tips of the fingers are free, and the palms rest on the cranial part of the distended abdomen. The thighs and the toes have appeared, and the tail has begun to fuse with the caudal end of the body (Fig. 107).

At the end of the **eighth week**, when the embryo becomes a fœtus, it has attained a length of about 25 mm. (CR). The auricles project from the sides of the head, the tail has almost disappeared from the surface, and the toes are free from one another. The cervical flexure is now very slight, and although the head is still relatively large, the disproportion between it and the body has begun to decrease (Fig. 108).

Third Month.—The head grows less rapidly, and, though it is still large, it is relatively smaller in proportion to the whole body. The eyelids close, and their margins fuse

FIG. 107.—EMBRYO (CR), greatest length 18·5 mm. Probably between seven and eight weeks old. (From Keibel and Elze's *Normaltafeln*.) The abdomen is very prominent on account of the rapid increase of the liver. The digits of the hand and foot are distinct but not separated from one another. The margin auricle of the external ear is completed. The eyelids have begun to form.

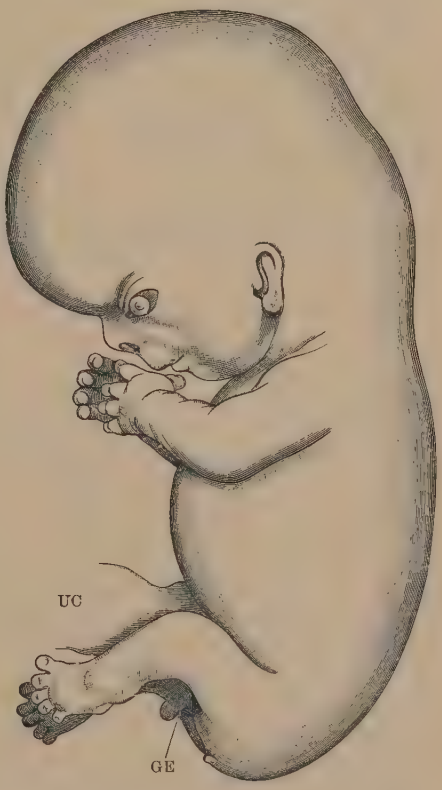

FIG. 108.—HUMAN FŒTUS EIGHT AND A HALF WEEKS OLD. (After His.)

GE, Genital eminence; UC, Umbilical cord.

together. The neck increases in length. The various parts of the limbs assume their definite proportions, and nails appear on the fingers and toes. The proctodæum is formed and the external generative organs are differentiated, so that the sex can be distinguished on external examination. The skin is a rosy colour, thin and delicate, but more consistent than in the preceding stages. By the end of the third month the CR length of the fœtus is 87 mm. ($3\frac{1}{2}$ in.), and it weighs about 45 grams ($1\frac{1}{2}$ oz.).

Fourth Month.—In the fourth month the skin becomes firmer, and fine hairs are developed. The disproportion between the fore- and hind-limbs disappears. If the fœtus is born at this period it may live for a few hours. Its CR length is 142 mm. ($5\frac{2}{3}$ in.), and it weighs 198 grams (7 oz.).

Fifth Month.—The skin becomes firmer, the hairs are more developed, and sebaceous matter appears on the surface of the body. The legs are longer than the arms, and the umbilicus is farther from the pubis. At the end of the month the CR length of the fœtus is 186 mm. ($7\frac{1}{2}$ in.), and its average weight is 460 grams ($1\frac{1}{4}$ lbs.).

Sixth Month.—The skin is wrinkled and of a dirty reddish colour. The hairs

are stronger and darker. The deposit of sebaceous matter is greater, especially in the axillæ and groins. The eyelashes and eyebrows appear. At the end of the month the CR total length of the fœtus is 228 mm. ($9\frac{1}{8}$ in.), and its average weight is about 930 grams ($2\frac{1}{16}$ lbs.).

Seventh Month. — The skin is still a dirty red colour, but it is lighter than in the previous month. The body is more plump on account of a greater deposit of subcutaneous fat. The eyelids reopen, and the fœtus is capable of living if born at this period. Its CR length at the end of the month is 265 mm. ($10\frac{3}{5}$ in.), and its weight is about 1·323 kilograms ($2\frac{3}{4}$ lbs.).

Eighth Month.—The skin is completely covered with sebaceous deposit, which is thickest on the head and in the axillæ and groins, and its colour changes to a bright flesh tint. The umbilicus is farther from the pubis, but it is not yet at the centre of the body. The CR length of the fœtus is 302 mm. (12 in.), and its weight about 2·074 kilograms ($4\frac{1}{2}$ lbs.).

Ninth Month. — The hair begins to disappear from the body, but it remains long and abundant on the head. The skin becomes paler, the plumpness increases, and the umbilicus reaches the centre of the body. At the end of the ninth month, when the fœtus is born, its CR length is about 360 mm. ($14\frac{1}{3}$ in.), and it weighs from 3·150 to 3·405 kilograms ($6\frac{1}{2}$-7 lbs.).

The age of a fœtus may be estimated, approximately, by Hasse's rule, viz., Up to the fifth month the length in centimetres, the lower limbs being included, equals the square of the age in months, and after the fifth month the length in centimetres equals the age multiplied by five.

OSTEOLOGY.

INTRODUCTION.

BONES AND CARTILAGES.

The body is built around and supported by a framework of **bones** called the *skeleton* [σκελετός (skeletos) = dried]; and the bones are supplemented in many places by gristle or **cartilage**, more so in a growing person than in an adult.

Uses of Bones.—Bones make up the framework on which the form of the body is moulded. They give support to the softer tissues which are situated around them. They provide surfaces and projections for the attachments of certain of the softer structures, such as the muscles, tendons, and ligaments. Some of the bones are connected together in such a way that they form the walls of cages and boxes for the lodgment of internal organs, for example, the heart and the lungs in the chest, the brain in the skull, and the spinal marrow in the backbone.

In addition, the bones throughout the body are the chief factory, in the adult, for the production of the cells of the blood, for they contain a special tissue, called *bone marrow*, in which the blood corpuscles are made; and, further, many of the bones are used as passive levers in the movements of the body.

Articulation of Bones (see Figs. in Chapter on Joints).—Bones are held together indirectly by all the tissues which surround them and are attached to them, but bones which lie close to one another are connected together directly in a special way. The connexion or union between two or more adjacent bones is called a **joint** or articulation. The union is effected in most cases by special sheets and bands of fibrous tissue, called *ligaments*, which are fixed to adjoining parts of the two bones. The movements of the body take place at joints, and the bones are the levers in the movements at those joints at which free movements are possible. [*Articulus*, diminutive of *artus* = a joint; cf. "articulation" in speech, meaning the junction of words or syllables. *Ligamentum* = a band or bandage, from *ligare* = to bind.]

Bones which are united together at a joint are said to *articulate* with each other at that joint, and the part of the one bone that comes into relation with the other bone is called its **articular** surface or margin or end, as the case may be. At most of the joints of the *skull* there is a ribbon of fibrous tissue interposed between the two articular parts and firmly attached to both of them; and the articular parts are rough. At the joints between the *bodies* of the *vertebræ* (*i.e.* the segments of the backbone), and at the joint between the *two hip bones*, the articular parts are coated over with an adherent layer of **articular cartilage**, and interposed between them and firmly attached to them there is a plate or disc of a kind of cartilage called *fibro-cartilage*; at those joints also the articular parts of the bones are rough. But in the majority of joints the bones can either glide or rotate upon each other; the articular parts are covered with an adherent layer

of articular cartilage which is smooth and polished, and the underlying bone also is smooth, so that the articular part of a dried bone is easily identified, even though the articular cartilage has come off during the preparation of the bone.

Constituents of Bone.—Bone, or bony tissue, consists of equal parts of solids and water, but it is the hardest and most enduring tissue in the body, excepting only the enamel or adamantine of the teeth. Bones are not only hard but are also exceedingly tough and elastic. They are composed of *white fibrous tissue* with which various *mineral salts* are incorporated. The chief salt is phosphate of lime; on account of the large proportion of that salt in bones they are one of the sources of phosphorus; there are also small quantities of calcium carbonate and fluoride, magnesium phosphate, and sodium chloride. About 30 per cent. of the solids of a bone is the *organic* matter of its component fibrous tissue; the remaining 70 per cent. is mineral salts (*inorganic* matter), and six-sevenths of that is phosphate of lime.[1] The mineral salts are so perfectly distributed through the fibrous tissue that a bone retains its form both when the salts are dissolved out of it by immersion in acid, and when the fibrous tissue is burnt out of it. Bones owe their toughness and elasticity to the fibrous tissue, and their hardness to the salts. In old age bones become more brittle owing, not to an increase of salts, but to diminution of the elasticity of the fibrous tissue.

Structure of Bone.—There are two kinds of bone, called compact bone and spongy bone. (See Fig. 223, p. 266.) **Compact bone** is hard and dense; it is seen and appreciated best in a bone such as the thigh bone when it is sawn across the middle. **Spongy bone** also is hard, but it is full of little cavities like a sponge; it is well seen in the end of a bone like the thigh bone, for the end consists of a mass of spongy bone covered with a thin surface shell of compact bone. When a bone is fresh, the cavities of spongy bone are filled with a soft, reddish material known as *red marrow*. The cavities and their walls appear very irregular to a casual glance, but with careful examination it becomes apparent that the bony substance around the cavities in any bone is arranged so as best to withstand the strain and stress that will normally be put upon that bone.

The **microscopical structure** of bony tissue is essentially the same in spongy and compact bone. The bony tissue is arranged in thin, closely applied sheets or layers called **bone lamellæ** [*lamella* or *lamina* = a leaf, blade, layer]. Here and there, between the lamellæ, there are minute cavities called **lacunæ** [*lacuna* = a pit, hole, or cavity], and in each lacuna, when the bone is fresh, there is a little cell or body called a **bone corpuscle**. Several slender tubes or canals, called **canaliculi**, pass from a lacuna through the lamellæ and connect it with neighbouring lacunæ. Where compact bone is thick, as in the shaft of a long bone, most of the lamellæ are tubular, and are arranged in groups called **Haversian systems** (after Clopton Havers, who first described them in detail). In each group there are from three to ten tubes, called **Haversian lamellæ**, arranged concentrically one outside the other. The cavity of the central tube is called a **Haversian canal**, and contains blood-vessels, a lymph channel, a nerve, and some loose connective tissue. The Haversian canals are continuous with the small tunnels through which the blood-vessels enter or leave the substance of the bone, and the connective tissue in the canals is continuous with the fibrous lining of the tunnels. The lacunæ of one system communicate by means of canaliculi with the other lacunæ in that system, but not with those of adjoining systems. Haversian systems are present also in thin compact bone and in spongy bone.

Classification of Bones.—The bones are divided into four classes according to their shape: long, short, flat, irregular.

Long bones are found in the limbs, *e.g.*, the *humerus* or bone of the upper arm, and the *femur* or thigh bone. Small elongated bones, such as those of the fingers and toes, are called **miniature long bones.** Each long bone has a *body* or shaft and *two ends*. The **body** is a hollow, thick-walled rod of compact bone. The space inside is called the **medullary cavity**, and, when the bone is fresh, it is filled with soft, yellowish material known as *yellow marrow* [*medulla* = marrow]; the yellow colour is due to abundance of fat. Around the medullary cavity, inside the compact bone, there is a layer of coarse spongy bone. The medullary cavity serves not only for the lodgment of the marrow. Its presence makes the bone lighter, and it makes it stronger also, for up to a certain point a hollow cylinder is more resistant than a solid one of the same thickness and material. The body

[1] The actual percentages are given as: organic matter, 31·03; calc. phos., 58·23; calc. carb., 7·32; calc. fluor., 1·41; mag. phos., 1·32; sod. chlor., 0·69.

of a long bone is never quite straight; it is curved usually in more than one plane; its curvatures increase its strength and resistance, the more so as there is a greater thickness of compact bony tissue in the concavities of the curves than elsewhere. The **ends** of a long bone are broader and thicker than the body. They consist of spongy bone covered with a thin layer of compact bone; the cavities in the sponge-work makes the bone lighter. The objects gained by the greater bulk of the end of the bone are: (1) The surface for articulation is wider, and therefore movements at the joint can be regulated more precisely; (2) the chances of dislocation are diminished; (3) shocks received by the bone are diffused.

Short bones are more or less cubical in shape. They consist of spongy bone enclosed in a thin shell of compact bone. Examples of short bones are the eight *bones of the wrist* and the seven *bones of the hinder half of the foot.* **Sesamoid bones** are included among short bones. A sesamoid bone is one which is developed in the substance of a tendon or sinew; the patella or knee cap is by far the largest of the sesamoid bones. They get their name from the resemblance that some of them have to sesame seeds.

Flat bones are such as the *ribs*, the *shoulder blade*, and the bones of the *skull cap.* They are **thin** rather than flat, for nearly all "flat" bones are curved or bent. They consist of two thin plates of compact bone which enclose between them a layer of spongy bone. In the flat bones of the skull the layer of spongy substance is called the **diploë** [διπλόη (diploē), a fold or doubling, a junction of two plates].

Irregular bones are of various shapes, and include all those that cannot be classed as long, or short, or flat. Many of the *skull bones* are irregular, and so are the *vertebræ.* The thinner parts of irregular bones are like flat bones and consist of two plates of compact substance with spongy substance between them. The bulky parts, especially in vertebræ, are like short bones, and consist of spongy substance surrounded with a layer of compact substance.

Most of the flat bones and many of the irregular bones of the skull have spongy substance between their two layers of compact substance, but in some of them the spongy tissue is more or less completely removed, and is replaced by cavities containing air, the walls of the cavities being composed of compact bone. Those cavities are called **air sinuses**; they give lightness to the bones and act as resonating chambers for the voice; they are extensions from the cavity of the nose, with which they are permanently in communication (Figs. 146, 147); their walls are lined on the inside with a membrane, called *muco-periosteum*, which is continuous with the similar membrane lining the interior of the nose; inflammation of the mucous lining of the nose in a "cold in the head" extends to the lining of the sinuses and gives rise to dull headaches. The air cells in the part of the skull called the mastoid temporal are, however, rather different; they are extensions from the cavity of the tympanum or drum of the ear, and lie in the midst of spongy bone, having replaced the marrow and some of the spongy substance. The bones of the skull which have air cavities in their interior, are called **pneumatic bones** [πνεῦμα (pneuma) = wind or air].

Characters of Living Bone.—The following five points are to be noted in connexion with a bone when it is living, or when it is in the "recent state"—that is, when it has been only recently removed from the body and has not been cleaned and dried.

(1) The articular parts are covered with a layer of cartilage called **articular cartilage.** That is the case in all bones, except some of those of the skull. At joints at which the bones are free to move the articular cartilage is smooth and polished to facilitate movement.

(2) The whole of the bone, except the articular part, is covered with a membrane of fibrous tissue called **periosteum** [περί (peri) = around; ὀστέον (osteon) = a bone]. The periosteum is adherent to the bone owing to the number of blood-vessels and nerves which pass from the periosteum into the bone, and because numerous minute bundles of fibres, called the *perforating fibres* of Sharpey, pass from the periosteum into the substance of the bone; within the bone the bundles are calcified like the rest of the bone, and nail the bone lamellæ together. The blood-vessels which carry the blood to and from the bone and marrow lie in the periosteum before they enter the bone (arteries), and after they leave it (veins); if the periosteum is stripped off a living bone by accident or disease the underlying part of the bone may die owing to the loss of its blood supply.

(3) The muscles, tendons, intermuscular fibrous septa, and the ligaments are attached partly to the periosteum and partly to the bone directly. In muscles with fleshy attachments the muscle fibres have microscopic tendinous ends which blend with the periosteum; some of the fibres of the tendons, the septa, and the ligaments blend with the periosteum, but a great many are prolonged into the bone as perforating fibres, and therefore the tendons, etc., are very firmly attached to bone.

(4) The medullary cavity is filled with yellow marrow, and the cavities in spongy bone with red marrow.

(5) The cavities in spongy bone are lined with a delicate membrane of fibrous tissue called **endosteum** [ἔνδον (endon) = within]; and, in a long bone, the medullary cavity is lined with endosteum continuous with that in the ends of the bone. The endosteum within a bone is connected with the periosteum on the outside by means of the fibrous lining of the tunnels through which the blood-vessels pass, and the loose connective tissue in the Haversian canals.

Appearances of a Dried Bone.—The bones used for study have been macerated and dried. Maceration is a process by which all the structures attached to a bone, including the periosteum and articular cartilage, are removed. In the subsequent drying the marrow and endosteum shrivel up.

Though the articular cartilage is removed the **articular part** of a bone can still be identified. In the case of the vertebræ where the articular cartilage covering the upper and lower aspects of the bodies does not have a free surface, but is adherent to fibro-cartilage (see p. 88), the part covered by the articular cartilage can be recognised by its peculiar appearance, which resembles unglazed porcelain; but in most bones the articular cartilage has a free surface which is smooth and polished, and the bone which it covers is also smooth and polished; some other parts of the bone may be quite smooth but do not have the polished or glazed appearance. Over all the surfaces of a bone, except the smooth articular surfaces, there are numerous small apertures; the apertures are the outer ends of the canals or tunnels through which the blood-vessels pass on their way to and from the bone marrow and the substance of the bone. At the ends of a long bone those small foramina [*foramen* = a hole] are scattered near the margins of the articular surface. On the body of a long bone the foramina are very minute, and are barely visible to the naked eye, but there is always one relatively large foramen, called the **nutrient foramen**, the position of which is fairly constant for the same bone in different subjects; the tunnel into which it leads is the *nutrient canal*; the vessels which pass through it are called the *nutrient artery* and *vein*, and they convey the blood to and from the bone marrow and the substance of the shaft.

The exterior of bones shows many grooves and hollows, ridges, eminences, and projections. The depressions and elevations are chiefly for the attachment of muscles, tendons, and ligaments. For any one bone they vary in different subjects, but are sufficiently alike for a general description to be applicable to all. The **surfaces** of a bone are named usually from the direction in which they face; *e.g.*, a surface directed *forwards* is called the *anterior* surface. Sometimes surfaces are named according to their relative propinquity to a cavity; *e.g.*, the *outer* surface of a rib is the one further away from the cavity of the chest. Some surfaces are named after neighbouring structures; *e.g.*, the *costal* surface of the shoulder blade is the surface directed towards the ribs [*costa* = a rib]. The edge or ridge between two surfaces is called a **border** or margin, and is named from the direction in which it looks.

The depressions and elevations receive general names, most of which are included in the alphabetical list below, and special names according to their position or characters.

A student is often asked to say whether a given bone or other bilateral organ belongs to the right or the left half of the body. It is a ready means of testing whether he knows the broad, main features of the organ; for if a structure is held in the position it occupies in the erect body (*i.e.*, with its upper end upwards and its anterior surface facing forwards), then its lateral surface or end or border will

look towards the side to which it belongs. If a student does not know enough about a structure to enable him to distinguish which is the upper part, which is the front, and which is the lateral part, there is little merit and no advantage in his knowing whether it is left or right.

Definition of Terms.

The terms *median*, *medial*, *lateral*, etc., are explained on pp. 4 and 5.

Aditus. The entrance into a cavity. [*Aditus* = an entrance.]

Ala. A projection or a surface shaped like a wing. [*Ala* = a wing.]

Alveolus. A deep narrow pit. [*Alveolus* = a small cavity.]

Antrum. A cavity or hollow filled with air and lined with mucous membrane in the interior of a bone. [Ἄντρον (antron) = a cave.]

Canal. A passage or tunnel; unlike the artificial watercourses of the same name, a canal has complete walls round about it.

Condyle. A smooth rounded eminence covered with articular cartilage. [Κόνδυλος (condylos) = a knuckle.]

Cornu. A projection or prolongation shaped like a horn. [*Cornu* = a horn.]

Crest or *Crista.* A sharp upstanding ridge of bone; sometimes applied also to a border when it is sharp and prominent.

Epicondyle. A prominence or projection situated above a smooth articular eminence, though that eminence may not be called a condyle. [Ἐπί (epi) = above.]

Facet. A small smooth area usually covered with articular cartilage. Nearly all smooth articular surfaces on bones are referred to at times as facets.

Foramen. A hole; it may be an aperture through which one can see, or it may be the end of a canal.

Fossa. A depression, usually broad and shallow. [*Fossa* = a ditch].

Fovea. A small shallow depression. [*Fovea* = a small pit.]

Hamulus. A projection shaped like a hook. [*Hamulus* = a small hook.]

Hiatus. A slit or gap.

Incisura. A notch.

Labium or *Lip.* The margin of a groove or a hollow; when a ridge or a border is broad its margins are called its lips.

Lamina or *Lamella.* A thin plate or sheet.

Ligula or *Lingula.* A projection shaped like a tongue.

Line or *Linea.* A low ridge, usually narrow.

Meatus. A short canal. [*Meatus* = a way, passage.]

Planum. A flat surface.

Process or *Processus.* Any kind of projection or prolongation.

Sinus. A cavity in a bone lined with mucous membrane and filled with air; used with very different meanings in other systems. [*Sinus* = a curve, fold, interior, hiding place, bay, or gulf.]

Spina or *Spine.* A sharp pointed projection.

Squama. A portion of bone shaped like a scale. [*Squama* = a scale.]

Sulcus. A groove or furrow.

Trochlea. A pulley or pulley-shaped surface. [Τροχιλία (trochilia) = the sheave of a pulley.]

Tuber, *Tubercle*, and *Tuberosity* [*tuber* = a bump or swelling] are terms applied, without much distinction, to any kind of rounded swelling or eminence, large or small, smooth or rough. The term *tubercle*, with quite another meaning, is well known, owing to the endemic prevalence of disease caused by tubercle bacilli, but the origin of the term is the same. Tubercular diseases were so named because hard nodules or *tubercles* were found on the surface of affected organs.

Uncus. A part shaped like a hook. [*Uncus* = a hook or barb.]

Cartilage.

Cartilage or gristle is present in many parts of the body. It is supplementary to bones, and in many situations it takes the place of bone. It is much more abundant in a young animal than in a adult, for much of the cartilage present in the young animal is replaced by bone during the period of growth; but in many places cartilage persists throughout life. Cartilage is one of the few substances in which neither blood-vessels nor nerves have been found; it is nourished by lymph. It is elastic, but is not hard like bone; it is less yielding and pliable than tendons and ligaments, though it is cut more easily with a knife. Cartilage is covered with a fibrous membrane called **perichondrium**; the only exception is articular cartilage, which has a covering only on its margins. [Περί (peri) = around; χόνδρος (chondros) = cartilage.]

Classification of Cartilage.—There are three main varieties — hyaline cartilage; white fibro-cartilage; yellow fibro-cartilage.

Hyaline cartilage is bluish-white in colour, rather brittle, and easily cut into slices; the cut surface, to the naked eye, is homogeneous in texture, and a thin slice is translucent—hence the name "hyaline," from ὕαλος (hyalos) = glass. The following cartilages are of the hyaline variety: (1) The *costal cartilages*, which are connected with the anterior ends of the ribs. (2) The strips of cartilage between the segments of the *sternum* or breastbone, and a great part of the *xiphoid process*, which is the lowest part of the sternum. (3) The cartilages of the *nose*; most of the cartilages of the *larynx* or voice box; the cartilaginous rings of the *trachea* or wind-

pipe and of the *bronchi*, which are the branches of the trachea. (4) The *cartilage which precedes bone.* At birth a great deal of that cartilage has been changed into bone already; but much of it still persists, especially at the ends of bones, and is gradually replaced by osseous tissue as growth goes on. In the case of some bones the change is not complete until the body is fully grown; therefore a growing person has more hyaline cartilage in the body than an adult has; a ready example is furnished by edible animals: there is far more gristle about the bones in veal and lamb than in beef and mutton. (5) *Articular cartilage* is part of the hyaline cartilage in which a bone is formed; and it remains cartilaginous throughout life.

White fibro-cartilage consists of cartilage mixed with strong bundles of white fibrous tissue; it is therefore less homogeneous than hyaline cartilage and is tougher. It is found in the following situations: (1) In a few tendons as *sesamoid cartilages.* (2) In the joint between the lower jaw and the skull, the joints at each end of the collar bone and at the wrist joint, in the form of *articular discs.* (3) In the shoulder joint and the hip joint, in the form of a ring, called a *labrum glenoidale*, attached to the rim of the articular socket of the shoulder blade and hip bone respectively. [*Labrum* = labium = a lip; γλήνη (glēnē) = a socket.] (4) In the knee joint, in the form of two semilunar bodies called *menisci* [μηνίσκος (mēniscos) = a crescent, diminutive of μήνη = moon]. (5) In the backbone in the form of a thick plate, called an *intervertebral fibro-cartilage*, between the bodies of each two vertebræ and attached firmly to both of them uniting them together; those plates account for most of the white fibro-cartilage in the body; they are easily recognised between the bodies of the vertebræ on the sawn surface of a sirloin of beef. (6) A similar plate unites the two hip bones at the *symphysis pubis*—that is, the joint in the middle line at the lower part of the front of the abdomen.

Yellow fibro-cartilage resembles white fibro-cartilage, but it contains yellow elastic fibres. It is found in the *ear*, in the *auditory tube*—that is, the passage between the drum of the ear and the throat,—and in some of the cartilages of the *larynx.*

Development of Bone.

Bones are formed in mesodermal tissue (p. 27). In some cases, as in the vault of the skull, the mesoderm becomes fibrous tissue, and the bones are formed in it. In most cases, however, a small model of the bone is made of cartilage formed in the mesodermal tissue; the first step is a closer aggregation of the mesodermal cells in the situation where the model is to be made; the aggregation of cells is the **rudiment** of a bone, and the cells assume an appearance intermediate between fibrous tissue and cartilage, forming a substance called **pro-cartilage**, which is gradually transformed into true *hyaline cartilage.* The process of transformation of the fibrous tissue or of the cartilage into bone is called **ossification.** The bones ossified in fibrous tissue are called *membrane bones*, because the fibrous tissue is arranged in the form of a membrane. The bones which are preceded by cartilage are called *cartilage bones.*

Formation of Cartilage.—Each of the cells in the interior of the bone rudiment enlarges, and as it does so it makes a thick *capsule* or envelope round about itself, and then divides into two; each of the two enlarges, makes a capsule and divides; and so on—two new capsules being formed inside each older one. In that way the rudiment increases in size, until a mass of tissue is formed consisting of cells, now called *cartilage cells*, which are imbedded in a dense substance of fused capsules made by the cells themselves and called the **cartilaginous periblast** (or *matrix*, an unsuitable name). The outermost part of the bone rudiment is retained as the **perichondrium**, which consists of an outer layer mainly fibrous, and an inner layer mainly cells and blood-vessels. [Περί (peri) = around; βλαστάνω (blastanō) = grow; χόνδρος (chondros) = cartilage.]

Appearance of Ossific Centres.—The process of ossification commences at different dates in different bones, but nearly all the bones begin to be ossified during the second month of intra-uterine life, and the date is fairly constant for any one bone in different subjects. The point in a bone where ossification begins is called a **centre of ossification**, and the centre is said to *appear* at such and such a date. Many of the bones are ossified from more than one centre. When a bone has several centres of ossification and the centres appear at widely separated dates, the first to appear is called the **primary centre** and the others are called **secondary centres.** By far the largest part of a bone is ossified from the primary centre. When ossification starts at more than one point in a bone about the same time, each of those centres is called a primary centre.

Ossification in Cartilage.—Ossification begins usually about the *middle* of a cartilage bone. At that point there is a great *increase* both in the size of the cartilage cells and in the amount of the substance around the cells; and the next step is the *deposition of* calcareous or lime *salts* in that substance. As the process spreads from the centre the *cartilage cells* just ahead of the calcifying region *multiply* rapidly, so that the size of the "bone" as a whole is increased, the multiplication and increase in a long bone taking place chiefly lengthwise. The deposit of calcareous material goes on till, in a little while, the cartilage cells become imprisoned inside the calcareous walls built around them, and, having their supply of nutriment cut off at the same time, they die and shrivel, leaving the *spaces* they occupied *nearly empty.*

The calcified cartilage is not bone, though the process is called ossification; but while those changes have been taking place in the centre a similar change leading to the *production of real bone* has been taking place on the outside of the cartilage. The cells of the deeper layer of the perichondrium have formed a clear substance round about themselves; fibres have been laid down in that, and **bone** is produced by the deposit of lime salts between and among the

cells and fibres and within the fibres themselves; so that the calcified cartilage in the interior is encased in bone formed by the perichondrium; the perichondrium, since it now surrounds bone, is called periosteum, and that bone is called **subperiosteal bone.**

The calcified cartilage is short-lived. Blood-vessels grow in from the deeper layers of the periosteum, and they are accompanied by more than one kind of cell. Some of those cells are called **osteoclasts** [κλάω (claō) = break, destroy]. They eat their way through the subperiosteal bone, making passages through it for the blood-vessels they accompany to run along; and when they come to the calcified cartilage they consume a large proportion of it and so enlarge the spaces in the interior. Other cells accompanying the blood-vessels are called *osteoblasts* or **bone-forming cells** [βλαστάνω (blastanō) = grow, produce]. They are the same kind of cells around which, and under the influence of which, the bone is formed underneath the periosteum; they form layers of bone on the calcified cartilage that the osteoclasts have so far left untouched, and thus enclose the enlarged spaces with bony walls; the spaces become filled with marrow by the multiplication of fat-cells and other cells that accompany the blood-vessels. The remains of the calcified cartilage on which those layers of bone are laid down become in time destroyed by the osteoclasts, until no vestige of cartilage or cartilage cells is left in the interior.

Both under the periosteum and in the interior some of the bone-forming cells are left in little cavities between succeeding layers of bone; but they are not cut off from nutritive supply, and survive, under the name of *bone corpuscles*, as long as the bone lives.

It is not only the calcified cartilage that is destroyed by osteoclasts. The cavities in spongy adult bone are much larger than the cavities in newly-formed bone. The cavities are larger because osteoclasts have removed a great quantity of the first-formed bone, so that several of the original cavities or spaces run into one. The strength of the bone, however, is maintained and increased because bone-forming cells lay down additional layers of bone on what remains of the original bone, so that the walls of the enlarged cavities are thickened. And it is not only in the bone which is formed in cartilage that those changes occur; the original subperiosteal bone also is largely destroyed and is replaced by a second osseous deposit. If the horizontal diameters of the body of a vertebra of a new-born child are compared with the diameters of the body of an adult vertebra, it will be clear that only a small part in the centre of the adult bone is pre-formed in cartilage. The greater part in those diameters is formed by layer after layer deposited under the periosteum. In that subperiosteal bone the same process has gone on as in the centre—ingrowth of blood-vessels, excavation by osteoclasts, and a rebuilding and a strengthening of the remains by bone-forming cells; and that strengthening is especially marked in the last-formed layers in the adult bone so as to produce the compact bone at the surface.

Some of the tissue which grows in with the blood-vessels from the periosteum becomes converted into the perforating fibres of Sharpey.

In bones that have a medullary cavity the osseous tissue which succeeds the calcified cartilage is entirely removed in order that the cavity may be created; and, further, while new bone is being formed on the outside under the periosteum, osteoclasts are continually eating away the bony tissue next the medullary cavity in order to enlarge the cavity both in length and width, until it attains adult size. In a bone like the femur none of the bony tissue present at birth and none that was created during early life is left at all, for the medullary cavity of the adult femur is larger than the whole femur of a child.

The **Haversian systems** are produced in the following way: Blood-vessels from the periosteum grow into the original subperiosteal bone, and the osteoclasts create long and relatively wide spaces around those vessels. Then the bone-forming cells multiply and arrange themselves round the inside of the wall of the space, and produce layer after layer around the space, forming a series of concentric tubes, the innermost one enclosing the original space, now called the Haversian canal. As successive layers are produced, bone-forming cells are left between them as bone-corpuscles in lacunæ. Among the Haversian systems a few of the original layers of the subperiosteal bone survive, and they are called *interstitial lamellæ*; while, at the surface of the bone, the last-formed layers of subperiosteal bone are left unaltered and are called *circumferential lamellæ.*

Ossification in membrane occurs in certain skull-bones, in the lower jaw bone and in part of the collar bone. The cartilaginous stage is missed out; in other respects the process of ossification is the same as in a cartilage bone. There is a deposit of osseous tissue in or underneath the outer layers of the sheet or membrane of mesoderm, which thereupon becomes periosteum; that is followed by excavation by osteoclasts and rebuilding by bone-forming cells, just in the same sequence as in the case of ossification under the periosteum of a bone pre-formed in cartilage.

Formation of Joints.—The mesodermal tissue between two developing bones becomes converted into the structures that bind the two bones together, and those structures vary according to the class of joint. In the case of a **diarthrodial joint**—that is, one in which there is a cavity in the joint and the bones are free to move—the outer layers of the condensed mesoderm become converted into the *articular capsule* of the joint; the cells in the interior disappear and the *joint cavity* is formed. In certain joints all the cells inside do not disappear; those that remain give rise to the discs, menisci, and ligaments which are found in the interior of certain diarthrodial joints (see Figs. in chapter on Joints).

Growth of Bones.—Most bones grow in two dimensions by deposition of osseous tissue under the periosteum, and in the third dimension by multiplication of cartilage cells prior to ossification. For example, the body of a vertebra grows in breadth and in thickness by subperiosteal deposit of bone, and in height by increase of cartilage at its upper and lower surfaces;

a long bone grows in girth (*i.e.* breadth and thickness) under the periosteum, and in length by increase of the cartilage at its ends. Some bones, on the contrary, grow in one dimension by subperiosteal deposit, and in the other two dimensions by increase of cartilage,—for example, those cubical bones of the wrist and of the foot which have two sides covered with periosteum and four sides covered with articular cartilage. In bones such as those of the skull which are developed in membrane the growth takes place under the periosteum and in the membranous tissue that separates their margins from contiguous bones.

Some short bones and some flat bones are ossified wholly from the **primary centre** of ossification. They continue to grow: (1) in the case of flat bones developed in membrane, until the bone-forming cells in the periosteum and in the tissue separating the margins of bones cease to function as bone-forming cells; and (2) in the case of bones developed in cartilage, until the subperiosteal bone-forming cells cease to function and the cartilage cells in the cartilage covering an articular surface cease to multiply. At the articular part of a bone the multiplication of cartilage cells and the process of ossification cease before the cartilage is all used up, so that a layer of articular cartilage is left which survives till death or until destroyed by disease.

All the long bones and many of the others acquire **secondary centres** that appear in outlying cartilaginous parts into which ossification from the primary centre has not had time to extend. Nearly all the secondary centres appear after birth, and the method of ossification from them is the same as from primary centres—multiplication of cartilage cells, calcification, subperiosteal deposit of bone, etc.

The part of a bone ossified from the primary centre is called (without good reason) the **diaphysis**. A part ossified from a secondary centre is called an **epiphysis**, and a secondary centre is therefore often called an *epiphyseal centre*. [Ἐπίφυσις from ἐπί (epi) = upon, φύω (phyō) = make to grow.]

Ossification in the cartilage (accompanied by ossification under the perichondrium) proceeds from the secondary centre till only one part or two parts of the cartilage are left: (1) A thin plate, called the **epiphyseal cartilage**, persists for a time between the diaphysis and the epiphysis; its edge at the surface of the bone is called the **epiphyseal line**. (2) In cases where the epiphysis is the articulating part of the bone the articular layer of cartilage survives.

As long as the epiphyseal cartilage lasts the bone continues to grow on each side of it—that is, both diaphysis and epiphysis continue to grow, the rate of growth being much more rapid in the diaphysis than in the epiphysis; both of them go on constantly increasing at the expense of the part of the cartilage nearest them, and the cartilage cells in the middle layers of the plate go on multiplying in order to maintain the existence of the plate. But a time comes when the cartilage cells cease to multiply, and the ossifying process in the diaphysis and that in the epiphysis, invading the cartilage from both sides, use it all up and meet together. The epiphysis is then said to have joined or *fused with* the diaphysis; and the bone ceases to grow in that situation. In the same way the bone increases under the articular cartilage. When the cells of that cartilage cease to multiply the growth of bone ends there also, but does so before the cartilage is all used up. Therefore articular cartilage persists, while epiphyseal cartilage disappears.

The growth of bone ceases when a person becomes an adult, but it can be resumed. Healthy periosteum retains the faculty of producing new bone when it is required; otherwise broken bones would not heal, nor would bony ridges become more pronounced to provide firmer attachments for muscles when they become stronger and larger as a result of unaccustomed exercise.

Epiphyses (Figs. 199, 222).—The shaft or body of a long bone is developed from a primary centre, and the shaft is therefore the diaphysis. Every long bone has an epiphysis at one end; most of them have epiphyses at both ends; in some bones there are more than one epiphysis at the end, *e.g.*, the distal end of the humerus, the proximal end of the femur. When a long bone has an epiphysis at only one end, it is at the end at which there is the more movement. Most epiphyses are ossified from one centre, but some are ossified from more than one, and the different parts ossified from those separate centres coalesce before the union with the diaphysis, *e.g.* the proximal end of the humerus. When there are more than one epiphyseal centre at the end of a bone, and the parts ossified from those centres do not coalesce but join the shaft separately, each part is called an epiphysis, *e.g.* the parts at the proximal end of the femur.

Dates of Appearance of Epiphyses.—Though most epiphyseal centres appear after birth, there is one notable exception and sometimes three. The centre for the *distal end of the femur* appears during the ninth month of intra-uterine life; the centre for the proximal end of the tibia often appears towards the end of that month, and the centre for the head of the humerus sometimes does so also. A still-born child is assumed to be at full time if one of those epiphyses is present.

The epiphyseal centres of *long bones* appear during **Infancy** and **Childhood**. A notable **exception** is the collar bone, which has an epiphysis only at its medial end, and the centre for that does not appear till the eighteenth or twentieth year. That epiphysis joins not later than 25. Its presence is useful for determining the age at death of a body found in a state of decomposition. If it is present, the age was not less than 18 and not more than 25.

In any one long bone the epiphyseal centres do not appear at the same time: weeks, months, or even years may elapse between the appearance of its centres. Nor do the epiphyses fuse with the shaft at the same time; there may be an interval of months or years. The epiphysis whose centre appears first is the last to fuse; the fibula is an exception to that rule, for the epiphysis at its distal end fuses first, though its centre appears before that of the proximal end. The end of a bone at which the epiphyseal cartilage lasts longer is sometimes called the "growing end"

of the bone; and in those bones which, like the collar-bone, have an epiphysis at only one end, that term applies to the end that has the epiphysis. The nutrient canal of a long bone is directed towards the epiphysis which fuses first; in bones that have only one epiphysis it is directed towards the end which does not have an epiphysis.

Many epiphyseal centres do not appear till **puberty**, *e.g.* most of those of the *hip bone* and of the *shoulder blade*, those of the *ribs* and of the *vertebræ*. The most important of the epiphyses of a vertebra are those which are formed in the hyaline cartilage covering the upper and lower surfaces of its body. In lower animals those epiphyses are thin plates; in Man they are flattened rings. Those ring-like epiphyses do not fuse with the body of the vertebra till the full adult stage is reached at the 25th year or later; the back, therefore, goes on growing for a longer time than the limbs, for the limb bones have usually all ceased to grow before the 25th year.

Separation of Epiphyses.—The epiphyseal plates of cartilage in long bones are not flat discs. If that was the case the epiphyses would be knocked off too easily, especially as the growing years of life are the most active and careless. The cartilages and the opposed surfaces of diaphyses and epiphyses have pronounced elevations and depressions which fit into one another, so that the bones can withstand knocks and jars and twists. None the less, an epiphysis sometimes is broken off. When a limb of an adult is subjected to great violence, a bone may be broken or put out of joint. Either accident may befall a boy or girl too, but while the bones are growing there is an added danger: an epiphysis may break away. When that happens, the epiphyseal cartilage is often so much injured that the bone ceases to grow at that end after diaphysis and epiphysis have reunited. When a bone is broken near one end in a young person, it may be either an ordinary fracture or a separation of the epiphysis. It is important to recognise at the outset which it is; and it is important, therefore, to remember the dates at which epiphyses usually join. Moreover, in an X-ray photograph of a young person an epiphyseal cartilage appears as a clear line which may be mistaken for a line of fracture, if it is forgotten that there is an unjoined epiphysis in the region.

Epiphyses can be seen in X-ray photographs and in museums where the skeletons of relatively young people or animals are kept. They can be seen at home also: epiphyseal plates of vertebræ can be seen in a sirloin of young beef; epiphyses of limb bones can be found in a leg of lamb.

THE SKELETON.

The human body is divided into the following parts: the **head** and **face**; the **neck**; the **trunk**, subdivided into the chest or *thorax* and the belly or *abdomen*; the two **upper limbs** or superior extremities; and the two **lower limbs** or inferior extremities. The abdomen is further divided into a larger, upper part called the *abdomen proper*, and a smaller part called the *pelvis*, situated below and behind the abdomen proper, between the two hips. The bones in the head, face, neck, and trunk are 80 in number in the adult and constitute what is called the *axial skeleton*. Excluding the small sesamoid bones, which are inconstant in number, there are 32 bones in each adult upper limb and 31 in each adult lower limb, and they constitute the *appendicular skeleton*.

The adult **axial skeleton** includes—(*a*) the backbone or vertebral column, which is made up of 26 separate bones; (*b*) the breastbone or sternum; (*c*) 12 pairs of ribs; (*d*) the skull, built up of 8 pairs of bones and 5 unpaired bones; (*e*) the lower jawbone or mandible; (*f*) the hyoid bone; and (*g*) 3 pairs of tympanic ossicles.

The **vertebral column** is the fundamental part of the skeleton; it is common to all the great class of animals called *vertebrates*, namely, fishes, amphibians, reptiles, birds, and mammals. It is situated in the middle line of the back of the body and extends through the whole length of the neck and the trunk. The **sternum** lies in the middle line of the front of the thorax. The twelve **ribs** form the framework of the side and front and back of each half of the thorax. The **skull** is the skeleton of the head and the upper part of the face, while the **mandible** supports the lower part of the face. The **hyoid bone** lies in the front of the neck, below the mandible and the tongue. The **tympanic ossicles** are little bones situated in the drum of the ear or tympanic cavity.

The bones of the **appendicular skeleton** are summarised in the sections on limbs.

The bones of the left forearm and hand are in the position of pronation.

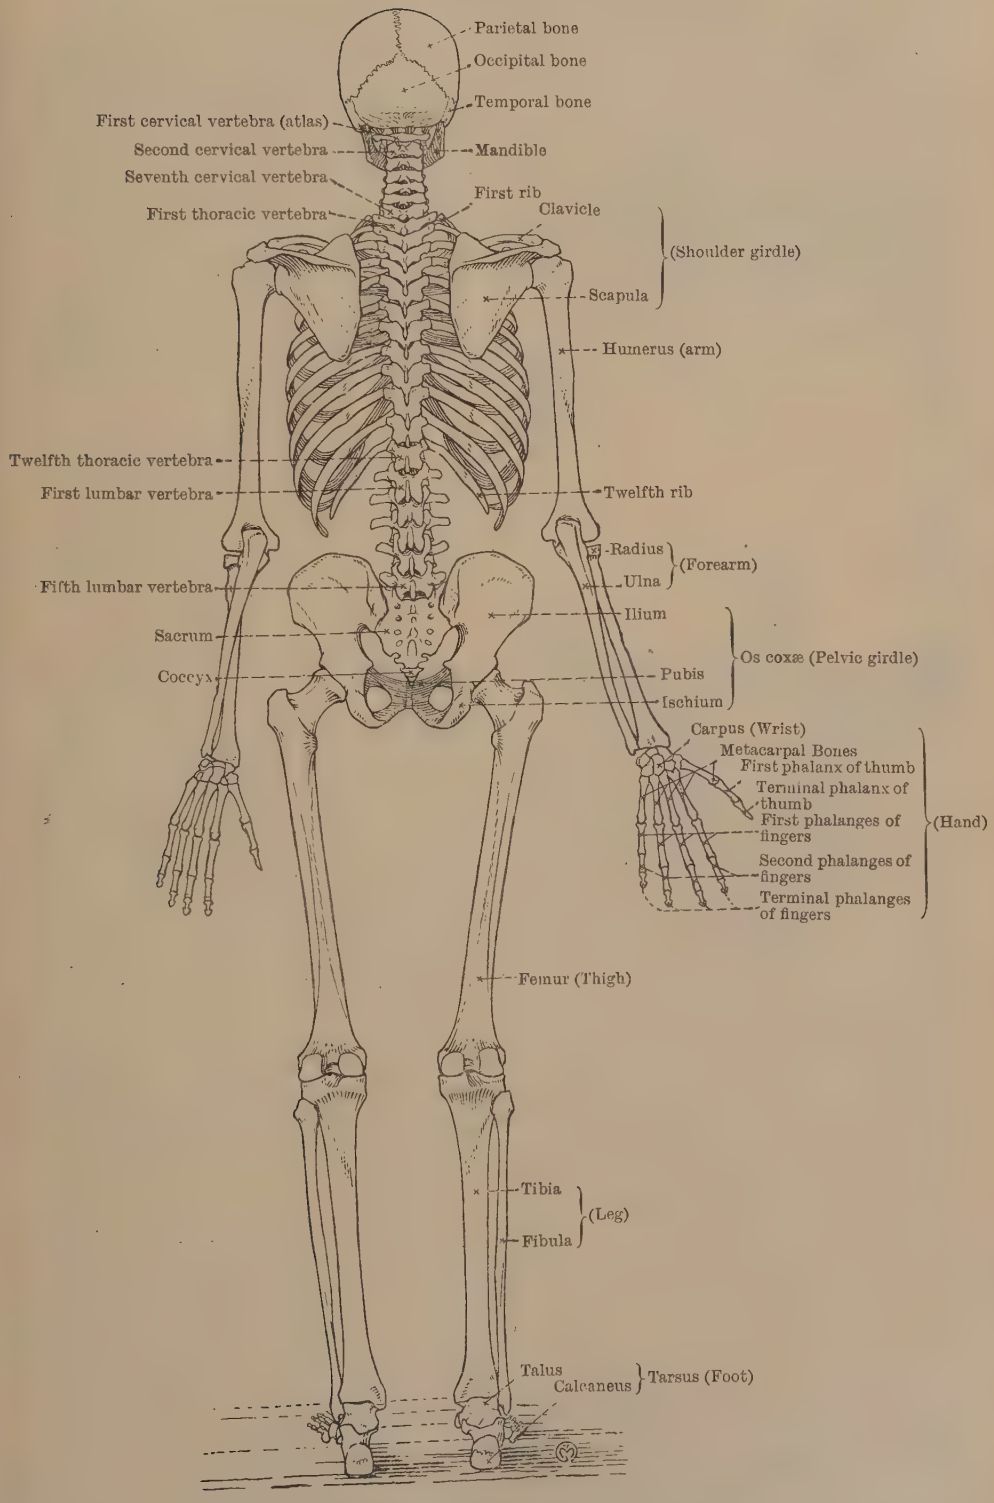

FIG. 110.—POSTERIOR VIEW OF THE SKELETON OF A MALE.
The bones of the left forearm are in the position of pronation.

COLUMNA VERTEBRALIS.

The **vertebral column** or backbone is a long, curved pillar (Fig. 120) composed of a number of segments, called **vertebræ**, which are placed in a series one above the other, and are connected together by fibro-cartilages and ligaments. The bulky part of each vertebra is its anterior part and is called its *body* (Fig. 111). The most posterior part of a vertebra is a projection called its spine or *spinous process*, whence arose the names "spine" and "spinal column" used as synonyms for backbone. The spines can be felt in the floor of the median furrow that begins at the nape of the neck and ends between the buttocks.

In the **child** there are 33 separate vertebræ, but in the **adult** vertebral column there are only 26 separate bones, for the lowest nine vertebræ are fused together to form two single bones; the upper of those two bones is called the *sacrum* and consists of 5 fused vertebræ; the lower is called the *coccyx* and consists of 4 fused vertebræ (Fig. 121). The vertebræ are classified in five groups from above downwards:—

Child.		*Adult.*		
Cervical vertebræ	7	Cervical vertebræ	7	True or movable vertebræ
Thoracic ,,	12	Thoracic ,,	12	
Lumbar ,,	5	Lumbar ,,	5	
Sacral ,,	5	Sacrum	1 = 5	False or fixed vertebræ
Coccygeal ,,	4	Coccyx	1 = 4	
	33		26	

The **cervical vertebræ** constitute the bony axis of the *neck*, and form a very flexible part of the vertebral column [*cervix* = neck]. The **thoracic vertebræ** lie in the posterior wall of the *chest* and the 12 pairs of ribs are attached to them [θώραξ (thōrax) = a cuirass]. The **lumbar vertebræ** lie in the *loins* or "small of the back" [*lumbus* = the loin]; they are the only bones that belong exclusively to the *abdomen proper*, which is less supported by the skeleton than any other part of the body. The **sacrum** lies in the dorsal wall of the *pelvis* in the hollow between the upper part of the hips, and between the two hip bones, to which it is firmly attached by strong fibrous bands or ligaments [*os sacrum*, a sacrificial bone in ancient times]. The **coccyx** or os coccygis has a fancied resemblance to the bill of a bird [κόκκυξ (coccyx) = a cuckoo]. It forms the lower end of the vertebral column and lies below the sacrum in the dorsal wall of the *pelvis*, in the floor of the groove between the buttocks just above the *anus* or opening of the bowel.

Vertebræ belong to the class of *irregular* bones. Most of them have characters in common, but the vertebræ of each group have also special characters by which they can be distinguished from those of the other groups; and while each vertebra has the distinctive characters of its own group, many of them have their own special features by which they can individually be recognised at a glance.

A Typical Vertebra (Fig. 111).—It is usual to select a vertebra from the *middle* of the *thoracic* region as a type. The beginner can pick out a thoracic vertebra from among the others because it has articular *facets* on the sides of the body; none but a thoracic vertebra has those facets; and those in the middle of the thoracic region have long spines. The main parts of a vertebra are a *body* and an *arch*; they enclose a large hole called the *vertebral foramen*; and various processes project from the arch, namely, the *spinous process*, a pair of *transverse processes*, and two pairs of *articular processes*—a superior pair and an inferior.

The **body** is the bulky, anterior part. The **vertebral foramen**, situated behind the body, is large enough to admit a finger; when the vertebræ are in column the series of vertebral foramina makes a long tunnel, called the *vertebral canal*, for the lodgment of the spinal medulla (spinal cord). The **vertebral arch** consists of four essential parts which bear the seven processes named above. The essential parts are a right and a left *root of the arch* or *pedicle* at the sides of the foramen, and a right and a left *lamina* at the back of the foramen; the two laminæ fuse together

in the median plane. When the vertebræ are in column there is, on each side, a row of holes, called the *intervertebral foramina*, between the pedicles; a spinal nerve passes through each intervertebral foramen. The **spinous process** or **spine** projects backwards and downwards from the junction of the two laminæ; its downward slant enables the beginner to distinguish the upper part of the vertebra from the lower; the tip of the spine is the only part of a vertebra that is *easily* felt in the living person, and owing to the slope it is at the level of the body next below. The other processes are at the junction of the pedicles with the laminæ; the **transverse processes** are the large projections that jut out from the sides of the arch; **superior articular processes** project upwards from the side of the arch; the **inferior** pair project downwards and articulate with the superior pair of the vertebra next below; in the thoracic vertebræ they are less distinct than the superior pair, and are on the lamina rather than at the junction of the lamina and pedicle.

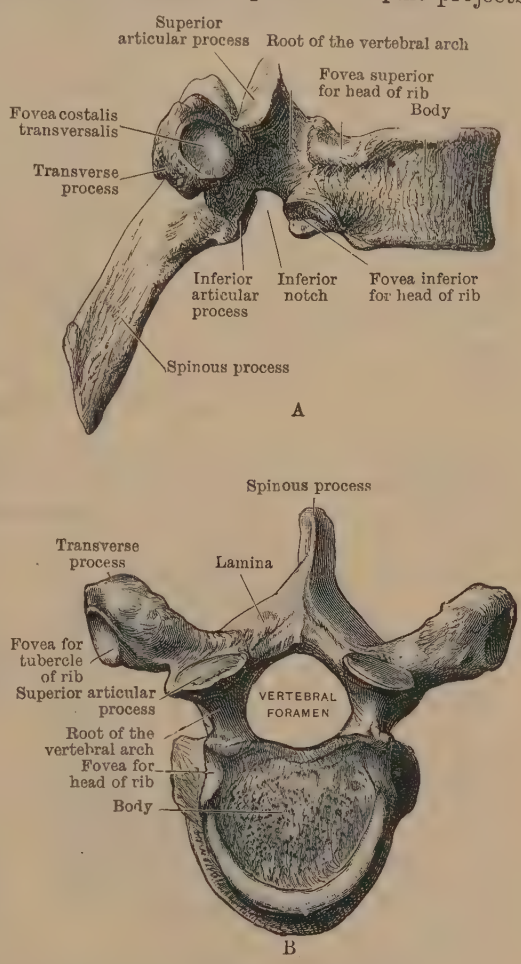

FIG. 111.—FIFTH THORACIC VERTEBRA, (A) as viewed from the right side, (B) as viewed from above.

The **body** has an *upper* and a *lower* surface; a *posterior* surface, forming the anterior boundary of the vertebral foramen; an *anterior* surface, merging into the *right* and *left* sides, so that the three form a continuous surface which is highly convex from side to side, and slightly concave from above downwards. The upper and lower surfaces are separated from and attached to the bodies of the vertebræ immediately above and below by thick plates of *fibro-cartilage*; and two long fibrous ribbons, called the *anterior* and *posterior longitudinal ligaments*, lie on the front and the back of the bodies, and are attached to them and to the fibro-cartilages throughout the series of movable vertebræ. **Nutrient foramina** are present here and there on the front, the sides, and the back; the largest is on the back and transmits a vein.

The **roots** or **pedicles** of the arch project backwards from the back of the body and are continuous with the laminæ posteriorly. The upper and lower borders of each root are slightly concave, forming the floors of notches called the **superior** and **inferior vertebral notches**; in the thoracic and lumbar regions the superior notch is very shallow, for the pedicle springs from the upper part of the body. The pedicles are the only parts of two contiguous vertebræ that are not united by ligaments; they are separated by the **intervertebral foramen**, which is bounded *above* and *below* by the vertebral notches, *posteriorly* by the articular processes of the two vertebræ, *anteriorly* by the upper of the two bodies in the thoracic and lumbar regions and by both bodies in the cervical region. When the vertebræ are in column there is a linear series of intervertebral foramina on each side, through which the spinal nerves and vessels pass on their way from and to the spinal medulla.

The **laminæ** are plates of bone which slope towards each other from the posterior ends of the pedicles and fuse together in the median plane behind the vertebral foramen. [*Lamina* = a plate, a leaf.] Their posterior surfaces are covered by and give attachment to muscles (see p. 109). Laminæ of contiguous vertebræ are united by flat fibro-elastic bands, called *ligamenta flava*, which are attached to their borders and the rough lower parts of their anterior or inner surfaces and upper parts of their outer surfaces. [*Flavus* = yellow.]

The **vertebral canal**, formed by the series of **vertebral foramina**, is bounded *anteriorly* by the bodies of the vertebræ, the fibro-cartilages, and the posterior longitudinal ligament, *posteriorly* by the laminæ and the ligamenta flava, *at each side* by the pedicles, between which are the intervertebral foramina. The canal *contains* the spinal medulla and its membranes, the roots of

the spinal nerves, vessels supplying the spinal medulla and the vertebræ, and a quantity of loose fat.

The **spines** of the vertebræ are united by fibrous bands called *interspinous ligaments*, which lie in the interval between each two, and *supraspinous ligaments*, which pass from tip to tip forming a continuous band from the sacrum to the neck, where they form a wide sheet called the *ligamentum nuchæ*, which is set as a median partition between the muscles of the two sides of the back of the neck, and is attached superiorly to the posterior part of the base of the skull. [*Nucha* (derivation uncertain) = the nape of the neck.] Numerous muscles are attached to the spines (see p. 109).

The **transverse processes** give attachment to numerous muscles (see p. 109), and are connected with those of the vertebræ above and below by weak fibrous bands called *intertransverse ligaments*. In the case of a typical thoracic vertebra each transverse process articulates with a rib, and has a facet on the front of its free end, and is connected to ribs by ligaments.

The **superior articular processes** have smooth articular surfaces on their posterior aspects The **inferior articular processes** are not so prominent; they are surfaces rather than processes in cervical and thoracic vertebræ, and look forwards to articulate with the superior pair of the vertebra below. The margins of the articulating surfaces give attachment to the *joint capsules*, and the non-articulating parts give attachment to muscles (see p. 109).

Vertebræ Cervicales.

Cervical vertebræ are small; their distinctive character is that each of them has three holes in it—the large **vertebral foramen** posteriorly, and a smaller hole at each side, called the **foramen transversarium** because it is partly bounded by the transverse process. The foramina transversaria form a vertical series on each side, and through the upper six of them there runs a large artery called the *vertebral*

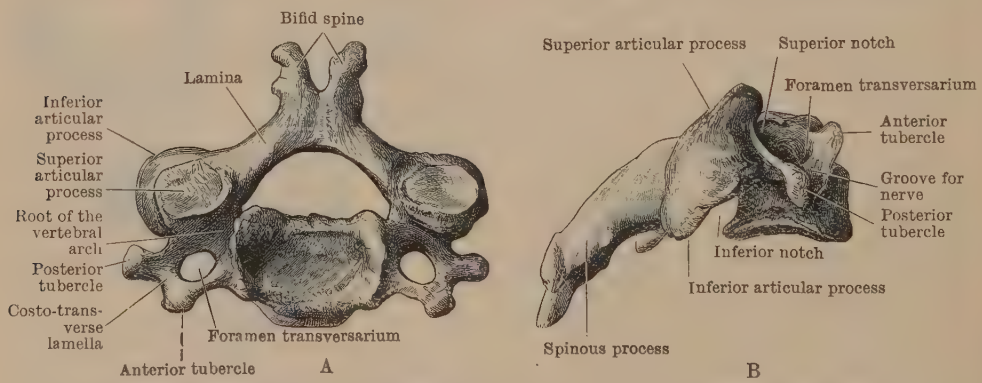

Fig. 112.—Fourth Cervical Vertebra, (A) from above, and (B) from the right side.

artery. In most cervical vertebræ the **transverse process** has two tubercles at its free end called the *anterior* and *posterior tubercles* of the transverse process. The free ends are little more than an inch from the median plane, and can be felt as an uneven bony resistance when pressure is made on the side of the neck. The lower border of the *third* vertebra is at the level of the upper border of the thyreoid cartilage—that is, the prominence in the front of the neck known as the laryngeal prominence or "Adam's apple." The *sixth* vertebra is at the level of the cricoid cartilage—that is, the rounded bar felt in the front of the neck below the thyreoid cartilage; the anterior tubercle of its transverse process is called the *carotid tubercle* because the carotid artery can be compressed against it.

The first, the second, and the seventh cervical vertebræ have special characters, but the other four are very much alike and are regarded as typical vertebræ.

A Typical Cervical Vertebra.—The **body** is small and is elongated transversely. It is lipped up at the sides on the upper surface and correspondingly bevelled off on the lower surface; between the lip and the bevel of contiguous vertebræ there is a small diarthrodial joint at the side of the fibro-cartilage. The posterior surface is flat. The lower part of the anterior surface juts downwards and overlaps the fibro-cartilage below; the upper part of the surface may be slightly bevelled.

The **vertebral foramen** is triangular in outline, with the angles rounded off; and it is large in order that the spinal medulla shall not be compressed in the movements of the neck, and also

because the medulla is thicker in the neck than lower down.] The **roots** of the arch are short and rounded, and project laterally and backwards; the superior and inferior **vertebral notches** are nearly equal in depth. The **laminæ** are thin and sloping; compared with laminæ in other regions, they are long in their horizontal measurement, and narrow from above downwards.

The **spine** is short, compressed from above downwards and bifid at its free end, and it overlaps the spine below. The articular surfaces of the **articular processes** are nearly flat; the upper pair look backwards and upwards; the lower pair look in the opposite direction. The **transverse processes** are short and inclined slightly downwards and forwards. Each has two distinct parts or roots—an anterior and a posterior. The *anterior root* corresponds to a rib and is sometimes called the *costal process*; it springs from the side of the body and ends laterally as the *anterior tubercle*. The *posterior root* is the true transverse process; it springs from the arch at the junction of pedicle and lamina, and ends laterally as the *posterior tubercle*, which is farther from the median plane than the anterior tubercle. Near their free ends the lower margins of the two roots are united by a curved bar of bone called the *costo-transverse lamella*. The **foramen transversarium** is bounded by the side of the body, the pedicle, the two roots of the transverse process and the costo-transverse lamella; in some vertebræ it is divided into two by a spicule of bone; it transmits the vertebral artery surrounded by a network of veins and a network or plexus of delicate sympathetic nerves derived from the inferior cervical ganglion. The cervical nerves, on emerging from the intervertebral foramina, lie behind the vertebral artery, where each one divides into an anterior and a posterior ramus; the posterior ramus turns backwards above the posterior root of the transverse process; the anterior ramus proceeds in a lateral direction and lies on the costo-transverse lamella.

The **Atlas** or **first cervical vertebra** is a ring of bone. It has no body and no spine. The two bulkier parts of it are called the **lateral masses**; they are united by two curved bars of bone called the **anterior arch** and the **posterior arch**, of which the posterior is much the longer. **Transverse processes**, enclosing **foramina transversaria**, project laterally from the lateral masses; they are further apart than the transverse processes of other cervical vertebræ; the tip of each is an inch and a half from the median plane, and is the bone felt by the finger pressed into the hollow below the ear. The lateral masses rest upon the second cervical vertebra, and they support the skull —hence the name "Atlas." Their upper and lower surfaces are readily distinguished, for the facets on their *lower* surfaces are fairly flat, while the facets on their *upper* surfaces are elongated and concave. The upper facets articulate with the occipital condyles at the sides of the foramen magnum—that is, with the smooth articular bosses at the sides of the large hole on the base of the skull.

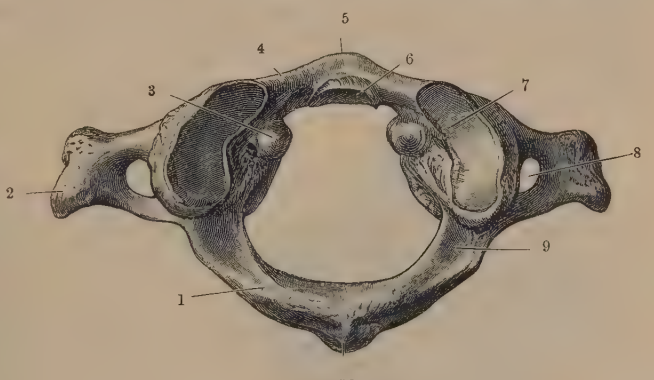

FIG. 113.—THE ATLAS FROM ABOVE.

1. Posterior arch.
2. Transverse process.
3. Tubercle for transverse ligament.
4. Anterior arch.
5. Anterior tubercle.
6. Surface for articulation with dens.
7. Superior articular surface.
8. Foramen for vertebral artery.
9. Groove for vertebral artery.
10. Posterior tubercle.

The **anterior arch** is short and is compressed from before backwards. On its posterior surface there is a facet for articulation with a part of the second vertebra called the dens or odontoid process. On its anterior surface there is a smooth eminence, called the **anterior tubercle** of the atlas, which gives insertion to the upper ends of the longus colli muscles. A continuation of the anterior longitudinal ligament is attached to the *lower margin* of the arch. A fibrous sheet, called the anterior atlanto-occipital membrane, stretches upwards from the *upper margin* to the anterior margin of the foramen magnum.

The **posterior arch** springs on each side from the back of the lateral mass and the posterior root of the transverse process. On the middle of its posterior surface there is a small projection, called the **posterior tubercle** of the atlas, which corresponds to a spinous process, and gives origin to a pair of small muscles named the recti capitis posteriores minores. On the *upper surface* of the arch, close to each lateral mass, there is a broad, oblique groove in which the vertebral artery lies, as it runs from the first foramen transversarium to the foramen magnum, and the first cervical nerve lies in the groove below the artery. The remainder of the upper surface or border gives

attachment to a thin fibrous sheet, called the posterior atlanto-occipital membrane, which stretches upwards to the posterior margin of the foramen magnum and also upwards and laterally to fuse with the capsule of the joint between the lateral mass and the skull; the infero-lateral margin of the membrane therefore bridges across the groove for the vertebral artery, and is sometimes ossified, converting the groove into a foramen. The *lower margin* of the arch is connected with the laminæ of the second vertebra by ligamenta flava.

The **transverse processes** are larger than those of other cervical vertebræ, and the *tubercles* are usually fused together. Each process gives origin to the following muscles—the rectus capitis lateralis, the obliquus capitis superior and a slip of the levator scapulæ, and insertion to the obliquus capitis inferior and a slip of the splenius cervicis.

The *lower surface* of each **lateral mass** is oblique, nearly flat, and nearly circular, and articulates with the second cervical vertebra. The *upper surface* articulates with the occipital condyle. The articular facet is oblong, concave, and set obliquely so that it slopes downwards and medially, and its anterior end is nearer the median plane than the posterior; it is often notched at the sides and may be divided into two parts. The capsules of the joints are attached to the margins of the upper and lower articular surfaces. The *posterior surface* is connected with the posterior arch. The *anterior surface* blends medially with the anterior arch, and laterally it gives origin to the rectus capitis anterior muscle. The transverse process springs by two roots from the *lateral surface*. The *medial surface* is rough and uneven, and has a small round *tubercle* for the attachment of a fibrous band, called the *transverse ligament* of the atlas, which stretches from one lateral mass to the other, across the back of the dens of the second vertebra, and keeps the dens in place against the anterior arch. The large hole surrounded by the lateral masses and the arches is divided by the transverse ligament into two parts—an anterior, which holds the dens, and a posterior, which is the vertebral foramen and contains the spinal medulla and its membranes.

The **epistropheus** or **second cervical vertebra** is easily distinguished. A thick process called the **dens** stands up from the upper surface of the body. The

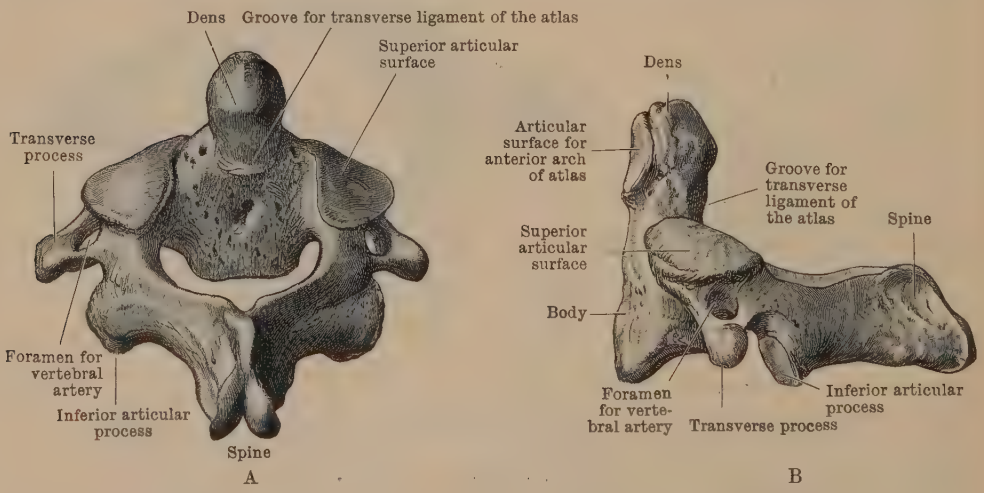

Fig. 114.—Epistropheus (O. T. Axis), (A) from behind and above, (B) from the left side.

spine is very thick compared with other cervical spines; it can be felt two or three inches below the *external occipital protuberance, i.e.*, the knob in the middle line where the back of the head joins the back of the neck; the spine is the first bony resistance encountered by the finger as it is drawn downwards from the protuberance.

The **second cervical vertebra**, when looked at from the front, is relatively very long in its vertical measurement, because of the upstanding dens and because the lower part of the front of the body juts downwards very considerably. The **dens** or **odontoid process** [ὀδούς (odous, *genitive* odontos) = dens = a tooth] is really the body of the atlas fused with the body of the second vertebra. When the first two vertebræ are fitted together properly the dens lies in the anterior compartment of the ring of the atlas; its anterior surface is smooth for articulation with the back of the anterior arch of the atlas and its posterior surface also is smooth for contact with the transverse ligament. The top of the dens is pointed. A weak band of fibres, called the ligamentum apicis dentis or *suspensory ligament*, stretches from the apex to the anterior margin of the foramen magnum; and a strong band of fibres, called the alar or *check ligament*, stretches from each side of the apex to a tubercle on the side of the foramen magnum. When the head and face are turned from side to side, the atlas, carrying the skull, pivots round the dens, and the movement is prevented from going too far by the alar or check ligaments. Since the dens is

the pivot round which the head turns, the second vertebra is given the convenient name of *axis*, and also the unwieldy name of *epistropheus* [ἐπί (epi) = upon ; στρέφω (strephō) = turn].

The **inferior vertebral notches** are deep ; the **superior** are absent ; the **laminæ** are thick. The **spine** is broad and thick, deeply grooved on its lower surface and keeled on its upper surface ; it gives attachment to several muscles (p. 109), the most important of which are the rectus capitis posterior major and obliquus capitis inferior arising from it, and a great part of semispinalis cervicis inserted into it. The **transverse processes** are the smallest of the series ; the *anterior root* is inclined backwards and the *anterior tubercle* is absent. The **foramen transversarium** is directed laterally as well as upwards, because the transverse process of the atlas is more laterally placed. The **inferior articular surfaces** are situated on typical *articular processes*. The **superior articular surfaces** are not situated on processes at the junction of the roots of the arch and the laminæ, but are placed on the body and the roots ; they articulate with the lower surfaces of the lateral masses of the atlas, and through them the weight of the head is transmitted from the lateral masses to the bodies of the vertebræ below. The joints between them and the lateral masses of the atlas, and also those between the lateral masses and the occipital condyles correspond not to the joints between typical articular processes, but to the small joints between the bodies of the cervical vertebræ at the sides of the fibro-cartilages ; therefore the first and second cervical nerves issue behind the joints connecting the atlas with the skull and with the second vertebra, while other spinal nerves issue through the intervertebral foramina in front of the joints formed by the articular processes.

The **seventh cervical vertebra** is distinguished from the others because its **spine** is long, and is not bifid, but is thickened at its free end ; the end of the spine is the upper of the two prominences at the root of the back of the neck, and on that account the seventh vertebra is called the *vertebra prominens*. The *posterior root* of the **transverse process** is large, the *anterior root* is small and the *anterior tubercle* is often absent, but in some rare cases the anterior root is large and separate, forming a **cervical rib**. The **foramen transversarium** is usually small, for it does not transmit the vertebral artery ; on one or both sides it may be double ; a small vein goes through it sometimes.

Vertebræ Thoracales.

Thoracic vertebræ are of medium size, and increase in size from above downwards ; their distinctive character is that they all have facets or foveæ on their sides for articulation with the heads of ribs (see Figs. 111 and 115). The **body** of each of the upper eight articulates with two pairs of ribs—the pair with which it corresponds numerically and the pair below ; for example, the body of the **first** articulates with the heads of the *first* pair of ribs and the upper part of the *second* pair ; the **second** body with the lower part of the heads of the *second* pair and upper part of the *third* pair ; and so on to the **eighth** body, which articulates with part of the *eighth* pair of ribs and part of the *ninth* pair. The bodies of the lower four articulate only with the ribs with which they correspond numerically. The upper ten have a facet or fovea on each **transverse process** for articulation with the tubercles of the ribs (see Fig. 128) with which they correspond numerically. The lower two do not have facets on the transverse processes. The thoracic transverse processes are thick, their posterior surfaces lie under cover of the muscles of the back, and their tips are a little more than one inch from the median plane. The **spines** are long and sloping, especially in the middle of the series, where the slope is so steep that the spine is almost vertical, and therefore one can say at once whether a given vertebra is from the middle of the series or not. In the upper and lower vertebræ the spines are shorter and slant very little in comparison ; and the lower can be distinguished from the upper by the large size of the bodies. The spine of the *first* thoracic vertebra forms the lower of the two knobs felt at the root of the back of the neck. The spine of the *third* is on a level with the point where the spine of the scapula joins the vertebral border, and that point is easily found in the living body. The spine of the *seventh* is on a level with the inferior angle of the scapula (Figs. 110, 132).

The first two thoracic vertebræ and the lower four have special characters by which they can be distinguished individually ; the other six belong to a common type ; but when the whole series in hand are from the same skeleton they are easily placed in their proper order, if the gradual changes in appearance are noted and experiments are made in fitting them together.

A Typical Thoracic Vertebra (Fig. 111).—The *upper* and *lower surfaces* of the **body** are almost flat, and are somewhat heart-shaped in outline. The *posterior surface* is slightly concave from side to side; it is slightly deeper than the *anterior surface*, and therefore from fœtal life onwards the thoracic part of the backbone is curved with the concavity forwards. There are two unequal *facets* on each side of the body, set far back, the larger one at the upper border and the smaller at the lower border. The lower facet of one vertebra is just above the upper facet of the vertebra next below; the two facets, together with the side of the fibro-cartilage between the bodies, make a socket for the head of the rib that corresponds numerically with the lower of the two vertebræ.

10. Facet for tubercle of IXth rib.
11. Facet for tubercle of Xth rib, in this particular instance well marked.

S. Superior, I. Inferior, E. Lateral — Tubercles corresponding to — Mamillary. Accessory. Transverse of lumbar.

The **pedicle** or **root** of the vertebral arch is compressed from side to side, and is inclined upwards. It springs from the body nearer the upper border than the lower, and, therefore, the **superior vertebral notch** is very shallow, while the **inferior** is deep. The **laminæ** are deep and overlap the laminæ below; overlapping of laminæ is called *imbrication* [*imbrex* = a tile]. The **vertebral foramen** is circular and is smaller than in the cervical or lumbar regions.

The **spine** is long, slender, and three-sided, and its free end is slightly thickened; it slopes so as to overlap the spine below. The **transverse processes** are long, thick, and rounded, and are inclined backwards and upwards. The free end of each is clubbed, and bears on its anterior aspect a *facet* for articulation with the tubercle of the rib of corresponding number; the process is connected with that rib by a joint capsule and by two bands called the ligament of the tubercle and ligament of the neck of the rib, and it is connected with the neck of the rib below by a flat band called the anterior costo-transverse ligament. The *superior articular surfaces* are flat, and look backwards and slightly upwards and laterally; they are situated on distinct **articular processes**. The *inferior articular surfaces* are situated partly on the lower parts of the laminæ near the pedicles, and partly on short **articular processes** that jut downwards from the laminæ; their direction is the opposite of that of the superior surfaces.

The *body* of the **first thoracic vertebra** resembles that of a lower cervical vertebra in general outline, and the facets on the sides of the body differ from those of a typical vertebra. It has a complete full-sized facet on each side, near the upper border, for the whole of the head of the first rib, and a small facet at the lower border for the upper part of the head of the second rib.

The **second** often closely resembles the first, but the large facet at the upper border is not quite complete.

The **ninth** has only one facet on the body; it is at the upper border and is incomplete; it is for articulation with the lower part of the head of the ninth rib. There may be a small facet at the lower border also, in which case the ninth would be a typical vertebra, and the tenth would resemble a ninth. Occasionally, the facet on the ninth is complete; in that case the eighth would resemble a ninth, and the ninth would not be readily distinguished from a tenth unless it was known that they both belonged to the same skeleton.

The **tenth, eleventh,** and **twelfth** have *large bodies* resembling those of lumbar vertebræ, and each of them has only one facet on each side of the body. The facet is large and complete, and is situated on the root of the arch as well as on the body; it is for articulation with the head of the rib of corresponding number. The facet on the *tenth* is near the upper border, while that on the *eleventh* is lower down; the tenth has a facet on the transverse process, and the eleventh does not; therefore, those two can usually be distinguished, though it is not always easy when they are from different skeletons. The **twelfth** is easily identified. Its *transverse processes* are short, and broken up into three tubercles. The articular surfaces of the *inferior articular processes* look in a lateral direction, while in other thoracic vertebræ they look forwards. In some skeletons the inferior articular processes of the eleventh resemble those of the twelfth, but the transverse processes of the eleventh are not broken up.

Vertebræ Lumbales.

Lumbar vertebræ are large. Their *large size* distinguishes them at a glance from cervical vertebræ and most thoracic vertebræ; the *thin transverse processes* and *hatchet-shaped spine* distinguish them (all except the fifth) from the bulky lower thoracic vertebræ. The negative distinctive characters common to all lumbar vertebræ are the *absence* of a foramen in the transverse process and the *absence* of facets for ribs.

The **bodies** are about an inch in depth; they are almost two inches wide at their widest part, and therefore structures that lie alongside the bodies are about an inch from the median plane; and the tips of the **transverse processes** are rather more than an inch and a half from the median plane. The **umbilicus** is opposite the fibro-cartilage between the bodies of the *third* and *fourth*. The *fourth* is on a level with the *highest* part of the **iliac crest** (Fig. 109), and the *fifth* is on a level with the *tubercle* of the **iliac crest.** The **laminæ** droop considerably below the level of the pedicles, so

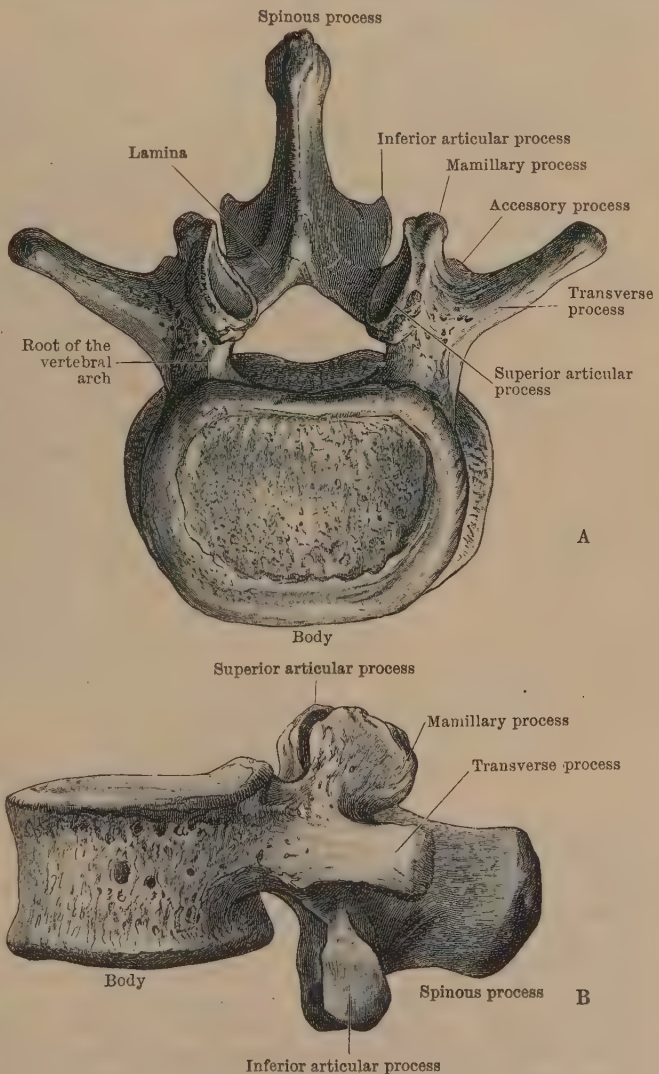

FIG. 116.—THIRD LUMBAR VERTEBRA, (A) from above, and (B) from the left side.

that though the spine is nearly horizontal its posterior edge is on a level with the lower part of the body of its own vertebra and the upper part of the body next below. The laminæ do not overlap (Fig. 132); there is an interval between the spines and laminæ of two contiguous lumbar vertebræ through which an instrument can be passed into the vertebral canal in a living person, the operation being called *lumbar puncture*. Lumbar vertebræ measure about three inches from the edge of the spine to the front of the body, and therefore account for a large proportion of the antero-posterior diameter of the trunk about the level of the umbilicus.

The fifth lumbar vertebra has distinguishing features of its own; the others belong to a common type.

A Typical Lumbar Vertebræ.—The **body** is large; its *upper* and *lower surfaces* are nearly flat and are somewhat kidney-shaped in outline; the *posterior surface* is slightly concave, and, in the lower three, is less in depth than the *anterior*, in conformity with the curve of the lumbar part of the backbone, which is convex forwards; the greater part of that convexity is, however, accounted for by the fact that the intervertebral fibro-cartilages are thicker in front than behind.

The **pedicles** or **roots** of the arch are horizontal and are compressed sideways; they spring from the upper part of the body, and therefore the **superior vertebral notches** are shallow, the **inferior** are deep. The **laminæ** are thick and uneven; they droop considerably below the level of the roots, but do not imbricate. The **vertebral foramen** is triangular in outline with rounded corners; it is larger than in the thoracic region, but smaller than in the cervical region.

The **spine** is large, hatchet-shaped and almost horizontal. The **superior articular processes** are broad and uneven; their articular surface is on the medial side, is concave from before backwards and faces medially and slightly backwards. The posterior border of each process is smooth, rounded, and slightly enlarged, and is called the *mamillary process* [*mamilla* = a nipple, a teat]. The **inferior articular processes** project downwards from the lower part of the laminæ. They fit in between the superior processes of the vertebra below; therefore they are closer together than the superior pair, and the articular surfaces look in a lateral direction and are convex.

The **transverse processes** are long and thin, being compressed from before backwards, and they incline slightly backwards and upwards. In the lower vertebræ they spring from the pedicle as well as from the junction of pedicle and lamina. On the back of the root of each process there is a little tubercle called the *accessory process*. The accessory process and the mamillary process correspond to the transverse process of a thoracic vertebra; the transverse process of a lumbar vertebra is the homologue of a rib. If the last two thoracic vertebræ and the first lumbar vertebra are placed together in proper order, the transition from the thoracic transverse process to the lumbar mamillary and accessory processes can be seen. In some rare cases the transverse process of the first lumbar vertebra exists separately as a **lumbar rib.**

The **fifth lumbar vertebra** is usually the largest of the lumbar vertebræ, though its body is usually of less depth than the fourth. The front of the **body** is usually much deeper than the back. The **spine** is small and its corners are rounded off. The **transverse process** is short, thick, and conical; its root is attached not only to the junction of lamina and pedicle, but also to the side of the pedicle and even to the side of the body; a strong band called the ilio-lumbar ligament stretches from its tip to the adjoining part of the iliac crest. The **inferior articular processes** are as wide apart as the superior, or even wider, for they have to articulate with the widely separated superior articular processes of the sacrum.

Os Sacrum et Os Coccygis.

The **sacrum** is a large bone made of the five sacral vertebræ, which are fused together in order to increase the stability of the pelvis. It lies below the small of the back between the upper part of the two hips and can be felt there as an uneven bony surface; it is wedged in between the two hip bones and forms by far the greater part of the dorsal wall of the cavity of the pelvis; it is held in place by exceedingly strong ligaments. It has the form of an inverted triangle, and possesses a wide upper end or **base**, a small lower end or **apex**, right and left **borders**, a rough, uneven **dorsal surface**, and a relatively smooth **pelvic surface.**

The **pelvic surface** is concave and looks downwards and forwards; it presents a large median column of bone separated from a smaller mass on each side by a vertical series of four holes. The median column consists of the **bodies** of the five sacral vertebræ and the ossified intervertebral cartilages all fused together. The block of bone on each side is called the **lateral mass** of the sacrum. The four pairs of holes are called the **anterior sacral foramina**; the anterior rami of the upper four pairs of sacral nerves issue through them. In specimens in which the coccyx has fused with the sacrum there are five pairs of foramina.

The **base** is directed forwards and upwards. In the middle there is the upper surface of the **body** of the first sacral vertebra; its anterior border is a prominent lip called the *promontory* of the sacrum. On each side of the body there is a wide, spreading surface called the **ala** of the sacrum; it is the upper end of the lateral mass. The promontory and the smooth anterior borders of the two alæ form the posterior part of the brim of the pelvis minor. The **vertebral foramen** is the large opening behind the body and it leads into a tunnel called the *sacral canal*. The **superior articular processes** are the upstanding projections at the sides of the vertebral foramen.

The **apex** is the lower surface of the body of the fifth sacral vertebra.

Each side or **border** of the sacrum is broad above and narrow below. The broad, upper part is a sharply defined area that has some resemblance to an ear

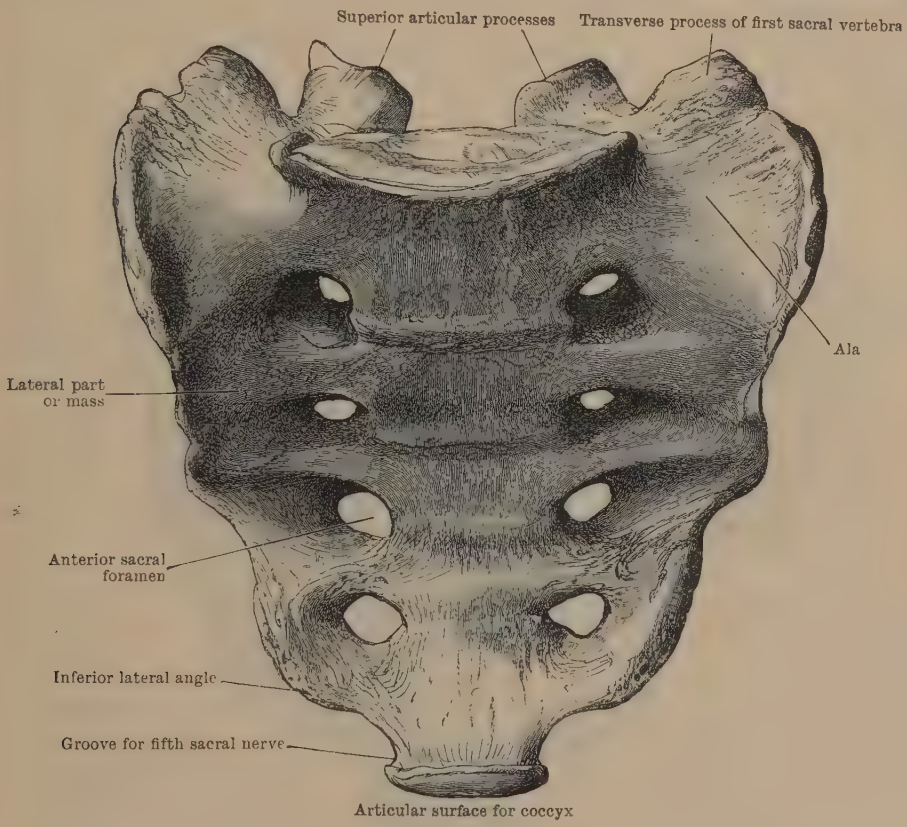

FIG. 117.—THE SACRUM (anterior view).

turned the wrong way, and is therefore called the **auricular surface**; it articulates with a corresponding auricular surface on the hip bone to form the *sacro-iliac joint*. The narrow, lower part of the border, as it is traced downwards, turns abruptly towards the body of the fifth vertebra, where it ends; the point where the change of direction takes place is called the **inferior lateral angle** of the sacrum.

The **dorsal surface** is very rough and uneven, and is convex. In the median plane there is a row of tubercles; they are the **spines** of the sacral vertebræ, and may be fused together, forming a *median crest*. About an inch lateral to the median plane there is a vertical row of four holes called the **posterior sacral foramina**; they are exactly opposite the anterior foramina, and the posterior rami of the upper four sacral nerves issue through them. The posterior parts of the vertebral arches of the lower two sacral vertebræ are absent, so that the median crest or row of spines does not reach the lower end. The lowest complete vertebral foramen is the lower end of the sacral canal; it is an oblique opening; its margins

are prolonged downwards to the fifth vertebra and end as two blunt projections called the **sacral cornua.**

The chief contents of the **sacral canal** are the roots of the sacral and coccygeal nerves, the filum terminale and the lowest parts of the dura mater and the arachnoid. The lower end of the sacral canal gives exit to the fifth pair of sacral nerves, the pair of coccygeal nerves and the filum terminale. (Dura mater and arachnoid are the names given to the outer two of the three membranes that surround the spinal medulla; they are continued downwards around the roots of the nerves as far as the second piece of the sacrum. The innermost membrane is called the pia mater; the filum terminale is a long, slender glistening thread continued downwards from the lower end of the pia mater and it ends by blending with the periosteum on the back of the coccyx.)

The **coccyx** forms the lower end of the backbone; it lies in the floor of the

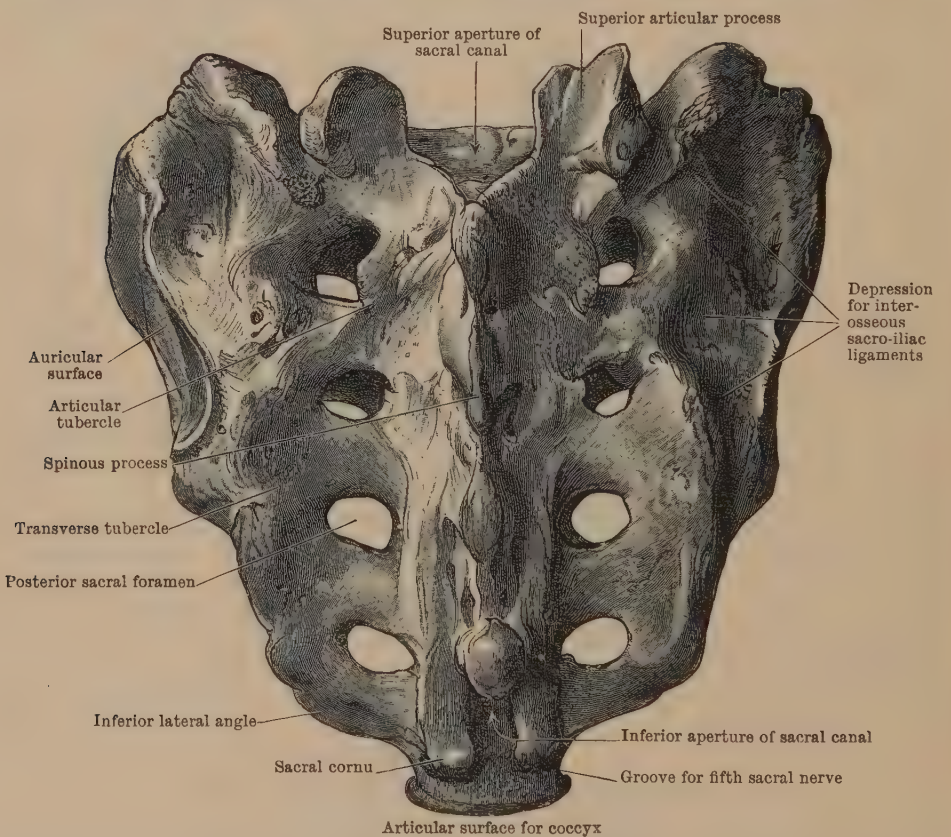

FIG. 118.—THE SACRUM (posterior view).

groove between the buttocks a little above the anus, and, at the same time, in the dorsal wall of the pelvis below the sacrum. It is composed of four small incomplete vertebræ fused together, and, like the sacrum, it is triangular in outline with the apex below. It has a base, an apex, a pelvic surface, a dorsal surface, and two sides or borders. The **first vertebra** is much the largest; its *upper surface* is the **base** of the coccyx and articulates with the apex of the sacrum; from its **dorsal surface** two processes called the coccygeal **cornua** project upwards; and from each side or border a **transverse process** juts out. The lower three vertebræ are mere nodules of bone, diminishing in size from above downwards, and the lowest one forms the apex of the coccyx. Occasionally the coccyx consists of three or of five pieces instead of four.

The **pelvic surface** of the **sacrum** is concave from above downwards, and slightly concave from side to side also, the degree of concavity varying greatly in different specimens. The fact that there are five bodies in the median column is indicated by four *transverse lines* or ridges.

The bodies diminish in size from above downwards; they are flattened from before backwards especially towards the lower end; and if a sagittal section (p. 5) is made, the remains of the fibro-cartilages are found between them. The four pairs of **anterior sacral foramina** are at the ends of the transverse lines; they also diminish in size from above downwards. Each foramen transmits the anterior ramus of a sacral nerve, a branch of a lateral sacral artery, and an accompanying vein; a short, shallow groove, in which the ramus lies, extends from the foramen on to the lateral mass. The **lateral mass** is made up of the *transverse processes* of one side all fused together. In the sacral region, as in the cervical region, a transverse process consists of a *rib element* in front and a *true transverse process* behind; the costal elements form the larger part of the lateral mass (Fig. 125), especially in the upper three segments, which articulate with the ilium.

The middle sacral artery, with a companion vein on each side, runs down the middle of the pelvic surface of the sacrum and ends on the pelvic surface of the coccyx. The sympathetic trunk runs down across the medial parts of the anterior sacral foramina and joins its fellow of the other side on the front of the coccyx. The greater part of the piriformis muscle arises from the middle three pieces of the sacrum between the anterior foramina. The rectum is closely related to the pelvic surface of the lower three pieces of the sacrum and the coccyx.

On the **base** of the sacrum the constituent parts of the first sacral vertebra may be made out fairly clearly. The upper surface of the **body**, situated in the middle anteriorly, resembles the body of the fifth lumbar vertebra in outline; it is bound to that body by the lowest intervertebral fibro-cartilage and the lower ends of the anterior and posterior longitudinal ligaments. The **vertebral foramen** is large, sloping, and triangular, and has the usual boundaries of body and **vertebral arch**. The **superior articular processes** stand up from the sides of the arch; their concave articular surfaces look medially and backwards and articulate with the inferior articular processes of the fifth lumbar vertebra, to which they are bound by articular capsules. The **laminæ** are connected with the laminæ of that vertebra by the lowest pair of ligamenta flava. The **root** of the arch or **pedicle** is the part between the superior articular process and the body; it may be marked off from the ala by a pit, or, in rare cases, by a foramen; it forms the lower boundary of the intervertebral foramen through which the fifth lumbar nerve issues, and the anterior ramus of the nerve, running downwards, forwards, and laterally from the foramen, sometimes makes a shallow groove on the ala. The **ala** is the transverse process; its posterior part is the *true transverse process* and may be marked off from the rest by a slight depression; the postero-lateral angle of the ala is the tip of the true transverse process and may be marked off from the margin in front of it by a notch. The ala is continuous with the iliac fossa of the hip bone when the bones are articulated; the lumbo-sacral ligament and some fibres of iliacus are attached to it. Its lateral margin is the upper or anterior boundary of the auricular surface.

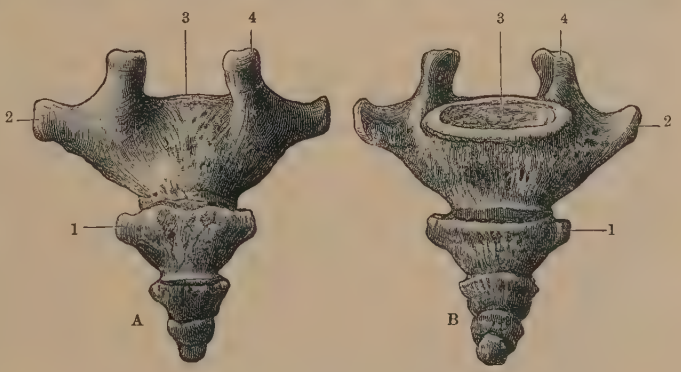

Fig. 119.—The Coccyx.

A. Posterior Surface. B. Anterior Surface.

1. Transverse process. 2. Transverse process. 3. For Sacrum. 4. Cornu.

The **apex** is the oval lower surface of the body of the fifth sacral vertebra. It is attached to the body of the first coccygeal vertebra by an intervertebral fibro-cartilage and by anterior and posterior sacro-coccygeal ligaments.

The **lateral border** is curved sinuously as it is traced downwards, for the third piece of the sacrum is rather wider than the second, and the border turns abruptly towards the body of the fifth piece. The **auricular surface** overlies the lateral aspects of the upper three pieces; it is uneven and usually rough, though it is the articulating surface at a diarthrodial joint; its inequalities fit into reverse inequalities of the auricular surface of the hip bone, so that very little movement is possible at the joint. The anterior and lower parts of the joint capsule are together called the anterior sacro-iliac ligament, which is attached to the convex margin of the auricular surface; the posterior or upper part is the interosseous sacro-iliac ligament, which is very thick and strong, and is attached to the concave margin of the surface and to the wide uneven depression behind and above it. The pelvic surface of the upper part of the sacrum is wider than the dorsal surface, and the auricular surface slopes accordingly, so that in the articulated pelvis the sacrum is the reverse of the keystone of an arch; the interosseous ligaments of the two sides are the principal factors in holding it in place.

The narrower part of the lateral border gives attachment to part of the sacro-tuberous ligament; the upper parts of the sacro-spinous ligament and coccygeus muscle are attached to the side of the fifth piece in front of the sacro-tuberous ligament; and the **inferior lateral angle** is connected with the transverse process of the coccyx by the lateral sacro-coccygeal ligament.

The **dorsal surface** is directed upwards and backwards. The row of **spines** or **median crest** varies greatly in its degree of prominence; its upper end gives attachment to a supraspinous and an interspinous ligament connecting it with the lowest lumbar spine, and the lower part of the lumbo-dorsal fascia is attached to each lip of the crest. At each side of the root of the crest there is a rough plate of bone consisting of the laminæ fused together. Lateral to that plate there are the four **posterior sacral foramina**; they diminish in size from above downwards, and each one transmits the posterior ramus of a sacral nerve, accompanied by small terminal branches of the lateral sacral vessels. At the medial margin of each foramen there is a small projection, called an **articular tubercle**, because it represents the inferior and superior articular processes of two contiguous sacral vertebræ fused together. The lowest of the series is the **sacral cornu**, which represents an inferior articular process of the fifth sacral vertebra; the two sacral cornua are connected by ligaments with the coccygeal cornua. Lateral to the posterior sacral foramina, on the back of the lateral mass, there is a row of **transverse tubercles**, representing the tips of the fused true transverse processes. The multifidus and sacrospinalis muscles are attached to the uneven surface between the tubercles and the median plane. The short posterior sacro-iliac ligament is attached to the first and second transverse tubercles (the first being the postero-lateral angle of the ala); the long posterior sacro-iliac ligament to the third tubercle; part of the sacro-tuberous ligament to the fourth and fifth; fibres of the gluteus maximus arise from the back of the sacrum, but they spring from those ligaments and the lumbo-dorsal fascia rather than from bone.

The **sacral canal** is the lowest part of the vertebral canal. It lies between the fused bodies and the fused laminæ. It is triangular above, flattened from before backwards below. On each side of it there is a series of four large apertures that correspond to **intervertebral foramina**; they transmit the upper four sacral nerves, and each one divides into two parts which end as an anterior and a posterior sacral foramen. The canal *contains* (1) a quantity of soft fat in which there lie small arteries and fairly large, thin-walled veins, (2) the roots of the sacral and coccygeal nerves, (3) the filum terminale, (4) the lower part of the spinal dura mater and arachnoid. The lower part of the posterior wall of the canal is deficient owing to the absence of the laminæ and spine of the fifth vertebra and, very often, of the fourth also. The lower opening of the canal is therefore very oblique, and is called the *hiatus sacralis*.

The coccygeal cornua correspond to pedicles and superior articular processes. In specimens in which the sacrum and coccyx are fused together the ligaments connecting the sacral and coccygeal cornua may be ossified, and so also may be the ligaments connecting the inferior lateral angles of the sacrum with the transverse processes of the coccyx; in such a case there are a *fifth pair* of intervertebral foramina and of anterior sacral foramina.

The filum terminale is attached to the back of the first piece of the **coccyx**, and a few fibres of the gluteus maximus arise from it. The lower parts of the sacro-tuberous ligament, the sacrospinous ligament, and the coccygeus muscle are attached to its margin, in that order from behind forwards. The posterior fibres of the levator ani muscle are inserted into the side of the lower pieces; the sphincter ani externus and the ano-coccygeal body—a fibrous nodule situated behind the anal canal—are attached to its apex.

Sexual Differences.—In the male the curve of the sacrum is fairly uniform and is deepest opposite the third piece. In the female the sacrum is said to be flat above and sharply bent forwards below. The female sacrum is shorter and wider, and is set more obliquely so that its pelvic surface looks more downwards than in the male. The auricular surface is borne by the first two pieces, instead of three as in the male. The coccyx is more movable in the female and less liable to be fused with the sacrum, and the first piece of the coccyx more often fails to fuse with the second piece than in the male.

VERTEBRAL COLUMN AS A WHOLE.

The **vertebral column** is about 28 inches (70 cm.) long in the male and 24 inches (60 cm.) in the female; the intervertebral fibro-cartilages account for nearly one-fourth of its length. In the male, approximate measurements for the different regions are: cervical, 5 in.; thoracic, 11 in.; lumbar, 7 in.; sacrum and coccyx, 5 in.

The vertebræ are joined together by the fibro-cartilages between the bodies and by the various ligaments that connect the body, laminæ, and processes of one vertebra with corresponding parts of its two immediate neighbours, so that the vertebræ make a strong column for the support of the trunk and neck and a pedestal for the head. It is not, however, a rigid column, but is flexible and resilient; although the vertebræ are firmly bound together, a little movement is possible between each two (with the exception of the segments of sacrum and coccyx), and the sum of the movements between each two over the whole movable part of the column is very considerable. [*Vertere* = to turn.]

The column of **bodies** is the chief axis of support; the **vertebral arches** close in the vertebral canal, in which the spinal medulla lies in safety; the **articular**

processes permit movement but also control its direction and help to limit its range; the **spines** and **transverse processes** are levers to which muscles are attached.

Curvatures.—The column is not straight. **At birth** it has two curves, both concave forwards. They are called **primary curvatures**; the lower one is formed by the sacral and coccygeal vertebræ, the upper one by all the rest of the column; the point where the two curves meet, at the junction of the last lumbar vertebra and the first sacral, is called the **sacro-vertebral angle.** **In the adult** there are four curves—cervical, thoracic, lumbar, and sacro-coccygeal.

The **cervical curvature** is convex forwards. It begins at the atlas, and, at its lower part, merges into the thoracic curve; the lower border of the second thoracic vertebra is taken as the level where the two curves meet, for that is the level of the upper border of the breast-bone, and the upper two thoracic vertebræ lie, therefore, in a sense, in the neck. The cervical curvature is the least marked of the four curves and is undone when the neck is bent forwards. It is a *secondary* or *compensatory* curve and is due chiefly to the shape of the fibro-cartilages; it begins to be formed two or three months after birth, when the child begins to lift its head up from the chest, and it becomes further developed at the eighth or ninth month when the child begins to sit upright. The **thoracic curvature** is concave forwards; it extends to the twelfth thoracic vertebra, where it merges into the lumbar curve; it is a primary curve and is due to the shape of the bodies of the vertebræ. The **lumbar curvature** is convex forwards; it is more pronounced in a woman than in a man, and in a youth than in an elderly person; it extends to the sacro-vertebral angle; it is a *secondary* or *compensatory* curve and is due chiefly to the shape of the fibro-cartilages; it begins to appear a year after birth, when the child, adopting the erect attitude, lifts up its trunk, straightens out its lower limbs and begins to walk. The **sacro-coccygeal curvature** is the original lower *primary curve* and is concave downwards and forwards.

Besides having those four curvatures the column of bodies is often slightly convex towards the right side in the thoracic region. That **lateral curvature** may be due to the greater muscularity and use of the right upper limb, for it is said to be convex towards the left in left-handed people; but much more probably it is due to the pressure that the upper part of the descending aorta exerts by its pulsations on the left side of the bodies of the middle four thoracic vertebræ, and in the rare cases in which the aorta is on the other side of those vertebræ the curve is convex towards the left. (The aorta is the great artery that springs from the heart and conveys blood to be distributed by its branches to all parts of the body.) When the lateral curvature is well marked there are compensatory curves, in the opposite direction, above and below it.

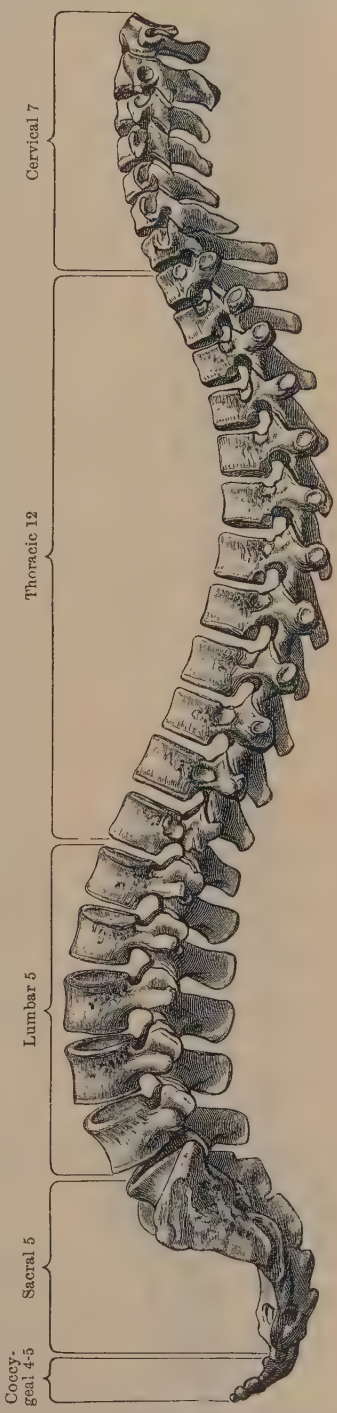

FIG. 120.—VERTEBRAL COLUMN FROM THE LEFT SIDE.

The curvatures of a line drawn along the tips of the spines are not repetitions

of the curvatures of the bodies, owing to the varying length and obliquity of the spines; and lateral curvature of the spines may be greater or lesser in degree than that of the bodies. Occasionally one or more spines may be deflected very considerably to one side without corresponding rotation of the body towards the opposite side and without any sign of past disease or of recent accident.

Curvatures of the backbone may become accentuated and distortions may occur as a result of weakness, disease, or accident. With advancing years the column loses its flexibility and resilience and becomes more or less set and rigid, especially in rheumatic people. In many skeletons evidence of rheumatism is seen in the "lipping" of the margins of the vertebræ and rough ridges and protuberances here and there.

The following points may be noted in the vertebral column:—

When viewed from the Side.—(1) The four curvatures. (2) The antero-posterior diameters of the **bodies** increase gradually down to the *second lumbar*, and then gradually diminish. (3) The **costal facets** on the sides of the bodies, from the first thoracic downwards, gradually take up a position farther back till that on the twelfth is more on the root of the arch than on the body. (4) The **intervertebral foramina** increase in size from above downwards. (5) The **transverse processes** of *cervical* and *lumbar* vertebræ are in front of the articular processes, while those of *thoracic* vertebræ are behind and have more of a backward inclination; they are between the intervertebral foramina in the *cervical* region, and behind the foramina in the *thoracic* and *lumbar* regions; the change of characters is abrupt between cervical and thoracic regions, and more gradual between thoracic and true lumbar transverse processes. (6) Owing to the direction of **articular surfaces** the clefts of the joints between articular processes are visible in the cervical and thoracic regions, but not in the lumbar region. (7) The varying length and slope of the **spines** and consequent lack of conformity of the curves of the spines and those of the bodies; the slope of the spines, though varying greatly, is always downwards, while in most lower animals the spines slope towards an "anticlinal" vertebra situated in the hinder part of the thoracic region. (8) The antero-posterior diameter of the *lumbar vertebræ* is much greater than that of the others.

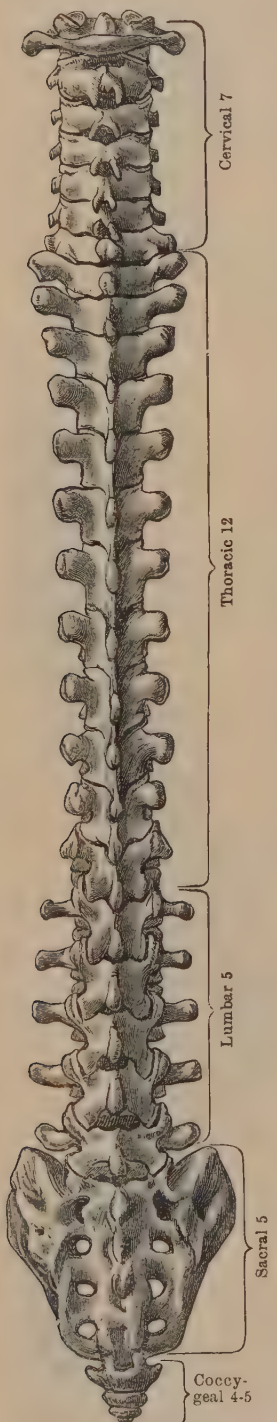

FIG. 121.—VERTEBRAL COLUMN AS SEEN FROM BEHIND.

When viewed from the Front.—(1) The lateral curvatures, when present. (2) The column is widest at the base of the sacrum; the **bodies** increase in width from the second cervical to the first thoracic and diminish slightly from the first to the fourth; they increase gradually from the fifth thoracic to the first sacral, below which there is progressive diminution in width. (3) The side-to-side convexity of the bodies is sharper in the middle thoracic region than elsewhere. (4) In the vertical diameter the body of the second cervical vertebra is deeper than those of the lower five, which are nearly equal in depth; below that there is gradual increase in depth down to the third or fourth lumbar; the fifth lumbar is usually of less depth than the other lumbar vertebræ; in different skeletons any one of the thoracic vertebræ may be of less depth than the one above it. (5) The **transverse processes** of the *atlas* are outstanding and are wider apart than the next five pairs, the tips of which are at nearly equal distances from the median plane; those of the *seventh* are almost as long as the first thoracic; they gradually diminish from the first thoracic to the twelfth, where they are mere tubercles; they are outstanding again in the lumbar region and vary in length, and though the third is usually the longest, its tip is not necessarily the furthest from the median plane, owing to the greater width of the fourth and fifth vertebræ as a whole. (6) The *sacrum* and *coccyx* rapidly diminish in width from above downwards, but there is little difference between the second and third pieces of the sacrum, and the third is usually the wider; the diminution is very sudden below the inferior lateral angle of the sacrum, and, again, below the transverse process of the coccyx.

When viewed from the Back.—(1) Differences in the lengths of the **transverse processes** as seen also from the front; in the cervical region they are hidden by the articular processes, so

that only the posterior tubercles are visible; the transition from thoracic transverse process to lumbar mamillary and accessory processes is well seen. (2) The **articular processes** of the lower six cervical vertebræ are at equal distances apart, and are wider apart than those of the thoracic vertebræ; the distance gradually diminishes from the first thoracic to the first lumbar, below which it increases; the joint clefts between articular processes are clearly visible in the lumbar region, less so in the cervical region and not at all in the thoracic region. (3) The **laminæ** overlap in the thoracic region; in the lumbar region there are intervals between them; in the cervical region they overlap very slightly when the neck is straight, but there are intervals between them when the neck is bent forwards, and there is always a fairly wide interval between the atlas and the second vertebra, and also between the atlas and the skull. (4) The different characters of the **spines** and their lateral curvatures or deflections if present. (5) The **vertebral groove** is the wide furrow alongside the spines; it is shallow in the neck and the loins, where its floor is made of the laminæ and inferior articular processes, and deep in the thoracic region, where its floor is formed of laminæ, inferior articular processes and transverse processes.

OSSIFICATION OF VERTEBRÆ.

A **typical vertebra** is ossified from three primary centres and five secondary centres. The three **primary** centres are one in the *body* and one in each half of the *vertebral arch*; the five **secondary** centres appear at the tip of the *spine*, the tips of the *transverse processes*, the upper and lower surfaces of the *body*.

The *primary centres* for the **arch** appear gradually from above downwards, appearing first in the upper cervical region about the seventh week of fœtal life and reaching the sacrum about the twentieth week. They appear at the roots of the articular processes; the arch and its processes are ossified from them, and also the postero-lateral parts of the body—the parts of the body which, in thoracic vertebræ, articulate with the ribs.

The *centre* for the median, larger part of the **body** appears dorsal to the notochord, first in the lower thoracic region about the tenth week; the process spreads up and down till by the twentieth week centres have appeared in all the bodies except in the coccyx, where they do not

appear till after birth. Occasionally there are two centres for the body which coalesce, but may fail to do so, so that in rare cases the body ossifies as two separate halves, or one half only ossifies.

At birth the vertebra consists of three pieces of bone—the median, larger part of the body and the two parts ossified from the centres for the arch. The laminæ are not osseously united; the spine is cartilaginous. The median part of the body is joined to each postero-lateral part by a plate of cartilage; the joint is called the *neuro-central synchondrosis*; the line of the joint is antero-posterior in the cervical region, oblique in the thoracic, and nearly transverse in the lumbar region (Fig. 125).

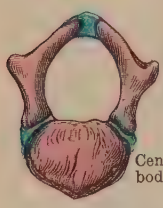

Fig. 122.—Ossification of Vertebræ.

The union of laminæ begins in the lumbar region soon after birth, and, spreading upwards, is completed in the cervical region early in the second year, but is deferred in the sacrum till between the seventh and tenth years. After fusion of the laminæ the ossifying process extends into the spine. The union of the body and arch, *i.e.* the disappearance of the neuro-central synchondrosis, begins in the neck in the third year, and spreading downwards, is completed in all regions in the sixth or seventh year.

The *secondary centres* appear at **puberty**, and the epiphyses formed from them fuse with the rest of the bone at 25. The epiphyses on the body are in the form of flat rings on the

Coccygeal . .	*none*	1st year to puberty	*none*	*none*	*none*	*none*

In many of the vertebræ the ossification departs from type.

In the **cervical region** the bifid tips of the **spines** have *two* epiphyses.

The Atlas Vertebra.—A primary centre for each half of the vertebral arch, including the lateral mass, appears at the seventh week. The two halves unite posteriorly in the third year, and their union may be preceded by a secondary centre in the cartilage between them. The anterior arch is cartilaginous at birth. One centre (sometimes two) appears in it during the first year and it fuses with the lateral masses about the seventh year. It includes the anterior part of the upper articular surface of the lateral mass. The epiphyses on the transverse processes unite about 18.

The Second Cervical Vertebra.—A primary centre for each half of the vertebral arch appears in the seventh week; one or two for the lower part of body early in the fifth month; two appear side by side for the upper part of the body and the lower part of the dens later in the fifth month, and fuse during the seventh month. *At birth* the vertebra consists of four bony pieces which unite between the third and sixth years. An epiphysis for the top of the dens appears between the third and sixth years and fuses before 12; another appears on the lower surface of the body at puberty and fuses about 25.

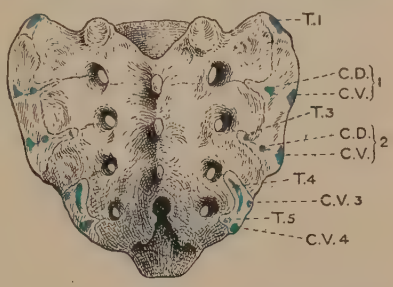

Fig. 124.—Diagram (after Fawcett) of the Arrangement of the Costal and Transverse Epiphyses at the Eighteenth Year.

T., Epiphysis of transverse process.
C.V., Ventral epiphysis of costal process.
C.D., Dorsal epiphysis.
The numbers indicate the segments to which the epiphyses belong.

The **sixth** and **seventh cervical vertebræ** may have separate primary centres in the costal processes, which join the rest of the bone about the fifth year. Sometimes in the seventh it does not join but forms a cervical rib.

Lumbar vertebræ have additional epiphyses on the *mamillary processes.*

The **first lumbar vertebra** may have a separate primary centre for its *transverse process*, which may remain separate as a **lumbar rib.**

The **fifth** may have two primary centres in each half of the arch, and the two parts of each half are united by a plate of cartilage set obliquely between the superior and inferior articular processes; its transverse process may have two epiphyses.

Sacrum.—**Primary centres** appear between the third and eighth months. One centre for each body and one for each half of the vertebral arch, and one for the costal element on each side in the case of the upper three or four vertebræ. The costal parts fuse with the arches at the fifth year. The arches fuse with the bodies a little later. The halves of the arches unite posteriorly between the seventh and tenth years. The segments of the lateral mass fuse together at puberty. **Epiphyseal centres** appear on the upper and lower surfaces of the bodies at puberty; the epiphyses fuse with the bodies and the bodies fuse together from below upwards between 18 and 25. Numerous epiphyseal centres appear on the ends of the costal and true transverse processes at 18. From them are formed an epiphysis which covers the auricular surface, and another which completes the margin below the auricular surface.

The **coccyx** is cartilaginous at birth. Each segment has one **primary** centre. They appear, from above downwards, between the first year and puberty. Fusion between segments takes place from below upwards, but is very variable. Epiphyses on the surface of the bodies and in the cornua have been described.

VARIATIONS IN VERTEBRÆ.

Variation in number is usually due to the coccygeal vertebræ being reduced to three or increased to five or even six. Variations in other regions may occur through increase or reduction or re-arrangement among the regions, so that the formula may be altered in several ways, as follows:—

Cervical . .	7	7	7	6	7	7	7
Thoracic . .	13	12	12	13	13	12	12
Lumbar . .	5	6	4	5	4	6	4
Sacral . .	5	5	5	5	5	4	6
Coccygeal . .	4	4	4	4	4	4	4

Atlas.—One or other of the arches may be incompletely ossified, or may have a facet for articulation with the margins of the foramen magnum. The foramen transversarium may be incomplete owing to absence of the anterior root of the transverse process. A bar of bone may bridge across the groove for the vertebral artery. The upper articular facet may be divided. The transverse process may be bifid; and it may articulate with an occasional projection, called the paroccipital process, that juts from the jugular process of the occipital bone. The atlas may be partially fused with the occipital bone, or with the second cervical vertebra.

Epistropheus.—The dens is sometimes a separate bone called the **os odontoideum.** Its apical part may be partially or completely detached. It may articulate with the anterior margin of the foramen magnum. A bifid or double dens has been described. The foramen transversarium may be incomplete, owing to imperfect development of the posterior root of the transverse process.

Small nodules representing ribs have been observed in one or two cases in the **fourth** and **sixth** cervical vertebræ.

The **seventh** has a cervical rib fairly often. The foramen transversarium may be absent on one side.

The **first thoracic vertebra** may have its transverse process connected with the neck of the first rib by a bar of bone; the posterior part of its vertebral arch has been found separate from the rest of the bone. The facets on the body of the **ninth** are variable. The **tenth** may have no facets on its transverse processes. The inferior articular processes of the **eleventh** may resemble those of the twelfth, on one or both sides, and the superior processes of the **twelfth** correspondingly resemble those of a lumbar vertebra.

In some cases the mamillary and accessory processes of the **lumbar vertebræ** are large, and occasionally are connected by a bridge of bone, forming a small foramen. The transverse process of the **first** is sometimes separate, forming a lumbar rib. The transverse process of the **fourth** has been observed springing from the side of the body, without connexion with the arch. A foramen has been observed in the transverse process of the **fifth.** The posterior part of the vertebral arch of the fifth, comprising the spine, the laminæ, and inferior articular processes, is occasionally separate from the rest of the bone, union during life being effected by synchondroses; the same condition has been seen in the fourth. The fifth may be fused with the sacrum partly or wholly, and may have pronounced sacral characters on one or both sides.

The **sacrum** may have six vertebræ, owing most often to inclusion of the first coccygeal, but occasionally to inclusion of the fifth lumbar. More seldom there are only four vertebræ; sometimes the first sacral is not united, or is only partially united, to the second, and it may resemble a lumbar vertebra on the un-united side. The posterior wall of the **sacral canal** is usually defective at its lower end, but may be defective in its whole length. A foramen may be present in the lateral part of the first sacral vertebra, between the pedicle and the costal element. The degree of curvature varies greatly in different specimens.

The **coccyx** varies in its number of segments and the extent to which they are fused together. The second piece may have rudimentary transverse processes and pedicles.

SERIAL HOMOLOGIES OF VERTEBRÆ.

The **body** is the only part which is present in the case of every vertebra from the first cervical to the last coccygeal. The homology of the bodies is manifest throughout the series, except that the median part of the body of the first cervical is detached from its own vertebra and fused with the second, forming the dens or odontoid process. The lateral parts of the body of the atlas, *i.e.* the parts which in other vertebræ are ossified from the vertebral arch, form the anterior, larger parts of the lateral masses. The anterior arch of the atlas does not correspond to the front of the body of a vertebra, but is ossified from a persistent "hypochordal bow," which disappears in the case of other vertebræ (p. 123).

The **vertebral arches** are incomplete below the third and fourth sacral, and wholly absent from the third and fourth coccygeal segments. Their homology is equally obvious, but the **pedicle** of the atlas is obscured in the posterior part of the lateral mass; the roots of the coccygeal cornua are pedicles, and there may be rudiments of pedicles on the back of the second piece of the coccyx. The **laminæ**, including the posterior arch of the atlas, are complete down to the third sacral; those of the fourth sacral may or may not be complete; those of the fifth are usually unossified; and they are quite unrepresented in the coccyx.

The **spine** of the atlas is represented by the tubercle on the posterior arch. Spines are absent below the level of the third sacral vertebra.

The **articular processes** of the atlas and the superior articular processes of the second cervical vertebra are absent; the articular surfaces of the lateral masses of the atlas and the upper articular surfaces of the second vertebra are not homologous with articular processes, but with the very small articular areas on the lateral parts of the bodies of the other cervical vertebræ. The superior articular processes of the first sacral vertebra function as ordinary articular processes; the other sacral articular processes are fused together to form the row of articular tubercles on the back of the sacrum, except the inferior articular processes of the fifth piece, which jut downwards as the sacral cornua. The upper parts of the coccygeal cornua are homologous with superior articular processes; they are absent from the other coccygeal segments.

The **transverse processes** are present in the whole series down to and including the first coccygeal vertebra; but their homologies are less obvious. The transverse processes of the **thoracic** vertebræ are taken as the type and standard. In a **cervical** vertebra the true transverse process is represented by the posterior root and posterior tubercle of the transverse process; the anterior root and tubercle are the homologue of a rib; the costo-transverse lamella corresponds to the joint between a transverse process and a tubercle of a rib; the foramen transversarium is homologous with the interval between a transverse process and the neck of a rib. In a **lumbar** vertebra the process called the transverse process is the homologue of a rib; the true transverse process is represented by the mamillary process and the posterior part of the root of the

transverse process including the accessory process. There is no interval left between the costal and true transverse elements as in the cervical and thoracic region, except in the rare instances where there is a foramen in the fifth lumbar transverse process. In the **sacrum** the lateral mass is made of the true transverse processes posteriorly, and the costal elements anteriorly, the ends of the true transverse processes forming the row of transverse tubercles on the back; each transverse tubercle represents part of the ends of two true transverse processes, for the end of each process expands, growing upwards and downwards, and unites with similar expansions of the process above and below to form the tubercles lateral to the posterior sacral foramina.

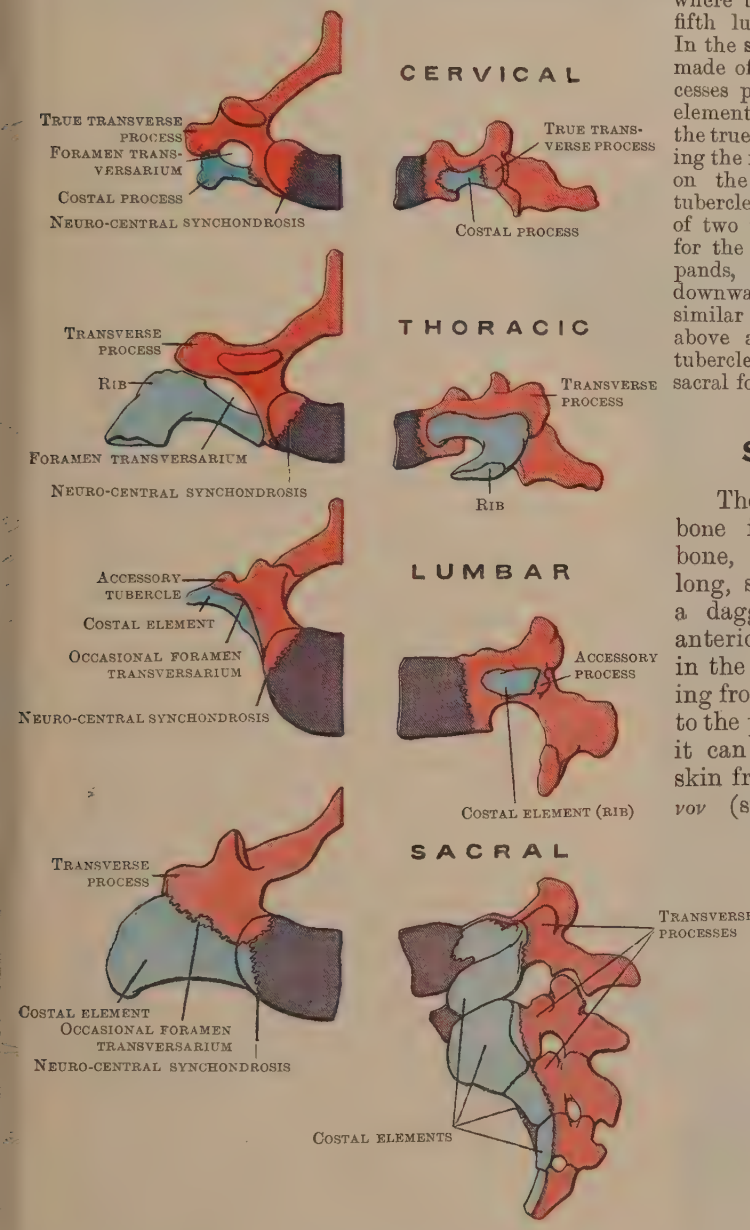

FIG. 125.—DIAGRAM TO ILLUSTRATE THE HOMOLOGOUS PARTS OF THE VERTEBRÆ.
The bodies are coloured purple; the vertebral arch and its processes, red; the costal elements, blue. A, from above. B, from the side.

STERNUM.

The **sternum** or breast-bone is an elongated flat bone, six to eight inches long, shaped somewhat like a dagger. It lies in the anterior wall of the thorax in the median plane, extending from the root of the neck to the pit of the stomach, and it can be felt through the skin from end to end. [*στέρνον* (sternon) = the breast.] It has an upper and a lower end, an anterior and a posterior surface, a right and a left border; the two clavicles articulate with its upper end, and the cartilages of the upper seven pairs of ribs articulate with it at intervals along its borders. It is divided into three main parts, named, from above downwards, the *manubrium*, the *body*, and the *xiphoid process*; the body, in youth, is divided into four segments.

Manubrium Sterni.—The **manubrium** [= a handle] is the widest piece of the sternum, and, unless the skeleton is that of an old person, it is a separate bone; for the manubrium and the body are united by cartilage and do not fuse together till an advanced age. It is triangular in outline, each side measuring about two inches; and the apex is cut off, so that it has a short lower border. The *posterior surface* is slightly concave from side to side and is not so rough as the *anterior surface*. The *upper border* is the upper end of the sternum and is more than

twice the width of the lower border. The middle part of the upper border is concave from side to side and can be felt in the root of the neck forming the floor of the **jugular** or *suprasternal* **notch** [*jugulum* (from jungere) = collar bone, and, later, the neck]; on each side of the jugular notch there is a larger notch or depression for articulation with the medial end of the clavicle or collar bone. On the *right* and *left margins*, just below the **clavicular notch**, there is a rough mark or a pit on which the cartilage of the first rib is implanted.

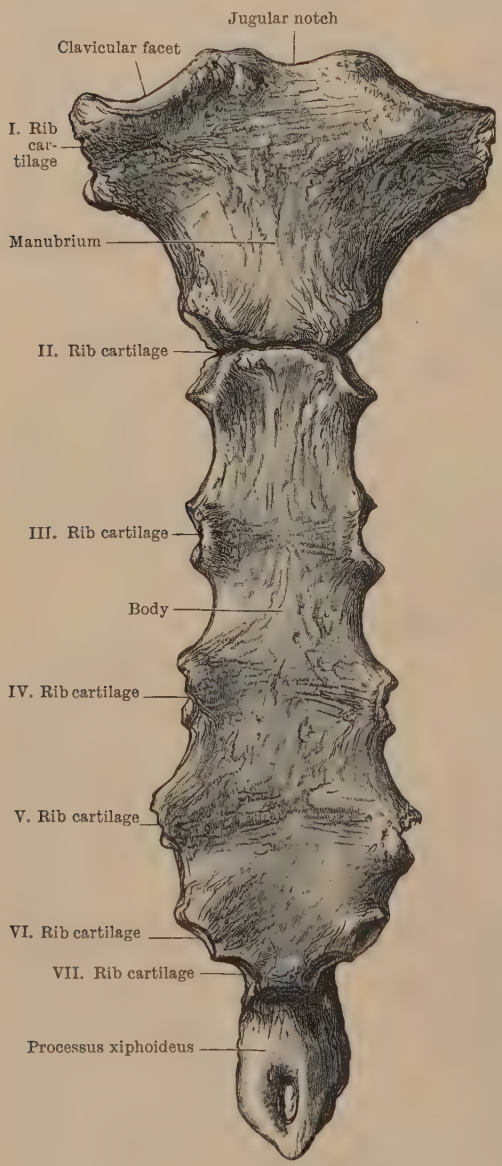

FIG. 126.—THE STERNUM (anterior view).

The lower border of the manubrium and the upper end of the body of the sternum, together, can be felt and often seen as a transverse ridge on the front of the chest, for the two bones are slightly thickened at their junction, and the manubrium is not quite in line with the body, but joins it at a very obtuse angle called the **sternal angle**. The ridge is about two inches below the jugular notch; it can be felt in stout people as well as in thin, and is the most serviceable of the landmarks on the front of the chest. The cartilage of the second rib joins the side of the sternum at the junction of manubrium and body, *i.e.*, at the sternal angle, and therefore the second rib is easily identified.

Corpus Sterni.—The **body** is the longest of the three parts of the sternum; it is about twice as long as the manubrium; it is about an inch wide at its *upper end*, increases slightly down to the fourth segment and then dwindles in breadth, so that the *lower end*, at its junction with the xiphoid process, is the narrowest part. The *posterior surface* is slightly concave from above downwards and usually is smoother than the *anterior surface*. Each *margin* bears four pits for articulation with costal cartilages. The upper three pairs of pits are at the ends of indistinct **transverse lines** that indicate the subdivision of the body into four segments; those three pairs of pits are therefore at the junction of segments; the fourth pair are on the sides of the fourth segment. In addition there are, on each side, an articular pit or notch between the body and the manubrium, and one between the body and the xiphoid process, the latter notch being on the front of their junction rather than at its side. The second rib cartilage articulates with the notch between manubrium and body; the third, fourth, fifth, and sixth with the pits or notches on the body; and the seventh with that between the body and the xiphoid process.

Processus Xiphoideus.—The **xiphoid process** or ensiform cartilage is the smallest piece of the sternum; it juts down into the anterior wall of the abdomen in front of the liver. It can be felt in the floor of the depression known as the *epigastric fossa* or "pit of the stomach." Its junction with the body—the *xiphi-*

sternal joint—can be felt as a short transverse ridge in the upper margin of that fossa; the ridge marks the lower limit of the thorax in the middle line in front, and is the landmark, in the middle line, for the diaphragm, the upper surface of the liver, and the lower border of the heart.

The xiphoid process is usually flat and pointed [ξίφος (xiphos) = *ensis* = a sword; εἶδος (eidos) = *forma* = shape], but it may be almost any shape; it may have a hole in the middle of it or it may be bifid. It is made of cartilage with a central core of bone; the osseous core enlarges with age at the expense of the cartilage, till the process is quite ossified; therefore it is more yielding in youth than in old age. At first it is united to the body by cartilage or fibrous tissue, but fuses with it after middle age.

The sternum slopes from above downwards and forwards, the manubrium slanting more than the body. The *upper* margin of the **manubrium** is on a level with the *lower* border of the **second** thoracic vertebra; the **sternal angle** with the *upper* border of the **fifth**; the **xiphisternal joint** with the *middle* of the **ninth** thoracic vertebra (Fig. 131).

The **manubrium** is thicker at its upper and lower parts than in the middle. Its thickest and strongest part is below and medial to the clavicular notch, where it receives shocks transmitted through the clavicle. The slightly raised area on the *anterior surface*, below the medial part of the clavicular notch, gives origin to the sternal head of the sterno-cleido-mastoid; part of the pectoralis major arises from the large concave area that accounts for most of each half of the front of the manubrium. On the *posterior surface* of the manubrium, part of the sterno-hyoid arises medial to the clavicular notch, and part of the sterno-thyreoid about half-way down. The capsule of the sterno-clavicular joint is attached to the margins of the **clavicular notch**; the articular disc of that joint to the junction of the manubrium and first costal cartilage; the interclavicular ligament, slightly, to the floor of the **jugular notch**.

The chief structures *behind the manubrium* are: (1) the edges of the pleuræ and lungs, (2) the remains of the thymus, (3) the left innominate vein, (4) the arch of the aorta and its three branches, and (5) the trachea, which ends opposite the sternal angle.

The **body** is thinner along its middle than at the margins. Its *anterior surface* gives origin to part of the pectoralis major; the lower part of its *posterior surface* to part of the transversus thoracis; the sterno-pericardial ligaments are attached to its upper and lower ends.

The chief structures *behind the body* are the edges of the pleuræ and lungs, the pericardium and heart; and the ascending aorta and right pulmonary artery, behind the first segment.

The **xiphoid process** is thicker in the middle than at the sides. It is thinner than the body, but their posterior surfaces are flush—hence the depression called the epigastric fossa. It varies in length, so that its lower end, though palpable, is of no use as a landmark.

The linea alba is attached to its *lower end*. Fibres of the rectus abdominis and of the external and internal oblique aponeuroses are inserted into its *anterior surface*; of the internal oblique and transversus aponeuroses into its *margin*; part of the transversus thoracis and a slip of the diaphragm arise from its *posterior surface*.

The sterno-chondral ligaments are attached to the front and back of the sternum at the pits or notches for the rib cartilages, and the inter-articular ligaments, when present, to the floors of the notches.

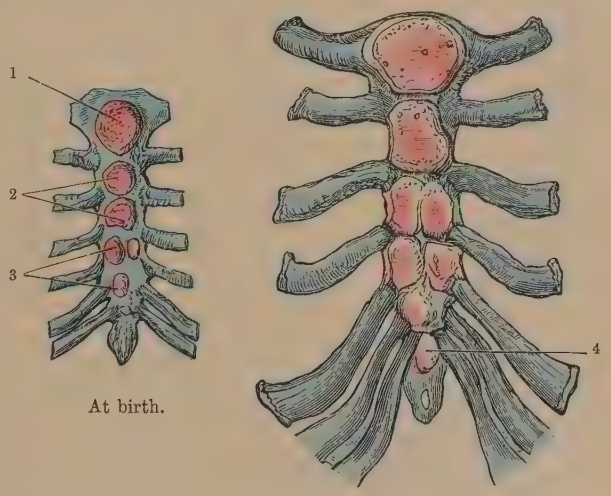

Fig. 127.—Ossification of the Sternum.

In this figure the second as well as the third segment of the body possesses two centres.

1. Appears about 5th or 6th month. 2. Appear about 7th month; unite from 20 to 25. 3. Appear about 8th or 9th month. 4. Appears about 3rd year or later.

Ossification.—The following table gives in a convenient form the approximate dates of the appearance of centres and of fusion of segments, but there is a certain amount of variation, and centres for adjoining segments may appear almost simultaneously:—

	Manubrium.	Body, 1st Seg.	2nd Seg.	3rd Seg.	4th Seg.	Xiph. proc.
Centres (one or two) appear	5th month of fœtal life	6th m.	7th m.	8th m.	9th m.	3rd year
Parts unite	Old age	21st yr.	Puberty	Child	Middle age	

The fourth segment does not always have a separate centre. Epiphyses have been found at the clavicular notches in an adult.

Structure and Variations.—The sternum is composed of highly vascular spongy bone enclosed in thin compact bone. Occasionally there is a hole in the lower part of the body, and more rarely the sternum is fissured longitudinally to a greater or lesser degree, the gap being wider above; the cleft is sometimes associated with *ectopia cordis*—a condition incompatible with life. Deformities, such as a bending back of the lower part of the sternum, arise from disease and in certain occupations. The two halves of the sternum are often asymmetrical, the clavicular notch being higher and the costal notches more crowded together on one side, with the junction of manubrium and body oblique; occupational use of the right upper limb may account for the asymmetry in some cases. Occasionally the manubrium includes the first segment of the body and carries three pairs of ribs, as in the gibbon; in such a case the *sternal angle* is opposite the third costal cartilage, and is felt about 3 inches below the jugular notch. The eighth costal cartilage in about ten per cent. of cases reaches the sternum, more often on the right side than the left; and in rare cases the seventh cartilage fails to reach the sternum. Small ossicles called *episternal bones* are sometimes found in the ligaments of the sterno-clavicular joint.

In women the manubrium is at a rather lower level and is narrower and longer than in men, but the body of the sternum is wider and shorter.

COSTAE OR RIBS.

There are twelve **ribs** on each side in both sexes. They are thin, narrow, curved strips of bone, and, though elongated, they are classed among the "flat" bones. They are attached posteriorly to the thoracic vertebræ and curve round the sides of the chest, slanting downwards and forwards; anteriorly each of them ends by joining a bar of cartilage called **a costal cartilage.** The ribs lie at the back, at the sides, and at the front of the thorax, and they provide protection for the sides and back of the upper part of the abdomen also. The upper seven ribs increase in length from above downwards and are called *true* ribs because their cartilages are attached to the side of the sternum. The lower five are called *false* ribs; they diminish in length from above downwards and their cartilages fail, by increasing distances, to reach the sternum; but the eighth, ninth, and tenth are each joined to the one above it, edge to edge, forming diarthrodial joints at their points of contact. The cartilages of the eleventh and twelfth, however, are free, and they are called *floating* ribs.

A rib has an anterior and a posterior end, an external and an internal surface, and a superior and an inferior border. The *posterior end* is called the **head**, and is articular; the *anterior end* is hollowed out to form a pit into which the costal cartilage fits. The *upper border* is smooth and rounded; the *lower* is thin and sharp. The *outer surface* is convex; the *inner* is concave lengthwise.

The ribs are not all curved equally. The first rib has the sharpest curve, and the curve of each succeeding one is wider or more open; therefore, if the specimens are all from the same skeleton, one can arrange them in proper order by laying them on a table in a row with their posterior ends in a straight line and observing the progressive change of curvature. It will be seen that, when laid in a row in proper order, they increase in length down to the seventh or eighth and then diminish to the twelfth; and also that they are twisted, for, if they are lying on their lower borders, the posterior part of the inner surface looks largely upwards, while the anterior part looks slightly downwards. Ribs are not only curved and twisted, they are slightly bent as well (Fig. 129). The bend is called the *angle* of a rib; it takes place from one to three inches from the head, the

distance increasing as the series descends, and its position is marked by an oblique irregular ridge on the outer surface of the bone.

The **parts** of a rib are: head, neck, tubercle, body or shaft, and costal cartilage; and the body has an angle and a costal groove.

The first, second, tenth, eleventh, and twelfth have each some special characters of its own, but the third to the ninth belong to a common type.

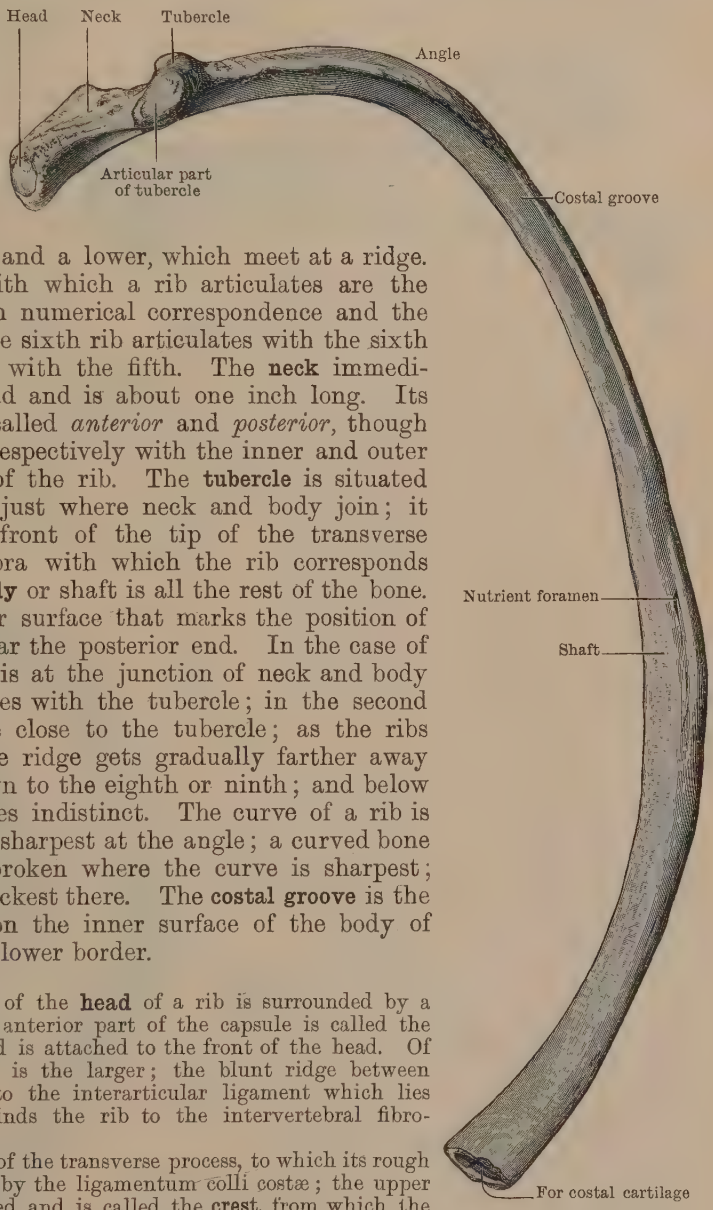

FIG. 128.—FIFTH RIGHT RIB AS SEEN FROM BELOW.

A Typical Rib.—The **head** articulates with two thoracic vertebræ and therefore has two articular facets on it, an upper and a lower, which meet at a ridge. The two vertebræ with which a rib articulates are the one with which it is in numerical correspondence and the one above that, *e.g.*, the sixth rib articulates with the sixth thoracic vertebra and with the fifth. The **neck** immediately succeeds the head and is about one inch long. Its surfaces are usually called *anterior* and *posterior*, though they are continuous respectively with the inner and outer surfaces of the body of the rib. The **tubercle** is situated on the outer surface just where neck and body join; it articulates with the front of the tip of the transverse process of the vertebra with which the rib corresponds numerically. The **body** or shaft is all the rest of the bone. The ridge on the outer surface that marks the position of the **angle** is placed near the posterior end. In the case of the first rib the angle is at the junction of neck and body and the ridge coincides with the tubercle; in the second rib the ridge is quite close to the tubercle; as the ribs are followed down the ridge gets gradually farther away from the tubercle, down to the eighth or ninth; and below that the ridge becomes indistinct. The curve of a rib is not uniform, and it is sharpest at the angle; a curved bone is most likely to be broken where the curve is sharpest; therefore the rib is thickest there. The **costal groove** is the long, shallow groove on the inner surface of the body of the rib just above the lower border.

The articular surface of the **head** of a rib is surrounded by a joint capsule; the thick anterior part of the capsule is called the ligamentum radiatum and is attached to the front of the head. Of the two facets the lower is the larger; the blunt ridge between them gives attachment to the interarticular ligament which lies within the joint and binds the rib to the intervertebral fibro-cartilage.

The **neck** lies in front of the transverse process, to which its rough posterior surface is bound by the ligamentum colli costæ; the upper border is rough and raised and is called the **crest**, from which the anterior costo-transverse ligament stretches up to the transverse process next above; the anterior surface is smooth and is covered with pleura. The **tubercle** has a *facet* on its lower and medial part for articulation with the transverse process; an articular capsule surrounds the facet, and the ligament of the tubercle connects the rough part of the tubercle with the tip of the transverse process.

The *upper border* of the **body** gives insertion in all its length to an external intercostal muscle, and, internal to that, a posterior intercostal membrane is attached between the neck and the angle, while an internal intercostal muscle is inserted into the rest of the length of the border. The **costal groove** is broad and well marked posteriorly, but indistinct in the anterior part of the rib; the intercostal vessels and nerve run along the groove. The groove has an upper and a lower lip, the lower lip being the sharp *lower border* of the bone; the external intercostal

muscle arises from the whole length of its lower lip; the posterior intercostal membrane is attached to the floor of the groove between the tubercle and the angle; an internal intercostal muscle arises from the upper lip from the angle forwards. The rest of the *inner surface* of the rib is smooth and is covered with pleura.

Many muscles are attached to the *outer surface* of the ribs (p. 122). The ridge that marks the angle is for the attachment of the ilio-costalis—*i.e.* the lateral subdivision of the large composite mass of muscle, called sacrospinalis, that lies alongside the spines of the vertebræ. On the longer ribs there is often an accentuation of curvature, called the *anterior angle*, marked by an indistinct ridge on the outer surface two inches or more from the anterior end; the ridge is for the origin of slips of the serratus anterior and obliquus externus abdominis. In each of the upper ten ribs the anterior end is the widest part of the rib.

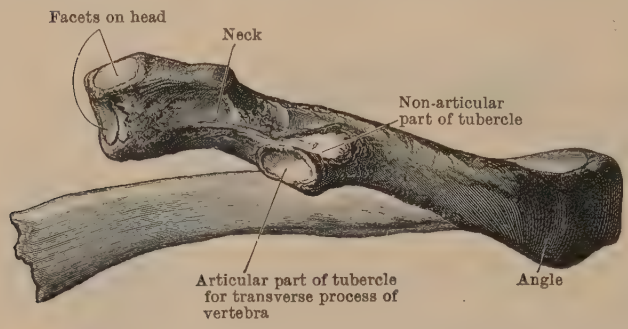

FIG. 129.—FIFTH RIGHT RIB AS SEEN FROM BEHIND.

The **first rib** is the shortest rib, except the twelfth; it is the most sharply curved, and it is broad in comparison with its length. It lies at the boundary between neck and thorax, largely under cover of the clavicle; its posterior end is above the level of the clavicle, and its anterior end is immediately below the clavicle (Fig. 131). Unlike the other ribs, its **surfaces** are *upper* and *lower*, its **borders** are *inner* and *outer*. The inner border is concave; the outer border is convex. The surfaces are not always easily distinguished at first glance, but if the rib is laid on the table and its head touches the table, then its lower surface is looking downwards; if it is turned upside down the head stands away from the table.

The **head** is small; it articulates with only one vertebra, namely, the first thoracic, and therefore it has only one facet. The **neck** is relatively long, and is compressed from above downwards; the top of the pleura and lung lie immediately in front of it. The **tubercle** is situated on the outer border and is relatively large.

The *lower surface* of the **body** is covered with pleura. The subclavian artery and vein lie across the *upper surface*, producing broad shallow grooves. The groove for the artery is about the middle of the body; the groove for the vein is nearer the anterior end. On the *inner border* there is a little tubercle continuous with a small rough area on the upper surface between the grooves for artery and vein; the tubercle is called the **scalene tubercle**, for the scalenus anterior muscle is inserted into it and into the rough area. The surface behind the groove for the artery—between that groove and the tubercle of the rib—gives insertion to the scalenus medius muscle, while the first digitation of the serratus anterior arises from it near the outer border immediately behind the groove for the artery. The greater part of the anterior ramus of the first thoracic nerve, on its way to join the brachial plexus, runs upwards and laterally in front of the neck and then lies in the posterior part of the groove for the artery, between the artery and the scalenus medius. On many specimens of the first rib the grooves and tubercle are faintly marked; while in others, there is a special groove for the lodgment of the first thoracic nerve, or the lowest trunk of the brachial plexus, immediately behind the groove for the artery. The

Groove for subclavian artery
Scalene tubercle of Lisfranc
Groove for subclavian vein

FIG. 130.—FIRST AND SECOND RIGHT RIBS AS SEEN FROM ABOVE.

subclavius muscle and the costo-clavicular ligament are attached to the upper surface of the rib at its junction with the cartilage.

The external and internal intercostal muscles of the first space arise from the *outer border*. A fibrous membrane, called Sibson's fascia, stretches fanwise from the transverse process of the seventh cervical vertebra to be attached to the *inner border*. (See also p. 122.)

The **second rib** is about twice as long as the first, and the sharpness of its curve distinguishes it from one of the lower ribs of similar length; it is not twisted; its surfaces are, in direction, intermediate between those of a first rib and those of a typical rib, and its costal groove is poorly marked. But the *special character* of the second rib is that on its outer surface, about its middle, there is a broad rough **tubercle** for the origin of part of the **serratus anterior** muscle. No other rib has a similar tubercle.

The **tenth, eleventh,** and **twelfth** ribs have each only one facet on the head, for each articulates with only one vertebra and that is the thoracic vertebra of corresponding number. The tenth, however, may be a typical rib. The eleventh differs from the tenth mainly in that its tubercle is small and has no articular facet, and the angle is ill defined; but the tubercle and angle of the tenth also may be ill defined, so that it is sometimes difficult to say whether a given rib is tenth or eleventh if the other ribs of the same skeleton are not at hand.

The **twelfth rib** is small and slender. It may be as short as, or shorter than, the first. *Tubercle, angle,* and *subcostal groove* are absent or are poorly marked. The **body** tapers off at the free end, while other ribs are nearly always slightly swollen at the anterior end.

Cartilagines Costales.

The **costal cartilages** are bars of hyaline cartilage which are fitted into the pits at the anterior ends of the ribs; the cartilage is held in place because its perichondrium is continuous with the periosteum of the rib. The cartilages of the **upper seven** ribs join the sternum and can be felt at the side of the sternum; they increase in length from above downwards, from one inch to four or five inches; the *first* cartilage is fitted on to a rough mark on the margin of the manubrium and is held in place by the continuity of its perichondrium with the periosteum of the sternum; the *other six* are joined to the sternum by diarthrodial joints; the first and second slope downwards slightly from the bony rib to the sternum; the third is horizontal; the fourth inclines upwards; the fifth, sixth, and seventh continue the direction of the rib for about an inch, and then turn upwards, with increasing degrees of obliquity, to reach the sternum. The cartilages of the **lower five** ribs diminish in length from above downwards; they can be felt in the costal margin between the thorax and abdomen. The eighth, ninth, and tenth continue in the direction of their ribs for about an inch and then turn upwards; they fail, by increasing distances, to reach the sternum, and each tapers off to a point; they are each united edge to edge with the one above, forming diarthrodial joints at the points of contact. The eleventh and twelfth are mere pointed cartilaginous tips on the ends of the ribs.

THORAX.

The **thorax** lodges the lungs and the heart and many other structures, and gives them protection; its skeleton provides attachment for many muscles besides those that belong to the thorax itself; but the chief use of the thorax in mammals is to act as a bellows by which air, for oxygenating the blood, can be drawn into the lungs contained within it. Its framework is a bony and cartilaginous cage, the bars of which are arranged so that they not only resist atmospheric pressure as the bellows is opened, but also, by their mobility, take share in the expanding movement.

The skeleton or cage is made of the thoracic vertebræ and intervertebral fibro-cartilages, the sternum, the ribs, and their cartilages. It is somewhat cone-

shaped, being narrowest above. It is longer behind than in front, and is compressed from before backwards, so that it is wider from side to side, the greatest width being at the level of the eighth or ninth rib. The antero-posterior diameter of its interior is greatly diminished by the forward projection of the bodies of the vertebræ. It communicates with the front of the neck by a superior aperture or inlet, and with the abdomen by an inferior aperture or outlet.

The **superior aperture** is small, and is kidney-shaped in outline; it slopes from above downwards and forwards; it measures about 2 inches or 50 mm. from before backwards, and 100 mm. across. It is bounded by the first thoracic vertebra behind, the manubrium in front, and the first pair of ribs and their cartilages at

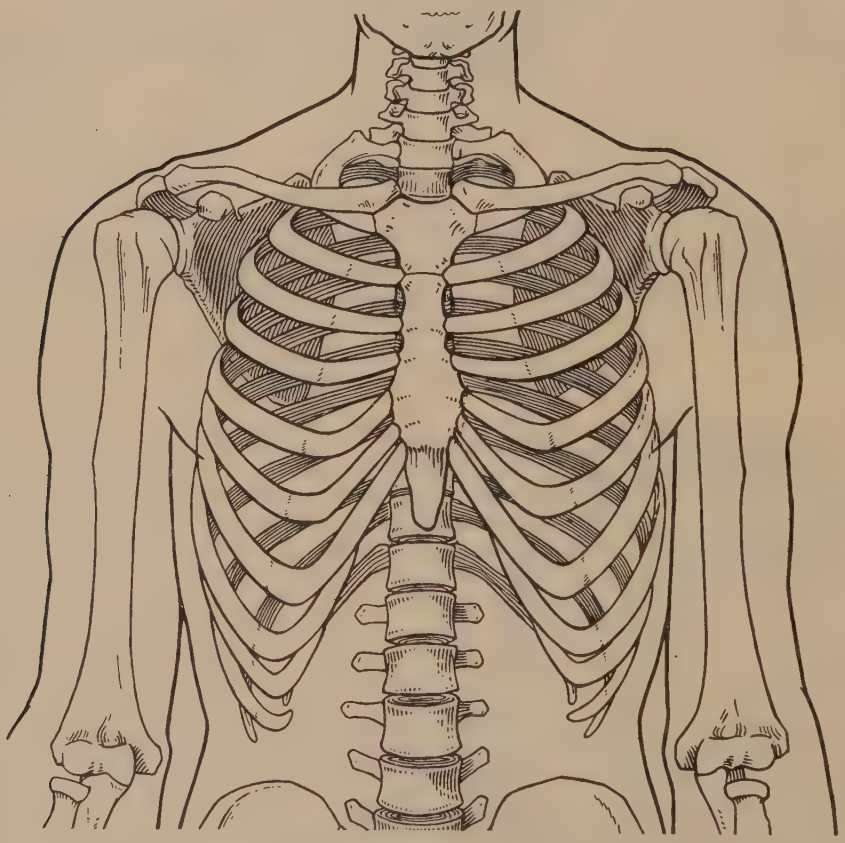

FIG. 131.—FRONT OF PORTION OF SKELETON SHOWING THORAX.
In the specimen from which the drawing was made the tenth costal cartilage did not join the ninth.

the sides. It is occupied by the apices of the lungs and pleuræ, the windpipe, the gullet, and numerous vessels and nerves that pass between neck and thorax.

The **inferior aperture** is large and is uneven in outline. It is bounded by the xiphisternal joint, the lower six costal cartilages, and the body of the twelfth rib, and by the last thoracic vertebra. It is closed by the diaphragm, which separates the interior of the thorax from the interior of the abdomen and forms a highly vaulted and very movable floor for the thorax and roof for the abdomen. The *infrasternal angle* is situated at the anterior part of the inferior aperture; its sides are the seventh pair of costal cartilages; its apex is the xiphisternal joint; and the xiphoid process juts down into the angle.

The **posterior wall** of the thorax is made up of the thoracic vertebræ and fibro-cartilages and the posterior part of the ribs. The ribs have a backward sweep as far as their angles which makes their angles nearly flush with the tips of the spines of the vertebræ, so that Man, unlike most animals, can lie on his back with

stability and ease. The forward projection of the vertebral bodies and the backward curve of the ribs create a large hollow, on each side, in the posterior part of the interior of the thorax for the lodgment of the thickest part of the lung.

The **sides** of the thorax are formed by the bodies of the ribs. The ribs are not all the same distance apart, nor are they parallel. The upper intercostal spaces are wider than the lower; and the ribs slope downwards and forwards with an obliquity which increases from the first down to the ninth or tenth, so that the intercostal spaces are wider in front than behind. The sides slope outwards, down to the level of the eighth or ninth rib, and may slope inwards slightly below that.

The **anterior wall** is formed by the manubrium and body of the sternum, the

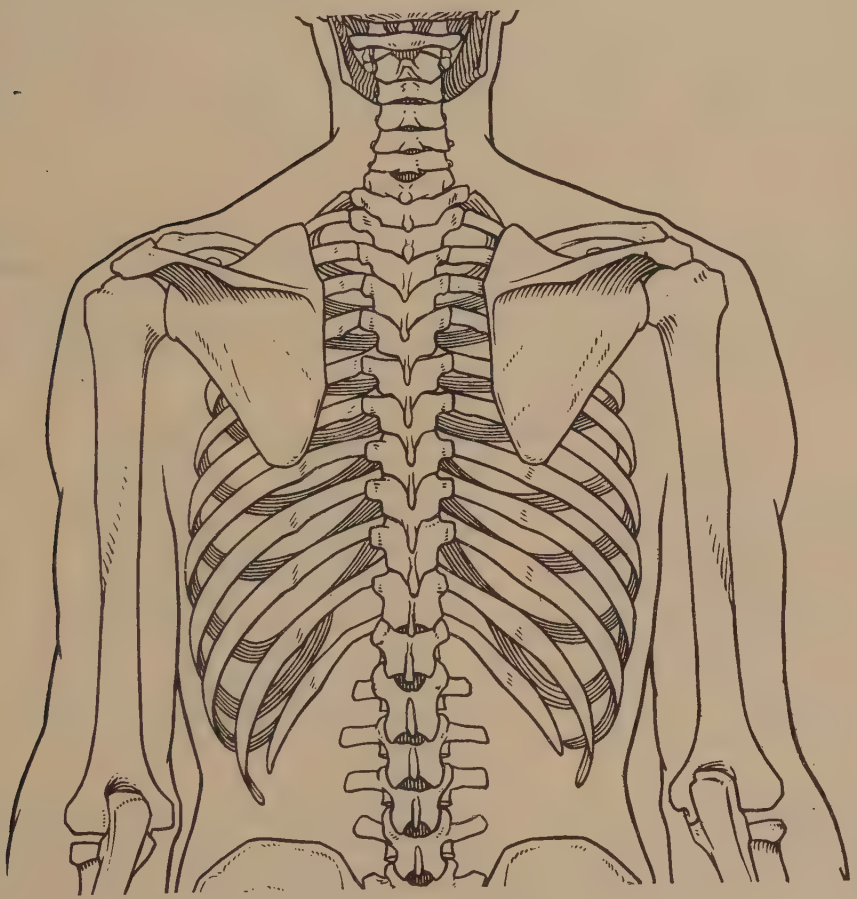

Fig. 132.—Back of Portion of Skeleton showing Thorax.

anterior ends of the upper ten pairs of ribs and their cartilages. It is shorter than the posterior wall or the sides, especially in the median plane, for the upper border of the manubrium is opposite the lower border of the second thoracic vertebra and the xiphisternal joint is opposite the ninth.

In the fœtus the thorax is compressed from side to side. At birth its form alters with the expansion of the lungs, but full expansion in a transverse direction does not take place till after the child begins to walk and to use its upper limbs more exclusively for prehensile purposes. *In a woman* the thorax is shorter and rounder than in a man, and the upper ribs are more movable.

Surface Relations.—The thorax is well covered externally with muscles belonging to the upper limb, the abdomen, the back, and the neck. There are only three parts that have no muscular covering. These are (1) a finger's-breadth down the middle of the sternum, (2) the middle line of the back, (3) a portion of the

seventh rib, just medial to the lower part of shoulder blade, especially when the shoulder is drawn forwards.

The **first rib** provides the bony resistance felt in the neck above the middle of the clavicle; its cartilage is immediately below the sternal end of the clavicle.

The **second rib** is the most easily identified of all on the front of the chest, because its cartilage joins the sternum at the **sternal angle**, which is always easily felt; both angle and second cartilage are often easily seen as well as felt. When ribs have to be counted, or when a particular rib has to be located in the living person, the best method is to find the second and count downwards from it. There are rough and ready, though uncertain, guides to some of the other ribs and cartilages. The *nipple* is usually opposite the **fourth intercostal space** between the anterior ends of the bony parts of the fourth and fifth ribs. The cartilage felt on the costal margin next the sternum is nearly always the **seventh**, though occasionally the eighth cartilage reaches the sternum. The cartilage felt where the groove that marks the lateral margin of the rectus abdominis reaches the costal margin is usually the **ninth**. The **tenth** cartilage is the lowest one felt when the costal margin is examined from the front, and it is on a level with the body of the *third lumbar vertebra*. A line drawn from the medial end of the clavicle to the point a thumb's-breadth behind the lowest point of the tenth cartilage will pass through or near the junction of ribs and cartilages from the second to the tenth. If the *posterior axillary line* is followed downwards, the lowest rib it crosses is the **eleventh.** The **twelfth** rib may be felt, but sometimes it is so short that it is hidden by the sacrospinalis. **On the back** the point where the *spine of the scapula* meets the vertebral border overlies the **fourth** rib; and the *inferior angle* of the scapula overlies either the **seventh** intercostal space or the eighth rib.

Ligaments and Muscles attached to Ribs and their Cartilages.

Heads.

- Articular capsules, Ligamenta radiata } 1-12.
- Interarticular ligaments, 2-9.

Necks.

- Lig. colli costæ, 1-12.
- Costo-transverse ligaments, 2-12.
- Lumbo-costal ligament, 12.

Tubercles.

- Articular capsules, 1-10.
- Lig. tuberculi costæ, 1-11.

Bodies.

- Costo-clavicular ligament, Sibson's fascia } 1.
- Posterior intercostal membranes, Posterior layer of lumbo-dorsal fascia } 1-12.
- Anterior and middle layers of lumbo-dorsal fascia } 12.
- Lateral lumbo-costal arch
- Scalenus anterior, Scalenus medius, Sterno-thyroid, Subclavius } 1.
- Ilio-costalis cervicis, 1-6.
- Serratus anterior, 1-8.
- Ilio-costalis dorsi, External intercostals, Internal intercostals, Levatores costarum } 1-12.

Bodies (contd.).

- Scalenus posterior, 2.
- Pectoralis minor, Serratus posterior superior } 2-5.
- Longissimus dorsi, 3-12.
- Obliquus externus abdominis, 5-12.
- Ilio-costalis lumborum, 7-12.
- Latissimus dorsi, Serratus posterior inferior } 9-12.
- Obliquus internus abdominis, 10-12.
- Quadratus lumborum, 12.
- Subcostales, inconstant.

Costal Cartilages.

- Articular disc of sterno-clavicular joint, Costo-clavicular ligament, Costo-coracoid membrane } 1.
- Anterior intercostal membranes, 1-10.
- Sterno-chondral capsules and ligaments, 2-7.
- Interchondral capsules, 7-10.
- Sterno-hyoid, Sterno-thyreoid } 1.
- Subclavius
- Pectoralis major, 1-6.
- Internal intercostals, 1-12.
- Transversus thoracis, 2-6.
- Rectus abdominis, 5-7.
- Diaphragm, Obliquus internus abdominis, Transversus abdominis } 7-12.
- External intercostals, 10-12.

Ossification, Structure, and Variations of Ribs.

Ossification.—A rib is ossified from one primary centre and one or two or three secondary centres. The **primary centre** appears near the angle (first in the sixth rib) in the sixth week of fœtal life, and ossification spreads rapidly through the rib. **Secondary centres**

appear at *puberty* and the epiphyses fuse with the rest of the bone at 25. The **first rib** has *one* epiphysis for the **head** and *one* for the **tubercle**. The **second to the sixth**, inclusive, have *one* epiphysis for the **head**, *one* for the *articular* part of the **tubercle**, and *one* for the *non-articular* part. The **seventh to the tenth**, inclusive, have *one* for the **head** and *one* for the **tubercle**. The **eleventh and twelfth** have *one* for the **head**.

Structure and Variations.—Like other flat bones, the ribs are composed of highly vascular spongy substance enclosed in compact substance, which is thickest at the angles.

The most important variation is the presence of a **cervical rib**, which may unite with the sternum or with the first costal cartilage, or with the vertebral end of the first rib, making a bicipital rib. Part of the cervical rib may be fibrous tissue, and in some cases only the sternal end is present. In some cases increase of number is due to a lumbar rib. Diminution in number is rare, but sometimes the twelfth rib is absent, or the first rib is rudimentary and may fuse with the second, making a bicipital rib. Sometimes two ribs are partly fused together. Occasionally the posterior parts of two ribs are united by a projection jutting out from each and articulating with an intervening nodule of bone. The anterior end of a rib is sometimes very wide and may have a hole or a cleft in it. *Costal cartilages* also may be broad and perforated. The seventh cartilage sometimes throws out a projection which articulates with a similar projection from the sixth. The seventh sometimes fails to reach the sternum, but a commoner anomaly is that the eighth articulates with the sternum. In old age the cartilages may undergo partial ossification; this condition may be regarded as normal in the first costal cartilage in elderly people.

Development of Vertebræ, Ribs, and Sternum.

Vertebræ.—In the Chapter on EMBRYOLOGY it is explained that the *paraxial mesoderm* is divided by transverse clefts into a number of segments called *mesodermal somites*, and that the cells of the ventro-medial or *scleratogenous* parts of the somites proliferate and form a continuous mesodermal sheath around the notochord and neural tube [σκληρός (sclēros) = hard; γεννάω (gennaō) = produce]. The sheath is called the **membranous vertebral column**: in it the vertebræ are formed, and pass through a pro-cartilage stage and a cartilage stage before ossification. Each *pro-cartilage vertebra* consists of a body enclosed in a horseshoe-shaped vertebral bow. The **body**

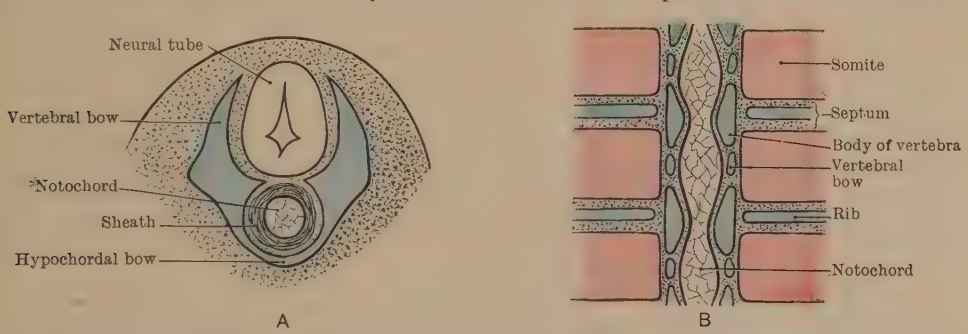

FIG. 133.—THE DEVELOPMENT OF THE MEMBRANOUS BASIS OF A VERTEBRA (after Keith).

A, in transverse section. B, in longitudinal section, showing the relation of the vertebræ to the primitive segments.

surrounds the notochord, and its position is such that it corresponds to the contiguous halves of two adjacent somites, its middle being opposite an *intersegmental septum, i.e.* the interval between two somites. The middle part of the **vertebral bow** is sometimes called the *hypochordal bow* [ὑπό (hypo) = below]; it is ventral to the headward part of the body to which it belongs; the two limbs of the bow slant backwards to enclose the neural tube on the tailward part of the body, and in time meet each other dorsal to the neural tube.

The scleratogenous tissue between two bodies, opposite the middle of a somite, begins about the fourth *week* of fœtal life to undergo fibrous and chondrifying changes, and becomes an *intervertebral fibro-cartilage*. About the fourth week also *chondrification* begins in the **body** and in the **limbs of the bow**; the body and the bow rapidly unite, and chondrification of the bow is completed dorsally during the fourth *month* of fœtal life. The body forms the median part of a body of a vertebra. The limbs of the bow form the postero-lateral part of a body and the vertebral arch and its processes; the transverse processes and the spine grow out from it into the intersegmental septum that lies on the tailward side of the two somites to which the vertebra corresponds. The scleratogenous tissue between the arches of two vertebræ becomes the ligamenta flava and the capsules uniting articular processes. *Ossification* begins at the seventh week of fœtal life in the arches and at the tenth week in the bodies.

The ventral or hypochordal part of the vertebral bow disappears, except in the case of the **atlas** vertebra, where it chondrifies and ossifies to form the anterior arch. The atlas therefore is a complete vertebral bow; its body becomes the dens of the second vertebra, and its lateral masses correspond to the parts of the body of a typical vertebra that are formed from the vertebral bow. The ligaments that connect the dens with the margins of the foramen magnum represent the fibro-cartilage between the atlas and the last occipital segment.

The rudimentary condition of a **coccygeal** vertebra is due to the failure of the limbs of the vertebral bow to develop. The incomplete condition of the laminæ of the last two **sacral** vertebræ is due to imperfect chondrification and ossification of vertebral bows. Imperfections in the formation of vertebral bows in regions farther up in the vertebral column give rise to the condition known as *spina bifida*.

The part of the *notochord* enclosed in the bodies of the vertebræ is first constricted, and finally disappears after ossification begins. The part enclosed in fibro-cartilages persists in them as their pulpy centres.

Ribs.—The ribs are developed in the intersegmental septa, and pass through pro-cartilage and cartilage stages before ossification. Each articulates at first with only one vertebra—not the vertebra opposite the septum in which the rib is developed, but the vertebra on the headward side of that. Later, the vertebral ends of the ribs, except the first, tenth, eleventh, and twelfth, are shifted headwards, so that each articulates not only with its own vertebra but also with the fibro-cartilage and the vertebra above.

Sternum.—The sternum is formed from mesodermal tissue in front of the pericardium; its origin is still under discussion (see Hanson, *Amer. Jour. Anat.* vol. xxvi. 1919–20, p. 41). The **manubrium** probably arises in association with the ventral part of the shoulder girdle, and the **body** and **xiphoid process** from two *sternal bars* which grow from the mesodermal rudiment of the manubrium and fuse together in the median plane. After chondrification the sternum becomes connected with the costal cartilages by diarthrodial joints.

THE SKULL.

The **skull** is the skeleton of the head and face. It is made of 22 bones, including the mandible, which is the skeleton of the lower part of the face, and is a movable bone. The other 21 bones are so firmly knit together that they are taken apart with difficulty; they are built together in such a way that they enclose one large cavity and three smaller ones. The large cavity is called the *cranial cavity*, and contains the brain and its membranes; the smaller cavities are the *cavity of the nose*, and the two *orbits*, which hold the eyeballs. There are lesser cavities contained within certain of the skull bones; those cavities are the *middle ear*, the *internal ear*, and the *air sinuses*. The skull bones consist of two plates or **tables** of compact substance enclosing between them a layer of spongy substance called, in the case of skull bones, **diploë**. In some of them the diploë is absorbed, leaving cavities or air sinuses between the tables of compact bone; the sinuses communicate with the cavity of the nose, and are lined with mucous membrane, continuous with that of the nose.

A specimen of skull for study is not complete without the mandible, but since the mandible is a movable, separate bone, the term "skull" very frequently means skull *minus* mandible, and is used largely in that sense in this text. The *hyoid bone*, which lies in the neck below the mandible, is described along with the skull bones, but is not part of the skull. The *auditory ossicles*, which lie in the middle ear, are described in the chapter on Organs of Sense.

Some of the 21 united bones of the skull are paired and some are unpaired. The paired bones are bracketed (2) in the following list of their names; the unpaired are bracketed (1).

Frontal (1)	Nasal (2)	The first six in the list, eight bones in all, are those which share in the formation of the walls of the cranial cavity.
Ethmoid (1)	Lacrimal (2)	
Sphenoid (1)	Inferior nasal conchæ (2)	
Occipital (1)	Vomer (1)	
Parietal (2)	Maxillæ (2)	
Temporal (2)	Zygomatic (2)	
	Palatine (2)	

In a young person, those 21 bones, though firmly bound together, are separable; the joints by which they are held together are either *sutures*, in which the articulating parts are connected by a ribbon of fibrous tissue, or *synchondroses*, in which they are connected by hyaline cartilage. With advancing years the joints disappear and neighbouring bones fuse together gradually.

There is some confusion in regard to the meaning of *skull*, *cranium*, and *calvaria*, and the classification of the bones of the skull.

In ordinary English the word "Skull" denotes the skeleton of the head without the lower jaw bone, and in medical text-books the word "Cranium" is employed usually as a synonym for "skull" in that sense, though κρανίον (kranion) originally meant only the part of the head covered with hair; further, in medical text-books, "*calvaria*" (from *calvus* = bald) usually means the top part of the skull or skull-cap, though it is defined in Andrewe's Latin dictionary as the *brain pan, skull*, of man and beasts. But in catalogues of craniological collections the following meanings are attached to the terms: *Skull* = entire skeleton of head and face, including mandible; *Cranium* = skull without mandible; *Calvaria* = skull after bones of face have been removed or destroyed.

An old classification of the bones is: (1) Cranial bones = those that form the adult brain case; (2) Facial bones = all the others. In the Basle nomenclature the *ossa faciei* comprise maxilla, palatine, zygomatic, mandible and the hyoid bone; *ossa cranii* comprise all the others; and there is a subdivision also into *cranium cerebrale* and *cranium viscerale*. Quain's *Anatomy* 11th edition, suggests more than one classification. No classification has satisfied every one, and it is questionable if any classification of skull bones is either necessary or desirable.

It is much more important that the student should acquire a knowledge of the skull as a whole than of the separate bones. The detailed description of the separate bones is put at the end of the section for reference, and the skull as a whole is dealt with earlier. But so many of the parts of the skull are named from the particular bones to which they belong, that it is necessary to give a few brief, preliminary notes on the individual bones; and the student, with a skull before him, and with the aid of the figures of the skull in the text, should identify each of the bones and note the aspects of the skull in which they are visible, before commencing to read the description of the skull as a whole. It is convenient, however, to locate at the outset the following parts, for they will be referred to as landmarks.

(1) The **orbits** are the pair of large pyramidal cavities in the front of the skull (Fig. 134). They are so named because the eyes rotate in them. [*Orbita* = a wheel rut, a circuit.]

(2) The **apertura piriformis** is the large egg-shaped hole between and below the two orbits; through it one can see into the cavities of the nose. [*Pirum* = a pear; *forma* = shape.]

(3) The **external acoustic meatus** or ear-hole (Fig. 135) is the small, round, or oval hole or passage seen in the lower part of the side of the skull about midway between the front and the back. The proper position of the skull is not that which it occupies when it is set on a table. When the skull is held in its **proper position**, the lower margin of the orbit and the upper margin of the orifice of the meatus are at the same horizontal level. [Ἀκούω (akouō) = hear; *meatus* = a passage.]

(4) The **zygomatic arch** is the bridge of bone on the side of the skull that spans the interval between the lower part of the orbit and the front of the meatus [ζύγωμα (zygōma) = a bar, from ζυγόν = anything that connects two bodies.]

(5) The **foramen magnum** is the large, round hole on the lower surface of the skull a little behind its centre (Fig. 137).

(6) The **choanæ** are a pair of large openings about two inches in front of the foramen magnum; they are oval and oblique, and are set closely side by side; through them one can see into the cavities of the nose from behind [χοάνη (choanē) = a funnel].

(7) The **hard palate** is the platform of bone forming the median part of the front of the lower surface of the skull; its posterior edge is the *lower* margin of the two choanæ (when the skull is held right way up).

(8) If the interior of the skull is examined (Fig. 138), it will be noted that the lower part of the cranial cavity has a very uneven floor, and is divisible into three main regions which are at different levels. Those regions are called the **anterior, middle,** and **posterior cranial fossæ**; each of them has a median part and a right and a left lateral part.

Bones of the Skull.

The **frontal bone** (Figs. 134, 135, pp. 157, 158) is the large shell of bone in the anterior part of the skull; it forms the forehead and the anterior part of the top of the skull; and a pair of wide, thin shelves, called *orbital plates*, project backwards from its lower part and form the greater part of the roof of each orbit, and of the

floor of each lateral part of the anterior cranial fossa. In each half of the frontal bone there is a cavity, called the *frontal sinus*, situated just above the rim of the orbit and the root of the nose. [*Frons* = the brow.]

The **parietal bone** (Figs. 135, 160, pp. 137, 192) is the large, convex, four-square bone that lies behind the frontal bone; it forms a large part of the side of the skull, and a large part of the top, meeting its fellow of the opposite side at the middle line. [*Paries* = a wall.]

The **occipital bone** (Figs. 137, 138, 162, pp. 143, 156, 194) is the large bone which lies at the back of the skull behind the two parietal bones. It is shaped like a leaf, and it is bent so that it lies in the base of the skull as well as at the back. The foramen magnum is in the occipital bone. The thick bar of bone in front of the foramen magnum is called the **basilar part** of the occipital bone or **basi-occiput.** The region at each side of the foramen magnum is called the **lateral part** of the occipital bone, or **condylar part**, because the two eminences with smooth articular surfaces at the sides of the foramen are called the occipital **condyles.** [*Occiput* (*ob, caput*) = the back of the head up to the crown, while *sinciput* (*semi, caput*) = the front part of the head from the crown to the forehead.]

The **temporal bone** (Figs. 135, 137, 138, 165, pp. 137, 143, 156, 197) lies partly in the side of the skull below the parietal bone, and partly in the base of the skull in front of the condylar part of the occipital bone. The external acoustic meatus is in the temporal bone on the side of the head. The large piece of bone, shaped like a scale, that lies above the meatus is the *squamous part* of the temporal bone or **squamous temporal** [*squama* = a scale]; the *zygomatic process* of the temporal bone or **zygoma** is a projection from the squamous temporal, and it forms the posterior half or so of the zygomatic arch. The region of bone behind the meatus is the *mastoid part* of the temporal bone or **mastoid temporal**, and its lower part is a large, rounded projection, called the **mastoid process**, which is easily felt behind the ear in the living head. The mastoid process is named from its resemblance to a teat [μαστός (mastos) = the breast] and gives its name to the mastoid temporal.

The uneven plate of bone that forms the front and lower wall of the meatus, and part of the back wall, is the *tympanic part* of the temporal bone or **tympanic plate.** The long, slender process (often broken off in specimens of skull) which projects downwards and forwards from behind the lower edge of the plate is called the **styloid process** [στῦλος (stylos) = a pillar, a stake, a pen].

The remaining part of the temporal bone is called the *petrous part* or **petrous temporal**, and gets its name from its hardness [πέτρος (petros) = a stone]. It is an uneven wedge of bone situated in the base of the skull on the medial side of the tympanic plate and in front of the condylar part of the occipital bone. It is seen much better in the inside of the skull; it is the conspicuous elevation in the floor, on either side, about midway between the front and the back of the cavity of the skull, between the middle and posterior cranial fossæ.

The temporal bone contains the *middle ear*, the *internal ear*, a small cavity called the *tympanic antrum*, and a varying number of small spaces called *mastoid air cells.*

The **sphenoid bone** (Figs. 135, 137, 138, 146, 169, pp. 137, 143, 156, 170, 203) is more difficult to identify. It is wedged in among other bones of the skull [σφήν (sphēn) = a wedge]; parts of it can be seen in the floor of the cranial cavity, on the lower surface of the base of the skull, in the side of the skull, and in the upper and lateral walls of both orbits. The sphenoid bone has a body, a pair of small wings, a pair of large wings, and a pair of pterygoid processes.

The **body** is the middle part of the bone; it lies in front of the basilar part of the occipital bone, with which it is fused after the 25th year. On the lower surface of the skull it is to a large extent hidden; in the floor of the cranial cavity it forms an uneven, median elevation that extends from a point about an inch in front of the foramen magnum to a point about an inch behind the anterior boundary of the floor. The body is hollow; it is composed of a thin shell of bone enclosing a large air space, called the **sphenoidal sinus**, divided by a thin bony septum into a right and a left half.

The **small wings** form the posterior part of the roof of the orbit, but are seen

best in the floor of the cranial cavity; they resemble the wings of a bird very closely, and extend out from the anterior part of the upper surface of the body.

The **great wings** are behind the small wings and are at a lower level. They are large plates that spread out from the sides of the body in the base of the skull, and their antero-lateral parts turn up into the side of the skull. One surface of a great wing is seen in the floor and side wall of the middle cranial fossa; another surface is seen in the orbit forming the greater part of its lateral wall; a third surface is seen on the side of the skull in front of the squamous temporal; and, continuous with that surface, a fourth surface is seen on the lower aspect of the skull, lateral to the root of the pterygoid process.

The **pterygoid processes** resemble wings only remotely [πτέρυξ (pteryx) = a wing]. Each of them is a large process that projects downwards from the junction of body and great wing and is seen on the lower surface of the skull forming the lateral boundary of a choana. Each pterygoid process consists of two plates or laminæ, a lateral and a medial. It is the *medial lamina* which forms the side of the choana, like the jamb of a door; and it is separated from the *lateral lamina* by a hollow or fossa of some size called the *pterygoid fossa.*

The **ethmoid bone** (Figs. 138, 145, 146, 148, 172, pp. 156, 168, 170, 175, 206) lies in front of the body of the sphenoid and below the frontal bone, and is to a large extent hidden. It is set between the two orbits, so that the distance between the eyes depends upon the breadth of the ethmoid. It consists of a median perpendicular lamina, a pair of cribriform laminæ, and a pair of labyrinths.

The **perpendicular lamina** is a thin median plate of bone that forms part of the median partition or septum of the interior of the nose. If it has not been broken away, one can see it by looking into the nasal cavity through the apertura piriformis. The upper edge of the plate projects into the cranial cavity, forming a conspicuous crest, called the **crista galli** (cock's comb), in the median part of the anterior cranial fossa.

The **cribriform laminæ** are narrow horizontal plates placed one on each side of the crista galli. They lie in the floor of the anterior cranial fossa and, at the same time, in the roof of the cavity of the nose. They are full of little holes through which the olfactory nerves pass up from the nose to reach the brain [ἠθμός (ēthmos) = a colander; *cribrum* = a sieve].

The two **labyrinths** constitute the main part of the ethmoid bone. Each labyrinth is placed high up in the side wall of the cavity of the nose; the upper, narrow part of the nasal cavity separates it from the perpendicular lamina in the septum. The labyrinth is composed of very thin papery bone enclosing a number of irregular, small cavities which communicate with each other—hence the name "labyrinth." The cavities are called the **ethmoidal cells** or **sinuses.** From the medial or nasal side of the labyrinth, two thin plates of bone project into the nasal cavity and then curl downwards; they are called the **superior** and **middle nasal conchæ** [κόγχη (conchē) = a mussel-shell]. The lateral surface of the labyrinth is a smooth square plate of bone that forms a great part of the medial wall of the orbit, where it is easily seen; its anterior end is about half an inch behind the rim of the orbit, and it measures over an inch from before backwards and over half an inch in height.

The two **nasal bones** (Figs. 134, 181, pp. 131, 210) lie side by side in the bridge of the nose.

The **lacrimal bone** (Figs. 134, 135, 178, pp. 131, 137, 209) is a thin uneven scale of bone about the size of a finger-nail. It lies in the medial wall of the orbit near the orbital rim, immediately in front of the lateral surface of the ethmoid labyrinth. It is named "lacrimal" because its anterior part helps to form the groove in which the lacrimal sac lies. It is so thin that it is often broken away in a skull that has had much handling.

The **inferior nasal concha** (Figs. 145, 148, 177, pp. 156, 175, 208) is a thin, rough plate of bone attached by one of its edges to the lower part of the side wall of the nasal cavity; it projects into the cavity and its free edge curls downwards.

The **vomer** [= a ploughshare] is a thin bone which forms the posterior and postero-inferior part of the nasal septum (Figs. 137, 145, 179, pp. 156, 168, 209).

It lies behind and below the perpendicular lamina of the ethmoid. It is easily recognised in a skull turned upside down, for it is the partition between the two choanæ. At its upper end or border it splits into a right and a left half, called the **alæ** of the vomer, which spread out for a little distance on the lower surface of the body of the sphenoid bone [*ala* = a wing.]

The two **maxillæ** form the upper jaw. Each maxilla has a main part or body and four processes—alveolar process, frontal process, palatine process, and zygomatic process (Figs. 134, 135, 137, 146, 182, pp. 131, 137, 143, 170, 211).

The **body** of the maxilla lies below the orbit, and lateral to the lower part of the nasal cavity. Its superior or *orbital surface* forms a large part of the floor of the orbit; its medial or *nasal* surface forms the lower part of the side wall of the cavity of the nose; its anterior or *facial surface* is the bone alongside the lower part of the apertura piriformis; its *posterior surface* is the rounded surface of bone that looks backwards into the space below the great wing of the sphenoid. Those surfaces are like the walls of a box, for the body of the maxilla encloses a large cavity, called the **maxillary sinus**, which occupies its whole interior.

The **frontal process** of the maxilla is the projection which extends upwards to reach the frontal bone. It lies behind the nasal bone, taking share in the formation of the bony part of the external nose; it has a large share also in forming the medial part of the rim of the orbit.

The **zygomatic process** is the thick spur of bone that stands out from the junction of facial and posterior surfaces of the body, and is united to the zygomatic arch.

The **alveolar process** is the thick curved ridge which projects downwards from the body and carries the teeth. Its lower border is called the *alveolar margin*, and if the teeth have fallen out after the skull was dried, it presents a row of pits or *alveoli* for the roots of the teeth [*maxilla*, a diminutive of *mala*, which = the bone of the cheek that carries the teeth]. When teeth are removed during life the walls of the corresponding alveoli are soon absorbed and the alveolar process is greatly reduced in size at those points; in the skull of a person who had long lost all the teeth the alveolar process is a mere inconspicuous rim. The alveolar processes of the two maxillæ make a horseshoe-shaped ridge which bounds the hard palate in front and at the sides. The posterior part of the alveolar process is called the *tuberosity of the maxilla*.

The **palatine process** is the horizontal shelf of bone which forms the anterior, larger part of the half of the hard palate of its own side.

The **zygomatic bone** (Figs. 134, 135, 187, pp. 131, 137, 216) makes the hard prominent part of the cheek; it forms the anterior part of the zygomatic arch and has a considerable share in forming the lower and lateral parts of the rim of the orbit. The part of the zygomatic bone which projects backwards to articulate with the zygoma of the temporal bone is called its **temporal process**; the part that projects upwards along the side of the orbit to articulate with the frontal bone is called its **frontal process**, or *fronto-sphenoidal process*, because it articulates with the great wing of the sphenoid bone also.

The **palatine bone** lies in the posterior part of the hard palate and in the side wall of the nasal cavity. It is a small bone, and consists of three parts: a horizontal part, a perpendicular part, and a pyramidal process. The horizontal part is easily located; the other two parts are not (Figs. 137, 146, 185, pp. 143, 170, 214).

The **horizontal part** is the thin, square plate of bone that forms the posterior quarter or third of the corresponding half of the hard palate.

The **perpendicular part** is a still thinner plate of bone; it lies on the side wall of the cavity of the nose, directly in front of the medial lamina of the pterygoid process, and in many skulls one can see the suture between its posterior edge and the medial lamina by looking into the nose through the choana. The anterior and larger part of the lateral surface is closely applied to the medial surface of the maxilla, but the posterior part is further back than the maxilla and forms the medial wall of a space called the pterygo-palatine fossa that will be examined later. Its upper end is surmounted by two processes, an *orbital process* in front and a

sphenoidal process behind; the gap between the two processes is called the **spheno-palatine notch.**

The **pyramidal process** is irregular and is often so closely united to the bones among which it lies that it is difficult to see its outlines. It projects from the posterior border of the palatine bone just where the horizontal and perpendicular parts join one another, and it fits in (1) between the tuberosity of the maxilla and the lower part of the pterygoid process of the sphenoid, and (2) between the lower parts of the two laminæ of the pterygoid process.

The **mandible** (Figs. 134, 135, 149, 150), or lower jawbone, has a horseshoe-shaped **body** and two flat, broad **rami** which project upwards from the posterior parts of the two halves of the body. The body bears the teeth [*mandĕre* = to chew]. Two processes project upwards from the upper border of each ramus; the anterior one is named the **coronoid process**; the posterior is named the **condyloid process**, which is divided into a *head* and a *neck*. The head articulates with the temporal bone, forming a diarthrodial joint called the *mandibular joint*. In the living person, the projection that overlaps the ear-hole from in front is called the *tragus*. The head of the mandible can be felt immediately in front of the tragus when the mouth is shut; as the mouth is opened the head can be felt gliding downwards and forwards. The **angle** of the mandible is the point where the posterior border of the ramus joins the lower border; it is easily felt two or three finger-breadths below the lobule of the ear. The oblique opening on the medial side of the ramus is called the **mandibular foramen**; the narrow groove that extends downwards and forwards from the lower margin of the foramen is called the **mylo-hyoid groove**; the oblique ridge on the medial side of the body is called the **mylo-hyoid line.**

The mandible is a separate bone, and is not dealt with under the skull as a whole. It is an important bone, and is described on p. 177.

THE SKULL AS A WHOLE.

The **exterior of the skull** is examined from five points of view: from the front, the back, above, below, and from the side. Each of those aspects is called a "norma" [=a square]; and they are named, respectively, norma frontalis, occipitalis, verticalis, basalis, and lateralis. There are no boundary lines between the aspects, for they overlap each other to a large extent.

Norma Verticalis.

The **top of the skull** has convex contours, so that any impact received at a particular point is distributed over a considerable area, and the danger of fracture is thereby lessened. The horizontal outline varies considerably in different specimens, but in most European skulls the outline is ovoid, the wider part being nearer the back than the front.

The top of the skull is made of portions of four bones—the **frontal** bone in front, the **occipital** bone behind, and the right and left **parietal** bones in the middle between them, the occipital bone having only a very small share. The bones are united by serrated *sutures*, the jagged, saw-like edges of the bones interlocking with each other [*sutura* = a seam]. If the skull is that of a young adult the sutures are seen distinctly as irregular lines between the bones. If the skull is that of an old person the sutures are more or less obliterated and the bones are fused, but the positions of the sutures are usually indicated by narrow, irregular linear depressions. In many skulls there are small circumscribed pieces of bone, like islands, interposed in the sutures in certain places; those islands are called **sutural bones.**

The suture that unites the frontal bone to the two parietal bones arches across the skull from side to side, and is called the **coronal suture** [*corona* = a curved line, circle, crown]. The suture that unites the occipital bone to the two parietal bones is called the **lambdoidal suture**, because it is shaped like the Greek capital letter

Lambda [Λ = L]. The suture between the two parietal bones is called the **sagittal suture**; that name is given because in an infant's skull the sagittal suture, the lambdoidal suture, and an unossified region, called the frontal fonticulus or antero-median fontanelle, together, resemble a heraldic arrow [*sagitta* = an arrow].

The point where the sagittal suture meets the coronal suture is called the **bregma** [βρέγμα = the front part of the head]. At birth the parts of the frontal and parietal bones around the bregma are not fully ossified, and leave a large, lozenge-shaped membranous area which is yielding to the touch and is called the *antero-median fontanelle*, because it rises and falls with every beat of the heart; in a healthy child the bones have ossified and closed the fontanelle by the end of the second year. The coronal suture slopes downwards and forwards from the top of the skull, so that the bregma is the furthest back point on the suture, and it lies just in front of the mid point of a line drawn from one external acoustic meatus to the other in the vertical transverse plane, and is occasionally felt as a depression in the living head.

The point at which the sagittal suture meets the lambdoid suture is called the **lambda**.

The **vertex** or highest point of a skull held in proper position is on the sagittal suture near its middle, but varies slightly in different skulls. The **parietal foramen** is a small hole present in many skulls in the parietal bone near the sagittal suture about 35 mm. from the lambda. It is usually only big enough to admit a pin; a small artery and vein pass through it; the vein connects the veins of the scalp with the superior sagittal venous sinus which lies along the middle line on the inside of the skull cap, and infection can travel along the vein from a wound in the scalp and attack the sinus.

The *sagittal fontanelle* is an unossified space in the region of the parietal foramina; it is usually closed at birth. If it is not closed at birth, the parietal foramen in the adult skull will probably be larger than usual, *i.e.*, large enough to admit a match. The point on the sagittal suture between the two parietal foramina is called the **obelion** [ὀβελός (obelos) = ÷, a mark used by literary commentators].

The **parietal eminence** or **tuberosity** is the most convex point of the parietal bone and is the region where the top of the skull and the side and the back merge into each other; its position varies with the shape of the skull, but none the less it is used as a landmark, for it is fairly easily identified in the living head. It overlies the part of the brain called the supramarginal gyrus.

The frontal eminences anteriorly and the temporal lines at the sides are visible, but will be dealt with later. In some specimens the zygomatic arches can be seen when the skull is looked at from above.

Norma Frontalis.

The **front of the skull** (Fig. 134) is uneven in contour and outline, and its two halves are seldom quite symmetrical, though nearly so. Almost more than any other aspect of the skull it varies with age, race, and sex, besides displaying individual variations in the details of its configuration.

The front of the skull is made up of: the frontal region or forehead; the two orbits; the bony external nose, between and in front of the orbits; the apertura piriformis; the two maxillæ, forming the upper jaw; the zygomatic bone or cheek bone, below the lateral part of the orbit; and the mandible, when it is in place.

Frontal Region.—The forehead is formed by the frontal bone, and is convex. Superiorly it merges into the top of the skull; inferiorly it is limited by the orbits and the root of the nose. The **nasion** is the point in the median plane at the root of the nose where the two nasal bones articulate with the frontal bone; it is opposite the anterior extremity of the brain. The **glabella** is the small region immediately above the nasion, between the two eyebrows [*glabellus* = without hair]. The **superciliary arch** is the smooth elevation that arches upwards and in a lateral direction from the glabella, a little above the margin of the orbit. Behind it, in the interior of the frontal bone, there is usually a large air-space called the **frontal sinus** (Figs. 145, 148, pp. 168, 175), from which a short channel

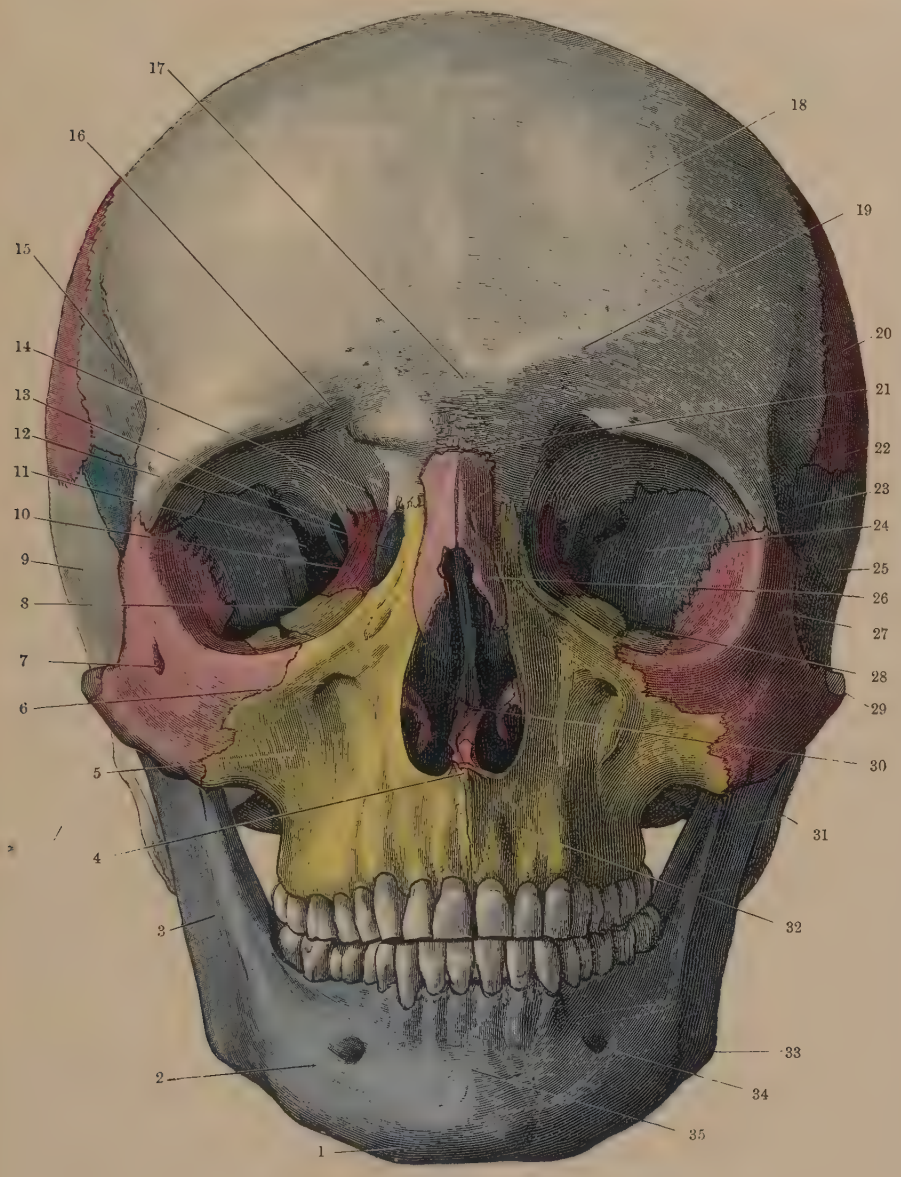

FIG. 134.—THE FRONT OF THE SKULL.

The nasal bones, lateral surface of the ethmoid, vomer, inferior conchæ, zygomatic, and parietal bones are coloured red. The sphenoid, lacrimal, perpendicular part of the ethmoid and middle conchæ and mandible are coloured blue. The maxillæ are coloured yellow. The frontal and temporal bones are left uncoloured.

leads down into the cavity of the nose. The **frontal eminence** or **tuberosity** is the most convex part of each half of the frontal bone; it is situated about two finger-breadths above the lateral end of the superciliary arch.

The **supra-orbital margin** or upper margin of the orbital opening is a curved border. At the highest point of the curve, about two finger-breadths from the median plane, there is usually a small notch called the **supra-orbital notch**; the notch can be felt in the living head by the thumb nail pressed on the margin *from below*. Laterally, the supra-orbital margin ends in a prominent projection which is named the **zygomatic process** of the frontal bone because it curves downwards and articulates with the upstanding frontal process of the zygomatic bone. The zygomatic process (external angular process) is easily felt at the lateral end of the eyebrow hairs and is one of the most serviceable landmarks in the head. The ridge that curves upwards and backwards from it is the anterior part of the **temporal line**, and can be both felt and seen in thin people between the brow and the temple.

The two halves of the **frontal bone** are separable at birth and are not fused together completely till some period between the sixth and the tenth year. The suture between the halves is called the *frontal suture*. Remains of the suture can often be seen in the adult skull at and above the glabella, and in some cases, especially in the more civilised races, the whole suture persists till late in life; it is sometimes called the *metopic suture* [μετόπη (metopē) = the interstice between two beam ends (in Doric architecture)]. The point in the middle of the forehead, on the shortest diameter between the two temporal lines, is usually a little above the glabella and is called the **ophryon** [ὀφρύs (ophrys) = the brow].

The **superciliary arch** is more prominent in men than in boys and women; the lower part of the forehead therefore protrudes more in a man, and the forehead is less vertical. Though the arch overlies the frontal sinus it is not produced by the sinus, for in a skull in which the sinus is small or absent the arch may be prominent. The upper part of the orbicularis oculi (corrugator supercilii) arises from the medial end of the arch. The **frontal eminence** is the region where the views of the skull from the front, from above, and from the side overlap; it is more conspicuous in the more vertical foreheads of boys and women than in men; it overlies the part of the brain called the middle frontal gyrus.

The **supra-orbital margin** is the lower limit of the forehead. Its lateral two-thirds is thin and sharp and bends down to the zygomatic process. The medial third is rounded; it bends down into the medial margin of the orbit, and its end is sometimes called the *medial angular process*. The **supra-orbital notch** is situated at the junction of the medial third and lateral two-thirds of the margin; the supra-orbital vessels and nerves lie in it as they pass out of the orbit and turn upwards on to the forehead to reach the scalp. In the floor of the notch there is a minute foramen through which the frontal diploic vein passes to join the supra-orbital vein. In some skulls there are two shallow notches instead of one; in others the notch is converted into a **supra-orbital foramen** by a bridge of bone.

Nasus Externus.—The bony part of the **external nose** is formed by the two *nasal bones* in the bridge of the nose, and, on each side, by the *frontal process of the maxilla*, which lies behind the nasal bone in the side of the nose, and forms also the medial margin of the orbital opening.

Apertura Piriformis.—The **apertura piriformis** is bounded above by the lower margins of the two nasal bones, and at the sides and below by the sharp anterior margins of the frontal processes and bodies of the two maxillæ. It is the anterior opening into the **cavity of the nose**, and one can look through it into the cavity and out through the choanæ at the far end. The cavity is divided by a thin median partition or **septum** into a right and a left half. Each half is called a cavity of the nose or nasal cavity, and the term may mean, according to the context, either the whole cavity or one of the halves. Most of the anterior part of the septum is composed of a plate of cartilage; the septum is therefore always incomplete in a macerated and dried skull, and considerable parts of the bony septum may have been broken away. If the bony septum has not been broken the principal part seen through the apertura piriformis is the *perpendicular lamina of the ethmoid* bone, which forms the upper part of the septum; it is usually slightly bent to one or other side.

The side wall of the nasal cavity is very uneven, because the three rough curled plates of bone called the *conchæ* project from the side wall and hang down into the cavity like curtains. The portions of the cavity which lie below the conchæ and lateral to them are called the *meatuses* of the nose—superior, middle,

and inferior. The superior concha is too far back to be seen through the apertura piriformis, but the inferior and middle conchæ and meatuses can be seen if the conchæ have not been broken away. The middle concha is on a level with the medial wall of the orbit, and is rather less liable to be broken off. The inferior concha is situated about half an inch above the floor of the nose, and even should it be broken away the ridge on the side wall of the cavity to which it was attached can be seen.

Maxillary Region.—A sharp spur of bone, called the **anterior nasal spine**, projects forwards from the two maxillæ at the lower margin of the apertura piriformis in the middle line; it is imbedded in the lower part of the septum of the nose immediately above the upper lip. In a much-handled skull it is usually broken off.

If the walls of the alveoli for the teeth have not been absorbed, smooth vertical ridges, produced by the roots or fangs of the teeth, are seen above the alveolar margin. The largest of those ridges corresponds to the root of the canine tooth and is called the **canine eminence**. (The *canine* tooth is the third tooth, counting from the middle in front; and the first two teeth are called *incisors*.) The **canine fossa** is the wide shallow depression above and lateral to the canine eminence, reaching up almost to the lower margin of the orbit. The *infra-orbital foramen* is the opening just above the canine fossa, about 5 mm. below the lower margin of the orbit; in the living person it is about a finger's-breadth lateral to the side of the nose, and may be felt indistinctly if pressure is made there with the finger-tip. It transmits the infra-orbital vessels and nerve.

Between the medial ends of the two supra-orbital margins there is a horseshoe-shaped suture uniting the frontal bone to the upper ends of the two nasal bones and frontal processes of the maxillæ. The middle of the suture is the **nasion**, from which a suture runs down the middle of the bridge of the nose between the two nasal bones; the most prominent point on the suture is called the **rhinion** [ῥίς (rhis) = the nose]. On each side of the bony external nose there is a linear suture between the nasal bone and the frontal process of the maxilla. On the nasal bone, at a varying point, there is often a minute foramen through which a vein passes from the skin to the interior of the nose and thence upwards to join the commencement of the superior sagittal sinus in the cranial cavity; infection can pass along the vein and attack the sinus. Some fibres of the procerus are attached to the nasal bone. The angular head of the quadratus labii superioris arises from the upper part of the frontal process of the maxilla; the nasalis arises from the bone near the lower boundary of the apertura piriformis.

The pliable, lower part of the external nose has a framework of cartilage united to the sharp margins of the apertura piriformis by fibrous tissue. The **apertura piriformis** is oblique, and is ovoid in outline with the narrow end above and in front. It measures about 30-35 mm. in height, and about 25 mm. across its widest part; it is shorter, wider, and more vertical in flat-nosed races. Parts of the septum and side walls of the **nasal cavity** can be seen through it, and also the floor and part of the roof when the skull is tilted.

If the bony **septum** is complete, its anterior edge forms an angle into which the septal cartilage fits. The upper limb of the angle is the perpendicular lamina of the ethmoid. The lower limb is formed *anteriorly* by the *incisor crest* of the maxillæ, a rough ridge which stands up from the junction of the palatine processes of the two maxillæ and is continuous with the anterior nasal spine; and *posteriorly* by the lower and anterior part of the vomer. On the **side wall** note again the inferior and middle conchæ. The inferior concha reaches the apertura piriformis. The middle concha is shorter than the inferior and does not reach so far forwards; the interval between it and the septum is very narrow, and also the part of the middle meatus that lies lateral to it is very narrow because a part of the labyrinth of the ethmoid, called the *bulla ethmoidalis*, bulges into the meatus; the lower part of the middle meatus is roomier, and in its side wall the opening of the maxillary sinus can be seen. Identify the floor of the fossa for the lacrimal sac in the orbit and locate it in the side wall of the nasal cavity, just in front of the middle meatus. The part of the **roof** visible is only the anterior, sloping part, which is formed by the nasal bone and the nasal part of the frontal bone and its frontal spine—a projection that juts down into the roof of the nose and is hidden from the exterior by the nasal bone. The whole **floor** can be seen. While the upper part of the nasal cavity is very narrow and the roof a mere groove, the floor is half an inch in width; it is made of the palatine process of the maxilla and the horizontal part of the palatine bone, which, at the same time, constitute the hard palate and are better seen on the lower surface of the skull.

The **anterior nasal spine** consists of a spicule from each maxilla; its apex is called the **akanthion** [ἄκανθα (akantha) = a thorn]. Running downwards from it there is the *intermaxillary suture*, the lower end of which, in the front of the alveolar margin, is called the **prosthion** [πρόσθιος = foremost]. On each side of the suture, immediately below the apertura piriformis, there is a shallow depression called the **incisive fossa**. The **canine fossa** lies below the infra-orbital foramen on the anterior wall of the maxillary sinus; the caninus muscle arises from its

floor. The infra-orbital head of the quadratus labii superioris arises from the infra-orbital margin above the infra-orbital foramen; the incisive slips of the orbicularis oris arise from the incisive fossa and the canine eminence.

Lateral to the canine fossa, the suture between the maxilla and the zygomatic bone can be seen. It begins at the middle of the lower margin of the orbit and ends at the lower border of the zygomatic arch in line with the lateral margin of the orbit. The **zygomatico-facial foramen** is a small hole on the zygomatic bone about 5 mm. below the lateral part of the lower margin of the orbit; it is only big enough to admit a pin; it transmits the zygomatico-facial branch of the zygomatic nerve and a small branch of the lacrimal artery; sometimes it is represented by two openings instead of one. Below the foramen there is a smooth low eminence, called the *malar tuberosity*, which gives origin to the zygomaticus; the eminence is conspicuous in some thin people.

Orbita (Figs. 134, 147, pp. 131, 172).—The **orbit** is a cavity of a shape not unlike a four-sided pyramid laid on one side. The sides are called the *roof*, the *floor*, the *medial wall* and the *lateral wall*. The *base* of the pyramid is the opening on to the face, and the boundaries of the base are the **margins of the orbit**. At the *apex* there is a large aperture; it is the medial and lower part of a cleft called the **superior orbital fissure** (Fig. 148, p. 175); the rest of the fissure extends forwards, upwards, and in a lateral direction *between the roof and the lateral wall* of the orbit, becoming narrower as it does so. The fissure leads back into the middle cranial fossa, and its size varies in different skulls.

Between the roof and the medial wall there are three foramina, the optic and two ethmoidal. The **optic foramen** is the round aperture just above and medial to the apex of the orbit; it leads back into the middle cranial fossa. The **anterior** and **posterior ethmoidal foramina** are further forward; they are about half an inch apart and the anterior is the larger. They lead into canals that open into the median part of the anterior cranial fossa, but their openings there are difficult to find.

The **fossa for the lacrimal gland** [*lacrima* = a tear] is a broad, smooth depression of varying depth, in the anterior and lateral part of the roof of the orbit, under shelter of the zygomatic process of the frontal bone. The **fossa for the lacrimal sac** (Fig. 135, p. 137) is on the medial wall just within the orbital margin. If the lacrimal bone is broken away, only part of the fossa will be seen, for it is a fairly broad vertical groove partly on the lacrimal bone and partly on the frontal process of the maxilla. The fossa becomes continuous with the **naso-lacrimal canal**, the upper opening of which is seen at the *junction of the medial wall and floor* of the orbit; the canal is a short tunnel that leads down into the inferior meatus of the nose under cover of the anterior part of the inferior concha—a fact which one can demonstrate by pushing a match down through the canal from the orbit. The lacrimal sac is a wide tube, blind at its upper end, and its lower end is continuous with the naso-lacrimal duct which goes down through the canal into the nose. The lacrimal gland produces the lacrimal fluid, most of which evaporates, while the remainder passes into the sac and thence into the nose, any excess of fluid overflowing the eyelids as tears. The gland is at the upper, lateral part of the orbit, and the sac is at the lower, medial part; that arrangement ensures that the front of the eye shall be well washed.

Between the floor and the lateral wall of the orbit there is a long cleft, called the **inferior orbital fissure**, which opens into a space behind the maxilla called the infra-temporal fossa. The **infra-orbital groove** is in the floor of the orbit. It begins about the middle of the inferior orbital fissure and runs nearly straight forwards. The anterior part of it has a thin roof of bone and is called the **infra-orbital canal**, and the canal opens on the face as the infra-orbital foramen. In one or both orbits the groove may be roofed over in all its length; in that case one can locate it by passing a pointer back through the infra-orbital foramen.

The chief **relations** (Figs. 147, 148, pp. 172, 175) of the orbit are the following: *Superiorly*—The frontal sinus to a varying extent; the anterior cranial fossa, containing the frontal lobe of the brain. *Inferiorly*—The maxillary sinus in the body of the maxilla; the anterior part of the infra-temporal fossa. *Medially*—Near the apex, the sphenoidal air sinus in the body of the sphenoid; further forward, the ethmoidal air sinuses, which separate the orbit from the cavity

of the nose; within the orbital margin, the thin floor of the fossa for the lacrimal sac intervenes between the orbit and the nasal cavity, and an operator can reach the lacrimal sac by passing from the nose through the thin floor of the fossa, if he wants to avoid a scar at the medial corner of the eye. *Laterally*—The posterior part of the orbit is related to the middle cranial fossa, which lodges the temporal lobe of the brain; the anterior part is related to the anterior part of the temporal fossa (p. 138)

The two **orbits** are placed so that their medial walls are almost parallel, while their lateral walls are nearly at right angles to each other; therefore the axis of each orbit is directed forwards and in a lateral direction; none the less, the axes of the two eyeballs are antero-posterior and parallel. Each orbit is about 50 mm. long.

The **orbital opening** or base of the orbit is more or less four-square, measuring about 40 mm. each way; it is directed forwards and slightly in a lateral direction, and it is tilted so that the upper and lower margins slope slightly downwards from medial to lateral side. The *lower margin* of the opening is formed by the maxilla and the zygomatic bone. *The lateral margin* is formed by the frontal process of the zygomatic bone and the zygomatic process of the frontal bone; the suture between the processes, near the upper angle of the opening, can usually be felt in the living person; just within the middle of the margin, about 10 mm. below the suture, there is a slight eminence felt by the finger tip rather than seen, for the attachment of the lateral palpebral raphe and the check and suspensory ligaments of the eye. The *upper margin* is the supra-orbital margin of the frontal bone, and has the supra-orbital notch or foramen at the junction of the rounded medial third and sharp lateral two-thirds; the supra-trochlear nerve and the frontal vessels, passing out of the orbit on to the forehead, cross the margin about 5 mm. medial to the supra-orbital notch and may produce a shallow groove. The *medial* margin is formed by the medial angular process of the frontal bone and the frontal process of the maxilla; the medial palpebral ligament and orbicularis oculi are attached to the margin just in front of the groove for the lacrimal sac.

The orbit being pyramidal, its walls are more or less triangular in outline. The *roof* is concave; it is formed by the orbital plate of the frontal bone, complemented posteriorly by the small wing of the sphenoid. The frontal sinus extends for a variable distance backwards *in* the roof of the orbit between the two tables of the orbital plate. At the lateral angle of the roof there is the wide **fossa for the lacrimal gland**, part of which protrudes beyond the fossa into the upper eyelid. At the medial angle the trochlea is attached; the attachment may be marked by a very small pit or by a spicule of bone, the **fovea** vel **spina trochlearis**, or by both; the trochlea is a small fibro-cartilaginous ring through which the tendon of the superior oblique muscle of the eyeball passes.

The *lateral wall*, in the greater part of its extent, is formed by the great wing of the sphenoid, but the anterior part is formed by the fronto-sphenoidal process of the zygomatic bone. On the anterior part there is a small aperture called the **zygomatic foramen**, through which the zygomatic nerve leaves the orbit, accompanied by a small branch of the lacrimal artery; sometimes there are two apertures instead of one. A great part of the lateral wall is separated posteriorly from the roof by the **superior orbital fissure**, which is bounded medially by the body of the sphenoid, above by the small wing, below and laterally by the great wing. The two heads of the lateral rectus muscle of the eyeball lie across the wide, lower and medial part of the fissure. Some of the structures transmitted by the fissure pass between the two heads; the others pass above both heads. They are:—

(*a*) *Between the Heads.*—The ophthalmic vein or veins, passing backwards to join the cavernous sinus [ὀφθαλμός (ophthalmos) = *oculus* = the eye]; the abducent nerve, the naso-ciliary nerve, and the two divisions of the oculomotor nerve, all passing forwards.

(*b*) *Above the Heads.*—The trochlear nerve, the frontal nerve, and the lacrimal nerve, all passing forwards, in that order from medial to lateral side; a small branch of the lacrimal artery passing backwards to the dura mater; occasionally a small branch of the middle meningeal artery passing into the orbit; and sympathetic twigs from the carotid plexus [μῆνιγξ (mēninx) = any membrane, but especially a membrane around the brain].

The *floor* is formed chiefly by the orbital surface of the body of the maxilla, which is, at the same time, the roof of the maxillary sinus. But the antero-lateral corner of the floor is formed by the zygomatic bone; and the posterior corner is formed by the orbital process of the palatine bone—that is, the anterior of the two projections on the upper end of the perpendicular part of the palatine bone.

A great part of the floor is separated from the lateral wall posteriorly by the **inferior orbital fissure**, which is bounded *above* by the great wing of the sphenoid, *below* by the orbital surface of maxilla and the orbital process of the palatine bone, while its anterior end is closed either by the zygomatic bone or by an articulation between the great wing and the maxilla. The fissure *transmits*: the maxillary nerve, as it changes its name to infra-orbital nerve; the infra-orbital vessels; the zygomatic nerve; small twigs from the spheno-palatine ganglion to the periosteum of the orbit; a vein connecting the ophthalmic veins with the pterygoid venous plexus in the infra-temporal fossa.

The **infra-orbital groove** and **canal** lie in the floor of the orbit and in the roof of the maxillary sinus. The infra-orbital nerve (the continuation of the maxillary nerve), accompanied by the infra-orbital vessels, traverses the groove and canal, sends down branches through the facial wall

of the sinus to the incisor, canine, and premolar teeth, and enters the face through the infra-orbital foramen.

The upper end of the **naso-lacrimal canal** separates the anterior part of the floor from the medial wall; and at the medial corner of the floor, just lateral to the canal, there is a shallow depression for the origin of the inferior oblique muscle of the eyeball.

The *medial wall* of the orbit is formed, from behind forwards, by: the anterior part of the side of the body of the sphenoid; the lateral surface of the labyrinth of the ethmoid; the lacrimal bone; the posterior part of the frontal process of the maxilla. The optic foramen and the ethmoidal foramina lie between the medial wall and the roof. The **optic foramen** lies between the body of the sphenoid and the roots of the small wing; it transmits the optic nerve and the ophthalmic artery; note that the ophthalmic vein and artery pass through different apertures. The **anterior** and **posterior ethmoidal foramina** are the orbital ends of the anterior and posterior ethmoidal canals, which transmit vessels and nerves of the same name.

The **fossa for the lacrimal sac** is formed by the anterior part of the lacrimal bone and the posterior part of the frontal process of the maxilla; its margins are called the **lacrimal crests**; the anterior crest is part of the medial margin of the orbit; the posterior crest gives attachment to the pars lacrimalis of the orbicularis oculi muscle. The upper end of the suture between the two bones is called the **dacryon** [δάκρυον (dakryon) = *lacrima* = a tear].

Norma Occipitalis.

The **back of the skull** is markedly convex and has the outline of a wide arch; the arch is widest usually at the level of the parietal eminences. The bones seen are portions of the two parietal bones, and a portion of the occipital, while the mastoid portion of the temporal bone and its mastoid process are visible at the lower corner on each side. The parts already seen on the top of the skull but seen again in the back are the parietal eminences, the posterior part of the sagittal suture, the parietal foramina, the lambda, and the lambdoid suture, which is now seen in the whole of its extent.

From the lower end of the lambdoid suture, on each side, the *occipito-mastoid suture* descends between the occipital bone and the mastoid temporal. The **mastoid foramen** is the aperture situated in the suture or on the mastoid temporal near the suture, and it varies in size from a pin point to a match; it passes through the skull wall and opens internally in the posterior cranial fossa into the groove for the sigmoid part of the transverse venous sinus; it transmits an emissary vein that connects the sinus with the veins on the outside of the head, and a small branch of the occipital artery; it is on a level with the external acoustic meatus and about three finger-breadths behind it.

The **external occipital protuberance** or **inion** is the projection, usually well marked, in the median plane, at the lower part of the back of the skull, about midway between the lambda and the foramen magnum. It is easily felt in the living person just above the nape of the neck, and is a useful landmark. If two protuberances are felt there, one below the other, the lower one is the normal protuberance. The **superior nuchal line** is the blunt, curved ridge that arches laterally from the protuberance. The protuberance and the right and left superior nuchal lines mark the boundary between the back of the head and the back of the neck [*ἰνίον* (inion), used indifferently for back of head or nape of neck; *nucha* = nape of neck]. The part of the skull seen in perspective below the protuberance and the superior nuchal lines belongs to the lower surface of the skull.

In many skulls there is a curved ridge, called the *highest nuchal line*, immediately above the superior nuchal line; it gives attachment to the tendinous sheet in the scalp called the galea aponeurotica [*galea* = a helmet].

In most skulls the boss or most posterior part of the back of the head is not at the protuberance, but is a little distance above it.

The **lambda** is situated between two and three inches above the protuberance. In many heads it can be felt by the finger tip as an apparent depression, owing to the prominence of the apical part of the occipital bone; it overlies the interval between the two halves of the brain a little behind the cleft in the brain called the parieto-occipital fissure.

Norma Lateralis.

The **side of the skull** is divisible into two parts: a larger part above and behind; a smaller part below and in front. The smaller part belongs to the face,

FIG. 135.—NORMA LATERALIS OF THE SKULL

The occipital, sphenoid, and lacrimal bones and the mandible are coloured blue. The parietal, zygomatic, and nasal bones are coloured red. The temporal, frontal, ethmoid, and maxillary bones are left uncoloured.

32. Anterior nasal spine.

and is very uneven. The larger part is the brain-case; it is convex, and is ovoid in outline.

Many of the parts seen already when the posterior and the upper and the anterior aspects of the skull were examined, are seen again in the lateral aspect, such as the superior nuchal line, the lambdoid suture, the occipito-mastoid suture, the mastoid foramen, the parietal eminence, the coronal suture, the frontal eminence, the superciliary arch, the bony external nose, the maxilla, the zygomatic

bone, the margins of the orbit, and the zygomatic process of the frontal bone. Those are to be identified again, and the following parts looked for.

Linea Temporalis.—The **temporal line** is a long, curved ridge which begins at the zygomatic process of the frontal bone. From there it arches upwards and backwards across the frontal bone along the lateral margin of the forehead; then backwards over the parietal bone, passing just below the parietal eminence; having passed the parietal eminence it bends downwards and slightly forwards, and it ends by joining a blunt, prominent ridge, called the **supra-mastoid crest**, which is situated near the junction of the mastoid and squamous portions of the temporal bones. The anterior part of the temporal line is easily felt in the living head, above the zygomatic process of the frontal bone, between the forehead and the temple. Its middle part is usually represented by two lines, an upper and a lower, about half an inch apart; the bone between those lines is often more polished than that above and below, and if the lines are indistinct they can often be identified as the margins of a smooth strip along the upper part of the side of the skull. The posterior part of the line is frequently very indistinct. [*Tempora* = the temples, from *tempus* = time: grey hairs appear first in the temples.]

Fossa Temporalis.—The **temporal fossa** is the wide space outlined by the temporal line and the zygomatic arch. Parts of four bones are seen in the medial wall or **floor** of the fossa: (1) the lower part of the *parietal* bone; (2) the *squamous* part of the *temporal* bone, below the parietal bone and united to it by a curved suture called the *squamous suture*; (3) a small part of the *frontal* bone, in the upper and anterior part of the fossa; (4) a part of the *great wing of the sphenoid*, below the frontal and in front of the squamous temporal. In the anterior part of the fossa the four bones are so close together that a small circle, the size of a sixpence or a shilling, would include portions of them all; the region enclosed by such a circle is called the **pterion**, because one of the pairs of Hermes' wings was attached to the corresponding part of his head-piece [πτέρυξ (pteryx) = a wing].

In an adult male skull, the centre of the pterion is 30 mm. behind the zygomatic process of the frontal bone and at a rather higher level (10 mm.). It is a region made much use of as a guiding point when the position of deeper structures and their relations to the surface of the head are being explained. In many skulls sutural bones are present in the region of the pterion.

The part of the great wing of the sphenoid which is seen in the temporal fossa is called its *temporal surface*. The surface is limited below by a horizontal, antero-posterior ridge called the **infra-temporal line**. The ridge may be smooth and blunt or rough and prominent; it separates the temporal surface of the great wing from the infra-temporal surface, which is seen on the lower surface of the skull (Fig. 137, p. 143).

Arcus Zygomaticus.—The **zygomatic arch** is formed by the zygomatic bone and its temporal process and the zygoma of the temporal bone; it can be felt from end to end, and in thin people it stands out prominently between the temple and the side of the face. About an inch in front of the acoustic meatus the arch divides into two parts, called the **anterior** and **posterior roots** of the zygoma, which diverge from one another, the posterior root extending backwards, the anterior root turning medially towards the side of the skull.

The **anterior root** is easily found if one traces the lower border of the arch backwards; it is broad and its two surfaces look upwards and downwards; its lower surface is convex and is continuous, at the side of the skull, with a smooth, convex eminence, called the **articular tubercle**, which is seen on the lower surface of the skull in the front of a smooth concavity called the **mandibular fossa** (Fig. 137, p. 143). The lateral end of the lower surface of the root is rather prominent and is called the **tubercle of the root of the zygoma**; the tubercle is made use of as a landmark; it is felt just in front of and above the head of the lower jaw bone when the mouth is shut, and immediately above the head when the mouth is opened.

The **posterior root** is continuous with the upper border of the zygomatic arch. It joins the side of the skull and is continued backwards as a ridge immediately above the external acoustic meatus, and can be felt through the skin of the ear; it

ends by joining the supra-mastoid crest just behind the level of the meatus. The posterior root and the upper border of the arch are opposite the lower border of the brain.

From the lower aspect of the posterior root a smooth triangular prominence, called the **post-glenoid tubercle**, juts downwards immediately in front of the acoustic meatus, and extends medially for some distance, forming the posterior boundary of the lateral part of the mandibular fossa.

The **temporal line** gives attachment to the galea aponeurotica, to the temporal fascia, and to the uppermost fibres of the temporalis muscle; where the line is divided, the fascia is attached to the upper line, while the muscle fibres reach only the lower. The point where the temporal line crosses the coronal suture is called the **stephanion** [στέφανος (stephanos) = a circle or crown].

The **temporal fossa** contains the temporalis muscle, the middle and deep temporal vessels, the deep temporal nerves, the zygomatico-temporal branch of the zygomatic nerve, and a quantity of fat—all under cover of the temporal fascia; and the chief structures on the surface of the fascia are the superficial temporal vessels, the auriculo-temporal nerve, and the temporal branches of the facial nerve.

The depth and width of the fossa depend, in a measure, on the size of the temporal muscle, which is proportional to the size and weight of the mandible. The anterior and lower part of the fossa is much the deepest part and has an *anterior wall*, which separates it from the orbit; the anterior wall is formed by the zygomatic process of frontal, the frontal-sphenoidal process of zygomatic, and sometimes by the great wing of the sphenoid, where it articulates with that process of the zygomatic bone. On the part of the wall formed by the zygomatic bone there is a small aperture, called the **zygomatico-temporal foramen**, which transmits the zygomatico-temporal nerve, accompanied by a small branch of the lacrimal artery. The posterior border of the frontal process of the zygomatic bone gives attachment to the temporal fascia, and it shows a slight fulness or tubercle called the *marginal process*; the point where the posterior border of the frontal process joins the upper border of the zygomatic arch is called the **jugal point.**

The *floor* or medial wall of the fossa gives origin to the temporalis muscle, and is limited below by the infra-temporal line of the sphenoid, by the roots of the zygoma, and by a short ridge on the squamous temporal between the anterior root and the infra-temporal line. The part of the floor formed by the great wing sometimes shows grooves for the deep temporal arteries; and the part of the floor above the acoustic meatus shows a long and narrow vertical groove for the middle temporal artery.

The centre of the **pterion** is found in the living head, held in the proper horizontal position (p. 125) by drawing (1) a line horizontally backwards from the zygomatic process of the frontal bone for 30 mm., and (2) a line straight upwards from the posterior end of the first line for 10 mm. The pterion is opposite the point where the anterior branch of the middle meningeal artery is deeply imbedded in a groove on the inner side of the skull wall and is most liable to injury, and it is opposite the point on the brain where the stem of the lateral fissure breaks up into its three rami.

The suture between the two constituent bones of the **zygomatic arch** runs obliquely from above downwards and backwards.

The *upper* border of the arch, thin, sharp, and nearly horizontal, is formed chiefly by the zygoma, and gives attachment to the temporal fascia. The *lower* border, formed chiefly by the zygomatic bone, is thicker and rougher and extends much further forwards, but not so far back; it slopes downwards as it is traced forwards, for the arch is much deeper in front than behind; the lower border gives origin to the masseter muscle, which arises also from the *deep* surface of the arch, while the *superficial* surface is subcutaneous. The **tubercle at root of the zygoma** gives attachment to the temporo-mandibular ligament. The **anterior root** is not only continuous with the articular tubercle but also forms part of it. The **posterior root** and the **supra-mastoid crest** give attachment to the temporal fascia.

The *post-glenoid tubercle* is sometimes called the *middle root* of the zygoma; it corresponds to a prominent process developed in some mammals to prevent backward displacement of the mandible.

The **supra-meatal triangle** is a small, and often inconspicuous, depression below the posterior root of the zygoma, just behind the upper margin of the external acoustic meatus. Although small, it is very important, for the tympanic antrum lies about half an inch directly medial to it. The tympanic antrum is a cavity in the temporal bone, and often has to be opened into when diseased; the road to it is through the supra-meatal triangle, the position of which, therefore, has to be accurately known. If the depression of the triangle is fairly well marked, one may be able to feel it in the living head by pulling the ear vigorously forwards and downwards, and pressing with the finger tip immediately above and behind the meatus.

Meatus Acusticus Externus.—The entire **external acoustic meatus** is about 25 mm. long, but only the medial, bony part of it is left in a dried skull; the

lateral part is made of cartilage, and has been removed during maceration. The bony part is a tunnel about 15 mm. long. Its *inferior wall* and the greater part of the *anterior* and *posterior walls* are formed by the curled, lateral half of the *tympanic plate*; the *upper wall* and small adjoining parts of the anterior and posterior walls are formed by the squamous temporal. The *medial end* of the meatus is closed up during life with a tense vibratile membrane, called the **tympanic membrane,** which separates the meatus from the tympanic cavity or **middle ear** and forms the greater part of the lateral wall of the middle ear. The tympanic cavity or middle ear or drum of the ear [τύμπανον (tympanon) = a kettledrum] is a cavity in the temporal bone, and is narrow from side to side. The membrane is the drum head, and it, along with the contents of the middle ear, has been removed during maceration, so that, when one looks into the meatus, the bony surface seen at the far end is the medial wall of the middle ear (Figs. 139, 144, pp. 160, 167).

Processus Styloideus.—The styloid process, a slender process about an inch long, projects downwards, forwards, and slightly medially from behind the lower edge of the tympanic plate; it is situated deeply in the interval between the mastoid process and the mandible. It is dealt with more fully when the lower surface of the skull is examined.

Pars Mastoidea Ossis Temporalis.—The **mastoid temporal** lies behind the external meatus, wedged in between the parietal bone, the occipital bone, and the squamous temporal; it is united with the parietal and occipital by sutures, but is continuous with the squamous temporal; the line of fusion is a little below and behind the supra-mastoid crest (Fig. 165), but the crest roughly indicates the position of the junction of the two parts. The lower part of the mastoid temporal juts downwards as the thick, prominent *mastoid process.*

There may be no triangular depression to mark the **supra-meatal triangle** in the skull the student is using, and even a well-marked triangle measures only a few millimetres. The triangle is above and behind the opening of the meatus, close to the meatus, at the meeting of tangents drawn to the upper and posterior margins of the meatus. The *supra-meatal spine*, described as a spicule of bone on the antero-inferior side of the triangle, is seldom present.

The **external acoustic meatus** is barely wide enough to admit an ordinary pencil. It passes in a medial direction and slightly forwards; its opening into the middle ear is very oblique, so that the tympanic membrane, which closes the opening, looks downwards and forwards as well as in a lateral direction.

The parts of the outer orifice formed by the lateral margin of the curved tympanic plate are rough for the attachment of the cartilage of the auricle; the auricularis posterior muscle arises from the bone behind the meatus. In the child the meatus is very short, for the tympanic plate, which forms so much of the meatus, is at birth not a curved *plate* but an incomplete slender *ring*; in a child, therefore, the tympanic membrane is quite near the surface of the head.

The meatus as a whole is described in the chapter on Organs of Sense; the student is apt to get misleading ideas about the meatus if he studies the osseous portion apart from the cartilaginous portion.

The **medial wall of the tympanic cavity**, seen when one looks into the meatus, is uneven, and has about its middle a white bulging called the **promontory.** If the meatus is fairly wide, and the skull is tilted this way and that, a little hole may be seen above the posterior part of the promontory; it is called the **fenestra vestibuli,** because it leads into a part of the internal ear named the *vestibule.* During life the footpiece of the auditory ossicle called the *stapes* or stirrup fits into it. [*Fenestra* = a window.]

The **tympano-mastoid fissure,** which transmits the auricular branch of the vagus nerve, is a narrow slit between the posterior part of the lateral margin of the tympanic plate and the front of the mastoid temporal. In many skulls the tympanic plate is so closely applied to the mastoid that the fissure is represented by a minute foramen just large enough to emit the nerve.

The mastoid portion of the temporal bone or **mastoid temporal** is more or less triangular in outline, the apical part being the mastoid process. Anteriorly it fuses with the squamous temporal a little behind and below the *supra-mastoid crest*, and, below that, it is closely related to the tympanic plate. Posteriorly it articulates with the occipital bone. Its upper border or base articulates with the truncated postero-inferior angle of the parietal bone. The point, at the lateral angle of the occipital bone, where the lambdoidal, parieto-mastoid, and occipito-mastoid sutures meet together, is called the **asterion** [ἀστήρ (astēr) = a star]; the superior nuchal line of the occipital bone, when well marked, reaches the asterion. In skulls in which the supra-mastoid crest is not a mere curved ridge but is a broad, blunt, prominent elevation, there is a depression behind the crest in the angle between the squamous temporal and the base of the mastoid temporal. Note that, in the living head, the depression is just behind the top of the root of the ear, a full inch away from the meatus, and is not to be mistaken for the supra-meatal triangle; it is directly opposite the transverse venous sinus, just below the point where the sinus begins to bend downwards.

The **mastoid process** juts down from the mastoid temporal, and is felt as a prominence behind the lower part of the ear. It is opposite the foramen magnum, so that a line drawn from one mastoid process to the other passes just below the foramen. It is absent at birth, small in a child, variable in size in the adult, and is usually larger in men than in women.

The sterno-mastoid muscle is inserted into a strip which extends from the tip of the mastoid process to the asterion and then includes the lateral third of the superior nuchal line; the splenius capitis into a strip immediately below that for the sterno-mastoid; the longissimus capitis into the back of the root of the mastoid process; and the posterior belly of the digastric from the well-marked groove, called the **mastoid notch**, at the medial side of the root of the mastoid process.

Fossa Infratemporalis (Fig. 137, p. 143).—The **infra-temporal fossa** is the open space behind the maxilla; it communicates with the temporal fossa through a wide opening under cover of the zygomatic arch. Its *anterior wall* is the full, rounded posterior surface of the maxilla. The lowest part of that surface, behind the last molar tooth, is the **tuberosity of the maxilla.** (The *molar* teeth or grinders are the hindermost three teeth in a full set of eight a side.) Above the posterior surface of the maxilla, between it and the great wing of the sphenoid, there is the horizontal cleft, called the **inferior orbital fissure**, by which the infra-temporal fossa communicates with the orbit, where the fissure has been seen already (pp. 134 and 135).

The greater part of the *roof* of the fossa is a large, fairly flat surface of bone already pointed out as the *infra-temporal surface* of the great wing of the sphenoid; the lateral margin of the surface is the **infra-temporal line**, which also has been referred to already (p. 138).

The *medial wall* of the fossa is the *lateral lamina* of the pterygoid process. The lamina is a thin broad plate of bone set nearly perpendicularly behind the maxilla. Between its upper part and the upper part of the maxilla there is a narrow V-shaped cleft, called the **pterygo-maxillary fissure**, the upper end of which joins the inferior orbital fissure at almost a right angle. A large artery called the internal maxillary artery passes out of the infra-temporal fossa through the pterygo-maxillary fissure into the *pterygo-palatine fossa.*

Fossa Pterygo-palatina.—The **pterygo-palatine fossa** is the small confined space one sees immediately beyond the pterygo-maxillary fissure. If a pin or a match is passed through the upper part of the fissure into the fossa, and onwards through the fossa, it appears in the nasal cavity. The hole in the medial wall of the fossa through which the pin enters the nose is called the **spheno-palatine foramen.**

The **infra-temporal fossa** is a roomy space containing the two pterygoid muscles, the spheno-mandibular ligament, the pterygoid venous plexus, the internal maxillary artery (first and second parts) and its branches, the mandibular nerve and its branches, and the chorda tympani nerve—all imbedded in a quantity of fat and lying under cover of the tendon of the temporalis, the coronoid process, and the ramus of the mandible and the masseter muscle. The coronoid process and the ramus constitute a *lateral wall* of the fossa; the temporalis tendon is inserted into the process; the masseter lies on the lateral surface of the process and the ramus, being inserted into the lateral surface of the ramus. [μασητήρ (masētēr)=a chewer.]

The *anterior wall* of the fossa (*i.e.* the posterior or infra-temporal surface of the maxilla, ending inferiorly in the maxillary tuberosity) presents, about its middle, two or three small holes which are the upper ends of the **alveolar canals** through which vessels and nerves descend to the molar teeth of the upper jaw.

The *roof* of the fossa is formed chiefly by the infra-temporal surface of the great wing of the sphenoid, and partly also by a small triangular area that lies in front of the medial part of the articular tubercle and belongs to the squamous temporal. In the infra-temporal surface, close to its posterior border, there are two holes, called the **foramen ovale** and **foramen spinosum**, which will be considered with the lower surface of the skull (pp. 146 and 147).

The *medial wall* is formed by the lateral lamina of the pterygoid process and a narrow strip of bone, belonging to the pyramidal process of the palatine bone, which is wedged in between the lower part of the lamina and the maxilla; very often, however, the strip is so closely united to the bones between which it lies that it cannot be distinguished, and the lower part of the lamina appears to be fused with the maxilla.

The **pterygo-palatine fossa** is a small space situated *below* the apex of the orbit, bounded *anteriorly* by the maxilla, *posteriorly* by the combined root of the pterygoid process and great wing of the sphenoid bone, and *medially* by the perpendicular part of the palatine bone, which separates it from the cavity of the nose. The fossa is filled with fat in which there lie the third part of the internal maxillary artery and its branches, corresponding veins, the maxillary nerve the spheno-palatine ganglion and its branches.

The fossa communicates with the infra-temporal fossa by the **pterygo-maxillary fissure**, through which the internal maxillary artery enters it and the maxillary nerve leaves it. It is on a level with the zygomatic arch just below the jugal point, about two inches distant from the side of the head. In intractable neuralgia of the branches of the maxillary nerve a needle conveying analgesic fluid may be passed through the contents of the infra-temporal fossa into the pterygo-palatine fossa to reach the maxillary nerve.

The following apertures, several of which will be referred to more fully later, open into or out of the pterygo-palatine fossa: (1) the pterygo-maxillary fissure; (2) the inferior orbital

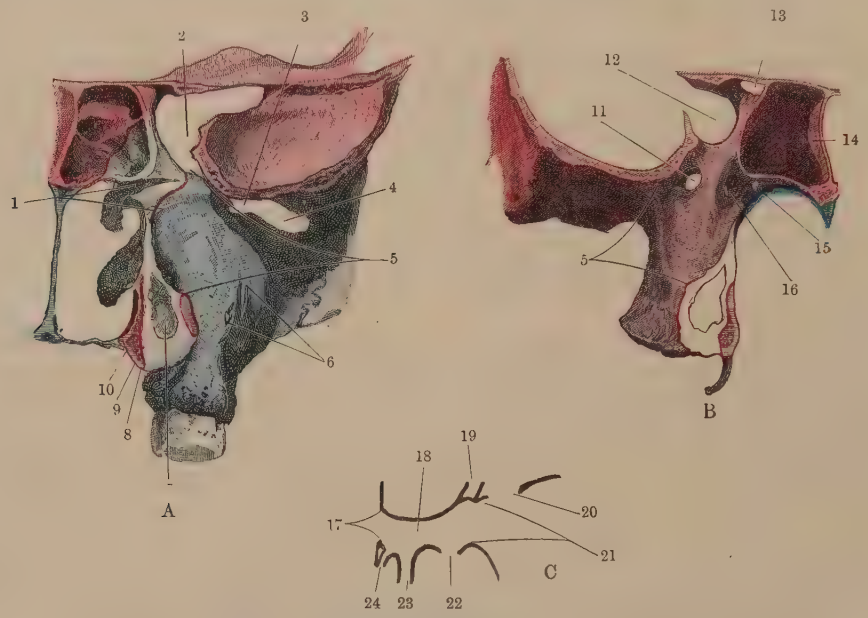

FIG. 136.—FRONTAL SECTION THROUGH THE PTERYGO-PALATINE FOSSA AND NASAL CAVITY OF THE RIGHT SIDE.

The sphenoid is coloured red. The maxilla and vomer are coloured blue. The palate bone and middle and inferior conchæ are left uncoloured.

fissure; (3) the greater palatine canal (canalis pterygo-palatinus), descending to the posterior corner of the hard palate; (4) the foramen rotundum, passing backwards into the middle cranial fossa; (5) the pterygoid canal, passing backwards through the root of the pterygoid process; (6) the pharyngeal canal, passing backwards and medially in the roof of the nose; (7) the **spheno-palatine foramen** is in the medial wall of the fossa and is bounded by the spheno-palatine notch and the lower surface of the body o the sphenoid. It opens into the superior meatus of the cavity of the nose immediately above the posterior end of the middle concha, but during life is closed up by the mucous membrane. It transmits the spheno-palatine vessels, the naso-palatine nerve, and one or more superior nasal branches of the spheno-palatine ganglion. The foramen can be identified in the dried skull if a match is pushed onwards through the pterygo-palatine fossa into the nose, where one can see it by looking through the choana of that side; the foramen is large and round, but by frequent examination the thin bone around it may have been broken down, so that it may be a large jagged opening.

Norma Basalis.

When the skull is turned upside down for the examination of the **lower surface** or *basis cranii externa*, many of the parts seen already from the other aspects or noted in connexion with the individual bones of the skull are seen again, and those parts should be identified at once:—

The *foramen magnum*; the *basilar part* of the occipital bone in front, and the

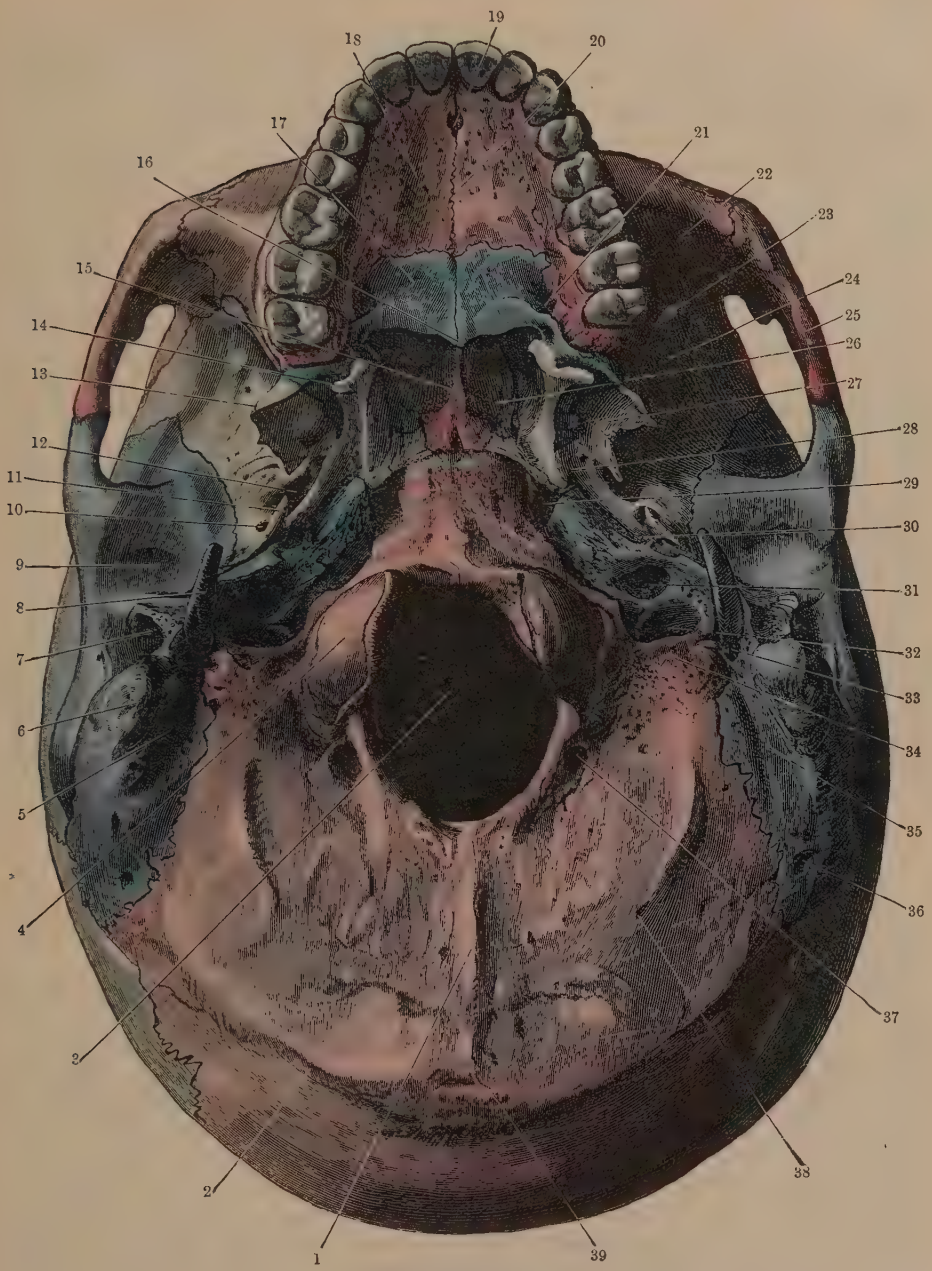

FIG. 137.—INFERIOR SURFACE OF BASE OF SKULL.

36. Mastoid foramen.
37. Canalis condyloideus.
38. Inferior nuchal line of occipital bone.
39. External occipital protuberance.

occipital condyles at the sides of the foramen. The *mastoid process*; the *styloid process*, in front of and medial to the mastoid process, may be broken off and only its root remain; the *tympanic plate*, in front of and above the styloid process, and forming a great part of the walls of the external acoustic meatus. (The skull under examination is upside down, but in whatever position the skull is held all the terms, *above*, *upper*, etc., are used as if it was in its proper upright position.) The *zygomatic arch*; the *posterior root* of the zygoma extending backwards; the *anterior root* bent in a medial direction and continuous with the smooth *articular tubercle*, which is the anterior boundary of the *mandibular fossa*. The *infra-temporal surface* of the great wing of the sphenoid, forming the greater part of the area in front of and medial to the articular tubercle; the *infra-temporal line* or ridge at the lateral margin of the infra-temporal surface; the *inferior orbital fissure* at the anterior margin of that surface; the *pterygoid process*, consisting of a *lateral* and a *medial lamina*, projecting downwards from the medial side of that surface. The *choana*, the large oval opening at the medial side of the pterygoid process, separated from the choana of the other side by the *vomer*. The *hard palate*, the large area of bone below and in front of the two choanæ, bounded in front and at the sides by the *alveolar processes* of the two maxillæ.

Besides the parts named in the foregoing paragraph, which are fairly large and easily identified, the lower surface of the skull abounds with smaller foramina, processes, etc., so that it is more difficult to learn than any other aspect of the skull. The surface is so uneven and its component bones so interlock with one another that it does not lend itself readily to a natural subdivision into well-defined areas which would simplify description, and an attempt to subdivide it may only add new elements to the puzzle. The surface is naturally subdivided into a right and a left half; and a line drawn between the right and left articular tubercles divides it into an anterior and a posterior part, though it is convenient to describe one or two points that lie behind that line along with points that lie in front of it, and *vice versa*.

Anterior Region of Lower Surface of Skull.

In the middle in front there is the *hard palate*, surrounded anteriorly and at the sides by the *alveolar processes*.

Processus Alveolares.—The **alveolar processes** of the two maxillæ form a thick horseshoe-shaped ridge which carries the upper or maxillary teeth. The lower border of each alveolar process is called the **alveolar margin**, and if the teeth have fallen out after death it exhibits a row of pits or **alveoli** which are the sockets for the roots of the teeth. The part of the alveolar margin behind the last molar tooth is called the **maxillary tuberosity**; it is not well developed till the third molar (the wisdom tooth) has erupted. If the teeth are all in place there are sixteen of them; on each side, beginning in front, there are two incisors, one canine, two premolars and three molars. If the teeth have fallen out after death there is a row of sockets, all single except those for the molar teeth (see p. 182). The walls of the alveoli for teeth that have been removed some time before death are absorbed, so that the corresponding part of the alveolar process is nearly flush with the hard palate.

Palatum Durum.—The **hard palate** is the skeleton of the roof of the mouth and the floor of the nose. It is formed of the palatine processes of the two maxillæ anteriorly, and the horizontal parts of the two palatine bones posteriorly. Those four subdivisions are united by a transverse suture and a median longitudinal suture. At the anterior end of the longitudinal suture, behind the incisor teeth, there is a small pit called the **incisive foramen.**

The posterior margin of the hard palate is free and sharp, and the soft palate is attached to it; from its middle a pointed process, called the **posterior nasal spine,** juts backwards. At each of the posterior corners of the hard palate, opposite the root of the last molar tooth, there is a hole almost wide enough to admit a match; it is called the **greater palatine foramen** and is the lower end of the greater palatine

canal (canalis pterygo-palatinus), the upper end of which opens into the pterygo-palatine fossa (pp. 141 and 142).

The sides of the **alveolar processes** are covered with mucous membrane, and their **alveolar margins** give attachment to the gums.

The **hard palate** is covered with the muco-periosteum of the roof of the mouth; it is rough and pitted, especially anteriorly, by the numerous palatine glands that lie under cover of the mucous lining. The **incisive foramen**, situated behind the incisor teeth, is a pit into which four small foramina or canals open. Those openings are not always easily seen, especially if the incisive foramen is narrow and deep. They all lead up into the cavity of the nose (p. 169). Two of them are in the median plane, one in front of the other, and are called the *foramina of Scarpa*; the other two, one on each side of the median plane, are called the *foramina of Stensen*. The right and left naso-palatine nerves descend from the nose through the foramina of Scarpa, the left nerve in front of the right. The terminal branch of the greater palatine artery ascends to the nose through a foramen of Stensen.

If the skull is that of a young person, a faint irregular suture may be seen extending from the back of the incisive foramen towards the interval between the canine tooth and the lateral incisor tooth. That suture cuts off a part of the maxilla called the **pre-maxilla**; the pre-maxilla carries the incisor teeth; originally it is separate from the maxilla, and in some animals it remains a separate bone.

The palatine aponeurosis and part of the pharyngo-palatinus muscle are attached to the *posterior border* of the hard palate, and the musculus uvulæ arises from the **posterior nasal spine**. A millimetre or two in front of the posterior border there is a ridge, called the **palatine crest**, into which part of the outspread tendon of the tensor palati is inserted; the crest may be blunt or sharp, and its lateral part is immediately behind the greater palatine foramen.

The **greater palatine foramen** is the lower end of the **greater palatine canal**. If a pin is pushed up through the foramen and canal, its point appears in the pterygo-palatine fossa, where the canal begins. The canal lies in the posterior part of the side wall of the nasal cavity, between the maxilla and the perpendicular part of the palatine bone. The greater palatine vessels from the third part of the internal maxillary vessels and the greater palatine nerve from the spheno-palatine ganglion descend through the canal and foramen and then run forwards in the poorly marked groove close to the alveolar process; they are the chief supply of the palate.

The **lesser palatine foramina** are the small holes behind the palatine crest and greater palatine foramen; there are usually two, but one of them may be so small that it almost escapes notice. The bone on which they are situated is the *pyramidal process* of the palatine bone. They lead up into the **lesser palatine canals**, which are branches of the greater palatine canal and convey the lesser palatine branches of the greater palatine vessels and nerve to the tissues of the soft palate.

Choanæ.—The **choanæ** are the two oval openings above the posterior edge of the hard palate, each of them large enough to admit the tips of two fingers; they are separated from each other by the posterior edge of the bone called the *vomer*; through them the cavities of the nose open into the uppermost part of the interior of the pharynx.

By looking into a choana one can get a partial view of the walls of a **nasal cavity**, and the following parts should be identified: The posterior part of the *floor*, formed by the horizontal part of the palatine bone. The posterior part of the *septum*, formed by the vomer. The posterior part of the *roof*, formed chiefly by the body of the sphenoid. The posterior part of the *side wall*, formed by the medial lamina of the pterygoid process and, in front of that, the perpendicular part of the palatine bone; the three nasal conchæ are seen projecting into the cavity from the side wall, in front of the pterygoid lamina; the inferior and middle conchæ have been identified already through the apertura piriformis; their posterior parts are seen here, and the **spheno-palatine foramen** opens into the cavity immediately above the posterior end of the middle concha; the superior concha lies only a little distance above the posterior part of the middle concha, and is very much smaller—may, indeed, be no more than a sharp ridge of bone.

Each **choana** is bounded inferiorly by the hard palate, medially by the vomer, laterally by the medial lamina of the pterygoid process, and superiorly by the lower surface of the body of the sphenoid, which is, however, concealed by two thin pieces of bones, called the ala of the vomer and the vaginal process of the medial pterygoid process, and they form the actual boundary. The upper boundary of the choana is the junction of the roof of the nasal cavity with the roof of the nasal part of the pharynx.

The *ala of the vomer* spreads in a lateral direction from the upper end of the vomer and covers the part of the lower surface of the body of the sphenoid near the median plane. The *vaginal process* is a thin sheet of bone that extends in a medial direction from the upper end of the medial pterygoid lamina; near the lamina it is fused with the lower surface of the body of the sphenoid, but its medial part is free and its medial edge articulates with the edge of the ala

of the vomer. Anteriorly the vaginal process is overlapped by the *sphenoidal process of the palatine bone*, which bends in a medial direction, covering part of the lower surface of the body of the sphenoid in the roof of the nasal cavity, and reaching the edge of the ala of the vomer. On the lower surface of the vaginal process, near the pterygoid lamina, there is a narrow, but fairly well marked, antero-posterior groove; the groove, when traced forwards, leads to a small foramen, which is the posterior end of the pharyngeal canal.

Canalis Pharyngeus.—The **pharyngeal canal** is a narrow, unimportant canal situated in the roof of the nasal cavity between the body of the sphenoid and the sphenoidal process of the palatine bone. Its anterior end opens into the pterygo-palatine fossa; its posterior end opens on the vaginal process in the roof of the choana. The pharyngeal branches of the spheno-palatine ganglion and of the third part of the internal maxillary vessels pass backwards through the canal and along the groove on the vaginal process to supply the mucous membrane of the roof of the pharynx. In a much-handled skull the sphenoidal process is often broken away and the canal is destroyed.

Processus Pterygoidei.—The **pterygoid processes** are two large processes, a right and a left, which project downwards from the roots of the great wings of the sphenoid bone. Each of them stands at the side of a choana, behind the maxilla, and separates the choana from the infra-temporal fossa. It consists of two plates or laminæ, a lateral and a medial, between which there is an interval, open posteriorly and nearly half an inch wide, called the **pterygoid fossa.**

The **lateral lamina** forms the medial wall of the infra-temporal fossa. The **medial lamina** is the lateral boundary of the choana and forms the most posterior part of the side wall of the nasal cavity. The lower end of its posterior border is continued into a slender process, called the **hamulus**, which curves downwards, backwards, and in a lateral direction. The hamulus [= a hook] may be a mere stump or may be 5 or 6 mm. long; if long it is very liable to be broken off in the dried skull; it can be felt, in the living head, by the thumb pressed against the lateral part of the roof of the mouth at the junction of hard palate and soft palate, rather behind the gum. The upper part of the posterior border of the medial lamina splits into two ridges which enclose a shallow oblong depression, about 3 mm. wide, called the **scaphoid fossa** [σκάφη (scaphē) = anything dug out, a trough, a boat].

The **infra-temporal surface** of the great wing of the sphenoid is the wide, spreading horizontal surface of bone lateral to the upper end or root of the lateral pterygoid lamina. Posteriorly, it extends backwards beyond the level of the lateral lamina, and close to its posterior edge there are two holes, a larger and a smaller, set close together and called the foramen ovale and the foramen spinosum; both foramina lead directly up into the middle cranial fossa. The **foramen ovale** is the larger opening and is named from its shape; it lies behind and lateral to the upper end of the lateral pterygoid lamina, and is opposite, and an inch and a half medial to, the tubercle of the root of the zygoma. The **foramen spinosum** is behind and lateral to the foramen ovale.

Behind and lateral to the foramen spinosum there is a sharp spur of bone which projects downwards from the posterior angle of the great wing of the sphenoid. It is called the **spine of the sphenoid**, and gives its name to the foramen spinosum; it is situated close to the medial end of the articular tubercle and mandibular fossa, and varies much in prominence in different skulls; in a few skulls a thin bar of bone stretches from the spine to the lateral pterygoid lamina, converting the interval between them into a foramen.

The two **laminæ** of the **pterygoid process** extend downwards to a level rather lower than that of the hard palate. Their posterior margins are free and sharp; the upper halves of their anterior borders are united together, the anterior aspect of their junction forming the posterior wall of the pterygo-palatine fossa, while the posterior aspect forms the upper part of the floor or anterior wall of the **pterygoid fossa**; the lower halves of the laminæ are quite separate from each other, but that is not apparent in the skull, for the pyramidal process of the palatine bone is wedged in between the maxilla and the lower part of the pterygoid process, filling in the interval between the lower halves of the anterior borders of the laminæ; if the skull is that of a young adult, the Λ-shaped suture between the pyramidal process and the two laminæ can be seen in the lower part of the floor of the pterygoid fossa.

The **pyramidal process** of the palatine bone, though so frequently mentioned, is not of outstanding importance, but the origin of the internal pterygoid muscle cannot be fully understood unless the relations of the process to the pterygoid laminæ are understood. Three aspects of the process have now been seen: (1) the uneven surface, showing the lesser palatine foramina, behind

the greater palatine foramen and between the lower extremities of the two pterygoid laminæ ; (2) an uneven Δ-shaped surface in the floor of the pterygoid fossa, between the lower halves of the two laminæ ; (3) a narrow strip in the infra-temporal fossa, between the lower part of the maxilla and the lower part of the lateral pterygoid lamina (p. 141).

The **medial lamina** of the pterygoid process is the most posterior bone in the side wall of the nasal cavity ; inferiorly a portion of it stands also in the side wall of the nasal part of the pharynx or naso-pharynx, *i.e.* the uppermost subdivision of the interior of the pharynx; its medial surface is clothed with mucous membrane. The posterior border is thin and sharp, and rather more than half-way up a sharp spur of bone, called the **tubal process** (processus tubarius), sometimes juts backwards from it ; above that spur, the border divides into two ridges which bound the **scaphoid fossa**, the medial margin of which is looked on as the real upper part of the border. The end of the auditory tube, as it opens on the side wall of the naso-pharynx, is closely related to the medial margin of the scaphoid fossa and is supported inferiorly by the tubal process. The lower or palatine end of the posterior border is continued into the hooklet or **hamulus**, the concavity of which is directed backwards and upwards towards the base of the skull ; the *lower* surface of the root of the hamulus is crossed by a groove. The anterior part of the tensor palati or tensor veli palatini muscle arises from the scaphoid fossa, descends along the lateral surface of the medial pterygoid lamina, and the slender tendon of the muscle turns at a right angle in a medial direction and forwards, in the groove below the hamulus, and spreads out as it enters the soft palate. The posterior border of the lamina, in its whole length, gives attachment to the pharyngeal aponeurosis ; its lower half or third, together with the hamulus, gives origin to the upper part of the superior constrictor of the pharynx ; the tip of the hamulus gives attachment to a fibrous band, called the pterygo-mandibular raphe, which extends to the posterior end of the mylo-hyoid ridge of the mandible and gives origin to most of the remaining fibres of the superior constrictor.

The **lateral lamina** of the pterygoid process is wider than the medial lamina, and is turned slightly in a lateral direction. Its posterior border is sharp and very uneven ; its surfaces give origin to the pterygoid muscles. The pterygoideus externus muscle has two heads, an upper and a lower. The lower head arises from the lateral surface of the lateral pterygoid lamina ; the upper head from the infra-temporal surface and infra-temporal line of the sphenoid. The two heads pass backwards, join together, and are inserted chiefly into the front of the neck of the mandible (the mandible should now be placed in position). The pterygoideus internus also has two heads, a superficial and a deep. The small, superficial head arises from the tuberosity of the maxilla and the strip of the pyramidal process of the palatine bone that appears between the maxilla and the lateral pterygoid lamina ; the large, deep head arises from the medial surface of the lateral pterygoid lamina and the surface of the pyramidal process that appears in the pterygoid fossa ; the two heads join and pass downwards and backwards to be inserted into the medial surface of the mandible above and in front of the angle.

The **infra-temporal surface** of the great wing of the sphenoid is limited in front by the inferior orbital fissure, laterally by the infra-temporal line, while posteriorly it extends backwards and ends as the spine of the sphenoid, at the medial side of the mandibular fossa. The **spine of the sphenoid** is grooved on its medial side by the chorda tympani nerve, and it gives attachment to (1) the posterior part of the tensor veli palatini muscle, (2) the spheno-mandibular ligament, which stretches to the margin of the mandibular foramen, and (3) the pterygo-spinous ligament, a weak fibrous band which stretches to the posterior border of the lateral pterygoid lamina, but may, however, be transformed into a bar of bone.

The **foramen spinosum** is antero-medial to the spine of the sphenoid. It transmits the middle meningeal vessels, an unimportant nerve filament called the nervus spinosus, and lymph vessels from the meninges.

The **foramen ovale** is antero-medial to the foramen spinosum. The only important structure it transmits is the mandibular nerve, including the motor root of the trigeminal nerve ; but there pass through it also the accessory meningeal artery, small veins connecting the cavernous venous sinus with the pterygoid venous plexus, lymph vessels from the meninges, and, sometimes, the lesser superficial petrosal nerve.

Very frequently there is a small aperture called the **foramen of Vesalius**, situated antero-medial to the foramen ovale and close to the scaphoid fossa. It opens directly into the middle cranial fossa and transmits a small vein that connects the cavernous sinus with the pterygoid plexus. And occasionally there is a very small hole called the **canaliculus innominatus**, behind the foramen ovale, for the transmission of the lesser superficial petrosal nerve.

Posterior Region of Lower Surface of Skull.

There are only three bones in the posterior part of the base of the skull—the occipital bone, and the right and left temporal bones. The **occipital** bone occupies a large part of the region in the middle and posteriorly ; the **temporal** bone is wedged in at the side, between the occipital bone and the great wing of the sphenoid, and the details of its surface present more difficulties than those of the occipital bone.

The **occipital bone** is divided into four parts which surround the foramen magnum—the *basilar part* in front, a *lateral part* at each side, and a large,

expanded *squamous part* behind. The four parts are separate at birth, but are usually fused together by the sixth year.

Foramen Occipitale Magnum.—The **foramen magnum** is the large opening in which the medulla oblongata, or lowest subdivision of the brain, becomes continuous with the spinal medulla (spinal cord). It is on a level with the mastoid process at the side of the head, while posteriorly it is on a level with a point midway between the external occipital protuberance and the spine of the second cervical vertebra.

The **foramen magnum** is usually ovoid in outline with the narrower part in front, and its antero-posterior diameter varies from 30 to 40 mm. It *contains* the upper end of the spinal medulla with its membranes and blood-vessels, the spinal roots of the accessory nerves, the vertebral arteries surrounded by plexuses of sympathetic nerves derived from the inferior cervical ganglion, lymph vessels from the meninges of the brain; the lowest part of the cerebellum lies in it; and the membrana tectoria and upper band of the cruciate ligament pass upwards through it to be attached to the upper surface of the basi-occiput in front of the foramen magnum. The posterior atlanto-occipital membrane is attached to the posterior margin of the foramen magnum; the anterior atlanto-occipital membrane and the lig. apicis dentis (suspensory ligament), to the anterior margin; the alar or check ligament, to the low tubercle on the medial surface of the occipital condyle on the side of the foramen magnum. The vertebral artery enters the foramen just behind the condyle, and sometimes grooves the margin of the foramen. The point in the middle of the anterior margin of the foramen magnum is called the **basion**, and the point in the middle of the posterior margin is the **opisthion** [ὀπίσθιος (opisthios) = posterior].

Pars Basilaris Ossis Occipitalis.—The **basilar part** of the occipital bone, or **basi-occiput**, is a wide bar of bone, thin at the margin of the foramen magnum, but thick at its anterior end, where it joins the body of the sphenoid. In youth it is united to the sphenoid by a plate of cartilage, and is fused with the sphenoid after the twenty-fifth year, but the position of their fusion may be indicated by an interrupted transverse depression. At the centre of the lower surface of the basi-occiput, about half an inch in front of the foramen magnum, there is a small elevation called the **pharyngeal tubercle**; the surface of bone in front of the tubercle is clothed with the mucous membrane of the roof of the pharynx, and is opposite and almost on a level with the mandibular fossa or lower jaw joint on the side of the head.

The hole, with jagged edges, seen alongside the anterior part of the basi-occiput is called the **foramen lacerum**; it leads directly up into the middle cranial fossa. On its anterior margin, as seen from below, there is a small rounded elevation, called the *pterygoid tubercle*, at the extreme upper end of the medial pterygoid lamina; and on the anterior margin of the foramen, above the tubercle, and rather hidden by it, there is an opening large enough to admit a thick pin. That opening is the posterior end of the **pterygoid canal**, the anterior end of which opens into the pterygo-palatine fossa; in some skulls it is so hidden that it cannot be seen, but a hook or a bent pin enables one to find it. (See also pp. 159 and 161.)

The **pharyngeal tubercle**, in an articulated skeleton, lies directly above the tubercle on the anterior arch of the atlas. It gives insertion to the uppermost bundle of fibres of the superior constrictor of the pharynx, and attachment to a median, fibrous longitudinal band, called the *pharyngeal raphe*, that lies in the posterior wall of the pharynx. The rectus capitis anterior is inserted into an impression on the basi-occiput in front of the occipital condyle, and the longus capitis into an impression lateral to and in front of the pharyngeal tubercle, so that the back of the upper end of the pharynx is recessed in between the longus capitis muscles of the two sides, and the prevertebral fascia is attached to a line which curves forwards from behind the pharyngeal tubercle to the front and lateral margins of the impression for the longus capitis.

The position of the junction of the basilar part of the occipital bone or basi-occiput with the body of the sphenoid bone corresponds to a line drawn between the tips of the pterygoid tubercles.

Partes Laterales Ossis Occipitalis.—The **lateral parts** of the occipital bone lie at the sides of the anterior half of the foramen magnum; they are named also the **condylar parts** because they bear the occipital condyles.

Condyli Occipitales.—The **occipital condyles** are the large, smooth, oblong protuberances that lie at the margins of the foramen magnum. They articulate with the lateral masses of the atlas vertebra and through them the weight of the head is transmitted to the vertebral column. The nodding movements of the head

take place at the joints between the condyles and the atlas. The condyles and the joints are on a level with, and almost directly opposite, the mastoid process on each side. The articular surface of each condyle is often notched at the sides, and in some skulls the notches meet and divide the articular surface into two parts.

Fossa Condyloidea et **Canalis Condyloideus.**—The **condyloid fossa** is the depression behind the condyle. In many skulls there is a **condyloid canal** which begins in the fossa, and passes obliquely forwards and upwards into the cranial cavity. The bony wall of the fossa is thin and may have an artificial perforation in it which may be mistaken for the canal, but the artificial opening leads directly up into the cranial cavity, and not obliquely.

The **occipital condyles** lie alongside the anterior part of the foramen magnum. They are placed obliquely, their anterior ends being nearer each other than the posterior ends. The articular surface of each is convex from before backwards and slopes downwards from lateral to medial side. The articular capsule is attached to the margins of the articular surface, and the check ligament is attached to the medial surface of the condyle.

The **condyloid fossa** accommodates the upper part of the back of the lateral mass of the atlas when the head is bent backwards.

The **condyloid canal**, when present, passes above the posterior part of the condyle and opens, in the posterior cranial fossa, into or near the groove on the upper surface of the jugular process that lodges the lower end of the sigmoid part of the transverse venous sinus. The canal transmits a vein that connects the sinus with the sub-occipital venous plexus.

Canalis Nervi Hypoglossi.—The external opening of the canal for the hypoglossal nerve, or **hypoglossal canal,** lies above the lateral margin of the anterior part of the condyle, and is usually largely hidden by it, so that the skull has to be tilted before the opening is seen. The beginner should not mistake the jugular foramen for it because the foramen chances to catch his eye first. The jugular foramen is a large irregular opening nearly half an inch away from the condyle, and through it one can see into the cranial cavity. The hypoglossal canal is only wide enough to admit a match; it is medial to the jugular foramen and quite close to the condyle; internally, it opens into the cranial cavity a little above the margin of the foramen magnum (p. 164).

Processus Jugularis.—The **jugular process** is the part of the occipital bone—about half an inch square—which lies lateral to the posterior half of the condyle. Its anterior border forms the posterior margin of the jugular foramen; the border is concave from side to side and the concavity is called the **jugular notch.**

The **hypoglossal canal** passes in a medial direction and backwards above the anterior part of the condyle. The important structure that passes through it is the hypoglossal nerve; but it transmits also a meningeal branch of the ascending pharyngeal artery, veins connecting the meningeal veins and the veins of the medulla oblongata with the pharyngeal venous plexus, and lymph vessels from the meninges.

The **jugular process** is the homologue of the transverse process of a vertebra. It blends medially and posteriorly with the rest of the occipital bone; its anterior margin is free and forms the floor of the **jugular notch**; its lateral margin is united to the petrous temporal by a plate of cartilage which ossifies about the twenty-fifth year; its rough lower surface gives insertion to the rectus capitis lateralis; and the prevertebral fascia is attached to the anterior margin in front of the rectus; its upper surface, in the floor of the posterior cranial fossa, has a broad shallow groove which lodges a part of a large venous sinus called the sigmoid sinus.

In some skulls a curved process, called the *intra-jugular process*, projects from the jugular notch and partially or completely divides the jugular foramen into two parts. Occasionally a tubercle or a process, called the par-occipital or *para-mastoid process*, projects downwards from the lateral part of the jugular process, and may be long enough to articulate with the transverse process of the atlas.

Squama Occipitalis.—The **squamous part** is by far the largest subdivision of the occipital bone. It lies partly in the base and partly in the back of the skull. The *external occipital protuberance* and the superior nuchal lines, already examined (p. 136), are the boundary between the base and the back.

Crista Occipitalis Externa.—The **external occipital crest** is a median ridge which extends from the protuberance to the posterior margin of the foramen magnum; in some skulls it is very poorly marked.

Lineæ Nuchæ Inferiores.—The **inferior nuchal lines** are two faint curved ridges, one on each side, situated about midway between the foramen magnum and the superior nuchal line. Each begins about the middle of the external occipital

crest and arches in a lateral direction and forwards and downwards towards the side of the occipital bone.

The upper end or border of the ligamentum nuchæ is attached to the **external occipital crest** and **external occipital protuberance**; the protuberance and the medial part of the **superior nuchal line** give attachment to the galea aponeurotica and origin to the uppermost fibres of trapezius; the lateral part of the line gives origin to the occipitalis and insertion to part of the sterno-mastoid and of the splenius capitis. The semispinalis capitis (complexus) is inserted into the medial half of the area between the superior and **inferior nuchal lines**; the obliquus capitis superior, into the lateral half; the rectus capitis posterior minor, into the medial part of the area below or in front of the inferior nuchal line; the rectus posterior major, into the lateral part. Though the oblique muscle and the two recti are small, their insertions are wide and in many skulls are mapped out by ridges.

All the subdivisions of the **temporal bone** appear in the lower surface of the skull: the lower end of the *mastoid temporal*; the *tympanic plate*; the lower surface of the *petrous temporal*, medial to the tympanic plate; the *styloid process*, emerging from behind the lower part of the tympanic plate; and the portion of the *squamous temporal* bearing the articular tubercle and mandibular fossa, in front of the tympanic plate.

Certain parts belonging to the temporal bone or placed close alongside it have been noted already, and are easily identified again. (1) The **articular tubercle**, medial to the posterior part of the zygomatic arch and continuous with its anterior root; (2) the **mandibular fossa**, behind the articular tubercle; the head of the mandible is in relation with the fossa when the mouth is shut, and is pulled forwards and downwards into relation with the tubercle as the mouth is opened; (3) the **spine of the sphenoid**, medial to the tubercle or medial to the fossa; (4) the **post-glenoid tubercle**, in the posterior boundary of the fossa immediately in front of the opening of the external acoustic meatus; (5) the **tympanic plate**, behind and below the fossa; (6) the **mastoid process**, behind and below the external acoustic meatus; (7) the **mastoid notch**, at the medial side of the root of the mastoid process; (8) the **foramen lacerum**, alongside the anterior part of the basi-occiput, between it and the petrous temporal.

The **mastoid notch** gives origin to the posterior belly of the digastric muscle. Close to the medial side of the notch and parallel with it, the occipital artery runs backwards and in a lateral direction, in contact with the mastoid temporal or with the suture between it and the occipital bone, and may produce a groove on the bone.

The following structures lie opposite the mastoid process, *i.e.*, a line connecting the two mastoid processes would pass through or near them: The posterior belly of the digastric, the occipital artery, the posterior part of the rectus lateralis, the posterior part of the atlanto-occipital joint, and the upper end of the spinal medulla—in that order latero-medially. The vertebral artery, as it enters the foramen magnum, lies just behind the line.

The **styloid process** lies deeply in the interval between the mastoid process and the mandible, and intervenes between the parotid gland and the internal jugular vein. It projects downwards, forwards, and medially from the petrous temporal, behind the lower part of the tympanic plate, which partly ensheathes its basal portion. Two ligaments and three muscles are attached to it. The stylo-hyoid ligament stretches from its tip to the hyoid bone; the stylo-mandibular ligament, which is a thickened part of the fascia covering the antero-medial surface of the parotid gland, extends from its anterior aspect to the posterior border of the mandible. The stylo-glossus arises from the anterior aspect near the tip; the stylo-hyoideus, from the postero-lateral aspect of the middle third; the stylo-pharyngeus, from the medial aspect near the root.

The following parts are now to be looked for:—

Foramen Stylo-mastoideum.—The **stylo-mastoid foramen** is the aperture immediately behind the root of the styloid process, between it and the mastoid process, in front of the mastoid notch. It is the lower end of a canal, in the substance of the temporal bone, through which the facial nerve travels on its way from the brain to the exterior of the skull; besides the facial nerve, it transmits the stylo-mastoid branches of the posterior auricular vessels, which pass upwards through it into the temporal bone.

Foramen Jugulare.—The jugular foramen is a large opening with uneven margins situated a little to the medial side of the root of the styloid process, and it leads into the posterior cranial fossa. It is bounded anteriorly by the petrous temporal and posteriorly by the jugular notch of the occipital bone.

The largest structure in the jugular foramen is the internal jugular vein,

which begins in it as a continuation of the sigmoid part of the transverse venous sinus. The vein is dilated at its commencement and the dilatation is called the *bulb* of the internal jugular vein. To accommodate the bulb there is a concavity, called the **jugular fossa**, on the petrous temporal where it forms the antero-lateral wall of the jugular foramen.

The jugular foramen is opposite and almost on a level with the lower margin of the external acoustic meatus. A portion of the bone forming the jugular fossa forms also the floor of the tympanic cavity or middle ear. That relationship can be verified if one looks at the medial wall of the tympanic cavity through the external meatus, and gauges the position of the floor of the cavity. In middle-ear disease, infection may pass through the bone, and attack the internal jugular vein.

The following parts lie opposite the external acoustic meatus, *i.e.*, a line drawn from one meatus to the other would pass through them or near them: the root of the styloid process, the jugular foramen, the hypoglossal canal, the anterior end of the occipital condyle, and the anterior margin of the foramen magnum, in that order latero-medially.

The **jugular foramen** leads upwards and backwards into the cranial cavity, and the structures it transmits will be enumerated more intelligibly when it is examined from inside the skull (p. 166). Sometimes spicules of bone project across the foramen from its margins, and may divide it into compartments.

The right internal jugular vein is usually larger than the left, and therefore the right jugular foramen and fossa are larger than the left. When the fossa is large there may be a very small amount of bony substance between it and the tympanic antrum, which lies above it.

On the lateral wall of the foramen, in the floor of the jugular fossa, there is a small "pin-point" aperture: it is the medial end of a narrow, horizontal canal, called the **mastoid canaliculus**, which passes through the temporal bone and opens laterally in the tympano-mastoid fissure. The canal is traversed by a slender but not unimportant nerve filament called the auricular branch of the vagus.

Canalis Caroticus.—Directly in front of the jugular foramen and fossa, in the lower surface of the petrous temporal, there is a circular or oval opening, wide enough to admit a thin pencil; it is the lower end of the **carotid canal**, through which the internal carotid artery travels to reach the cranial cavity. The carotid canal is in the petrous temporal; it leads upwards for a short distance and then, bending to become horizontal, it runs in a medial direction and forwards to open into the middle cranial fossa at the foramen lacerum. Since the lower end of the canal is anterior to the jugular foramen, the internal carotid artery, as it enters the bone, is in front of the internal jugular vein. The lower end of the canal is opposite the anterior margin of the orifice of the external acoustic meatus, and the ascending part of the canal lies below and in front of the middle ear and the internal ear; the thudding sound that one hears in the head during moments of excitement or after a spurt of violent exertion is due to the beating of the carotid artery against the bone which separates it from the internal ear.

The anterior margin of the jugular foramen and fossa is separated from the lower opening of the carotid canal by a ridge of bone on which there may be more than one small hole for small vessels that enter the bone. But one of those foramina is the lower end of the **tympanic canaliculus**, through which a small nerve, called the tympanic branch of the glosso-pharyngeal nerve, passes up to enter the tympanic cavity and form the tympanic plexus on its medial wall.

The **carotid canal** transmits the internal carotid artery, the internal carotid plexus of sympathetic nerves derived from the superior cervical ganglion, small veins connecting the cavernous venous sinus with the pharyngeal venous plexus, and lymph vessels from the meninges. On the postero-lateral wall of the canal, just above its lower aperture, there are the openings of the very narrow **carotico-tympanic canaliculi** for the tympanic branches of the carotid artery and of the carotid sympathetic plexus.

The **quadrate area** of the petrous temporal is the rough, nearly four-square area medial to and in front of the lower opening of the carotid canal, between that opening and the foramen lacerum. The *antero-lateral border* of the area lies against the posterior border of the great wing of the sphenoid, *i.e.*, the border immediately behind the foramen ovale and foramen spinosum; the two borders may touch one another or there may be a narrow fissure between them.

The *cartilaginous part* of the *auditory tube* (Eustachian tube) lies along the fissure, or the line of contact, in a shallow groove shared by both the bones. The postero-lateral end of the groove is at the medial side of the spine of the sphenoid, and it is continuous there with a canal in the interior of the temporal bone. The canal is called the **musculo-tubal canal**; it is divided by a thin bony septum into an upper canal and a lower; the *upper canal* lodges a tiny muscle called the tensor tympani; the *lower canal* is the **osseous part** of the **auditory tube.** If a pin or a hook is run along the groove to its postero-lateral end and pushed onwards, it will pass, usually without difficulty, into the canal; and, if one looks through the external acoustic meatus, the point of the hook will be seen in the tympanic cavity, for the auditory tube opens into the cavity and the tensor tympani muscle enters the cavity and is inserted into one of the auditory ossicles, namely, the *malleus.*

The **foramen lacerum** can be seen between the petrous temporal and the basi-occiput, and the posterior end of the **pterygoid canal** is situated on the anterior margin of the foramen, above and lateral to the **pterygoid tubercle**; they will be dealt with more fully when the floor of the cranial cavity is examined (p. 161).

The **quadrate area** gives origin to the levator palati or levator veli palatini muscle. Cartilage, or dense fibrous tissue, unites the *postero-medial border* of the area to the basi-occiput, and its *antero-medial border* to the posterior border of the great wing of the sphenoid; the cartilaginous part of the auditory (Eustachian) tube lies along its line of union with the great wing. The levator palati at its origin is therefore postero-medial to the tube. The tensor palati is a thin muscle with a triangular outline, the apex of the triangle being the tendon as it turns round the lower surface of the pterygoid hamulus, while the base is the origin of the muscle from the skull. It arises from the spine of the sphenoid and from the scaphoid fossa, and, between those points, from the cartilage of the tube; the upper part of the muscle therefore lies on the antero-lateral aspect of the tube and separates it from the mandibular nerve descending from the foramen ovale and the middle meningeal artery ascending to the foramen spinosum.

The **osseous part of the auditory tube** is about 10 mm. long. It is situated in the temporal bone, between the tympanic plate and the petrous temporal; and a thin bony septum separates it from the semi-canal for the tensor tympani, which lies above it. One end opens into the anterior part of the tympanic cavity; from there the tube passes medially, forwards and slightly downwards, and opens on the lateral end of the groove for the cartilaginous part, at the medial side of the spine of the sphenoid, where the opening is easily found. Push a pin through the opening and along the tube to the tympanic cavity, and note that the tube has the ascending part of the carotid canal on its postero-medial side, and the mandibular joint on the antero-lateral side.

Fissura Petro-tympanica.—The name **petro-tympanic fissure** is given usually to the whole length of the narrow slit seen between the mandibular fossa and the upper edge of the tympanic plate. The lateral end of the slit is directly in front of the opening of the external acoustic meatus; the medial end is directly behind the spine of the sphenoid.

The **tympanic plate** has three surfaces. The **posterior surface** is for the most part fused with the petrous and mastoid temporal. The curved **upper surface** forms the anterior wall, lower wall, and greater part of the posterior wall of the **external acoustic meatus**; its rough curved *lateral margin* gives attachment to the cartilage of the auricle. The **anterior surface** is concave and is related to the upper part of the parotid gland, which separates it from the back of the head and neck of the mandible; its uneven, sharp *lower border* gives attachment to the fascia covering the postero-medial surface of the parotid gland; its *upper border* forms the posterior boundary of the petro-tympanic fissure, and gives attachment to the fascia covering the antero-medial surface of the parotid gland.

The *lateral part* of the **petro-tympanic fissure** may be obliterated by fusion of the tympanic plate with the back of the post-glenoid tubercle. The *middle part* leads up into the tympanic cavity; the anterior process of the malleus is stuck into it; and the tympanic branch of the middle meningeal artery passes upwards through it. The chorda tympani nerve, having traversed the tympanic cavity, enters the *medial part* of the fissure, issues through its medial end, runs downwards, forwards, and in a medial direction, grooving the medial side of the spine of the sphenoid, and joins the lingual nerve below the foramen ovale. In some skulls a thin strip of bone is seen between the lips of the medial part of the fissure; that strip is the lower edge of the tegmen tympani (a part of the surface of the petrous temporal seen in the floor of the cranial cavity), which is continued downwards to form the antero-lateral wall of the bony part of the auditory tube. The slit below the tube, between that edge and the posterior lip of the fissure, is the cleft to which the name "petro-tympanic" properly applies, and through it the chorda tympani nerve makes its exit.

The **mandibular fossa** and the **articular tubercle** are for articulation with the head of the mandible, and their margins give attachment to the articular capsule, the thickened lateral part

which, called the temporo-mandibular ligament, is attached to the **tubercle at the root of the zygoma**; but the fossa and articular tubercle are separated from actual contact with the head of the mandible by an articular disc of fibro-cartilage, which is attached by its circumference to the capsule, and divides the cavity of the joint into an upper and a lower part.

CRANIAL CAVITY.

The **cranial cavity** is the large cavity which lodges the brain. The bones which share in its formation are the frontal, the ethmoid, the sphenoid, the occipital, the two parietal, and the two temporal bones. The cavity is lined with the outermost of the three membranes or meninges of the brain, namely, the **dura mater**, which consists of two closely adherent layers, the *outer* of which clothes the bone, serving the purpose of periosteum, and is called the *endocranium*. The periosteum on the outside of the skull is called the *pericranium*. The pericranium and the endocranium are both continuous with the fibrous ribbons, called *sutural ligaments*, that lie between the articulating edges of the bones, and are continuous with each other round the lips of the various foramina and fissures that lead from the cranial cavity to the exterior.

Section of Skull.—The cranial cavity can be exposed for examination either by a median section which splits the skull into a right and a left half, or by a horizontal section which removes the skull-cap. The second method is the more common; the saw-cut is usually made to pass through the *frontal* bone just above the superciliary arches, through the two inferior angles of the *parietal* bone and the upper part of the *squamous temporal* on each side, and through the *occipital* bone just above the external occipital protuberance. The two parts are then examined separately: the skull-cap shows the roof of the cranial cavity; the lower part of the skull shows its floor; the front, the sides, and the back of the cavity are included partly with the roof and partly with the floor.

The advantage of the median section is that it not only exposes the cranial cavity but also lays open the nasal cavity and the sphenoidal sinus. If the skull which the student has procured for himself has had the skull-cap removed, the lower part of the skull should then be divided into a right and a left half. If the student has an uncut specimen of skull he should remove the skull-cap by the saw-cuts indicated above, and then split the lower part of the skull into halves.

In making the sagittal section he should use a very fine saw, and should make the cut a little to one or other side of the median plane in order to avoid injury to the septum of the nose, but, at the same time, he must be careful not to injure the conchæ, which project from the side wall of the nasal cavity. The first cut should be made through the hard palate and the alveolar process of the maxilla; if they are not cut first they will break when the thicker parts of the skull are divided. The two halves can be tied together or hinged together with improvised pins and hooks when the student wants to examine both halves at once.

Thickness of Skull.—In cutting the skull the student will note that the thickness of the walls of the cranial cavity varies in different areas. The thicker and thinner parts are not all constant in position in different skulls, but the parts well covered with muscles are always thinner than the more exposed parts, *e.g.*, the floor of the temporal fossa and the floor of the posterior cranial fossa on each side of the median plane.

The bone of the skull as a whole is thicker in some races than in others, the more primitive races usually having the advantage of thicker skull bones; but in all races the skull bones are thinner in women and children than in men. The skull of a child is very thin, but it is more yielding and elastic than that of an adult and is less liable to fracture. There are, however, great differences in thickness in the skulls of adults of the same race and sex. About a quarter of an inch is an average thickness, but variations occur ranging from less than one-eighth of an inch to almost half an inch. There is no known relation between the thickness of the skull bones and the quality of the intelligence, but a thick skull obviously protects the brain more efficiently from injury by violence. It is

not possible to gauge the thickness of the skull with any certainty during life, except during the course of an operation; and in the early steps of an operation on the skull it is safer to assume that the skull is thin.

Roof of Cranial Cavity.

The **skull-cap** is the **roof** of the cranial cavity or **vault** of the skull. If the horizontal saw-cut has been made as indicated, the skull-cap includes part of the *frontal* bone in front, part of the *occipital* bone behind, nearly the whole of both *parietal* bones in the middle, and a very small part of the *squamous* portion of the *temporal* bone on each side, at the lower border of the parietal bone.

The internal or **cerebral surface** of the vault is highly concave in every direction. The dura mater is only loosely attached to the skull vault, except along the lines of the sutures, where, in a young adult skull, it is continuous with the sutural membranes or ligaments.

The **sutures** between the bones may be indistinct, for if their obliteration had commenced it will be more advanced on the inner surface than on the outer; and if the skull is that of an old person the sutures may have disappeared. The sutures are: The **sagittal suture**, uniting the two parietal bones; the **coronal suture**, uniting them to the frontal bone; the **lambdoidal suture**, uniting them to the occipital bone; and the **squamous suture**, on each side, uniting the parietal bone to the squamous temporal. The squamous suture is at a lower level on the inside of the skull than on the outside, because the squamous temporal overlaps the parietal bone on the outside, and the saw-cut may have been at such a level that the suture is seen only on the outside.

The following additional parts are to be noted on the cerebral surface of the vault:—

Crista Frontalis (Fig. 138, 41, p. 156).—The **frontal crest** is a median ridge on the anterior wall of the cranial cavity, on the lower part of the cerebral surface of the frontal bone, and it may extend far enough up to be seen on the skull-cap.

Sulcus Sagittalis.—The **sagittal groove** is a shallow median furrow on the cerebral surface of the vault, extending from above the root of the nose to the occipital protuberance. It begins on the frontal crest, passes upward and backwards on the frontal bone, backwards along the sagittal suture, and downwards on to the occipital bone, widening progressively during its course. The superior sagittal venous sinus lies along it, in the upper border of the falx cerebri, which is attached to its lips. (The falx cerebri is a fold of the inner layer of the dura mater, projected downwards from the cranial vault as a tense, median partition, to keep the two halves of the cerebrum apart and prevent friction between them in sudden movements of the head.)

Foveolæ Granulares.—The **granular pits** are small irregular depressions that are placed here and there alongside the sagittal groove. They are more numerous and larger in the skull of an old person than in a young skull, and the bone in their floors may be thin enough to be translucent. They lodge arachnoid granulations, which are small bud-like growths that protrude from the arachnoid. (The arachnoid is the middle and the thinnest of the three membranes that enclose the brain) [*ἀράχνιον* (arachnion) = a spider's web].

Foramen Parietale.—The **parietal foramen** (p. 130), when present, is situated in the parietal bone, close to the sagittal groove, about an inch or an inch and a half above the lambdoid suture.

Sulci Arteriosi (Fig. 146, 3, p. 170).—The **arterial grooves** are narrow branching grooves seen extending from the cut edges of the vault towards the top. They are grooves for meningeal vessels; the largest grooves are seen on the part of the vault formed by the parietal bone; those are for the branches of the middle meningeal artery and vein, and their direction is upwards and backwards.

Impressiones Digitatæ.—The **digital impressions** are the broad, shallow, ill-defined depressions, like finger-marks, found all over the vault. They correspond to the gyri or convolutions on the surface of the brain.

Floor of Cranial Cavity.

The **basis cranii interna**, or upper surface of the base of the skull, is the floor of the cranial cavity. Grooves for meningeal vessels are seen on it; and the digital impressions are better marked than on the vault. The dura mater is more firmly attached to the bone of the base than to that of the vault.

The floor is divided into three main districts, one behind the other and at different levels, corresponding to the anterior, middle, and posterior **cranial fossæ**, of which the anterior is at the highest level and the posterior at the lowest.

Fossa Cranii Anterior.

The **anterior cranial fossa** contains the lower part of the frontal lobes of the brain. It is bounded in front and at the sides by the frontal bone, while its floor is divided into (1) a median part, which lies above the nasal cavity and is formed by the ethmoid bone and the body of the sphenoid, and (2) a right and a left lateral part, each of which lies above the orbit and is made up of the orbital plate of the frontal bone and the small wing of the sphenoid.

In the **median subdivision** the chief parts to be looked for are the following:—

Crista Galli.—The **crista galli** is the upstanding process seen in the median plane in front.

Foramen Cæcum.—The **foramen cæcum** is the small pit in front of the crista galli [*cæcum* = blind]. The foramen, however, is not blind: there is a small aperture at its bottom which transmits a vein.

Crista Frontalis.—The **frontal crest** is the median ridge seen above the foramen cæcum, in the anterior boundary of the fossa; it extends upwards on to the vault and fades away there.

Lamina Cribrosa.—At each side of the crista galli there is a narrow, horizontal plate of bone, called the lamina cribrosa or *cribriform plate* of the ethmoid because it is full of little holes; it separates the cranial cavity from the nasal cavity (Fig. 146, 10, p. 170; Fig. 147, 4, p. 172).

Behind the two cribriform plates there is a broad, fairly flat area of bone; that is the anterior part of the upper surface of the body of the sphenoid, and it is limited behind by the anterior lip of a groove called the sulcus chiasmatis or *optic groove*, which leads laterally on each side into an aperture called the *optic foramen*. The optic groove and foramen are, however, included in the middle cranial fossa.

By far the greater part of the **lateral subdivision** is formed by the orbital plate; only a small part posteriorly is formed by the small wing. The **orbital plate** separates the cranial cavity not only from the orbit, but also from the ethmoidal air-cells; for the medial part of the plate overlies the labyrinth of the ethmoid, roofing in the air-cells. The *frontal sinus* extends backwards for a variable distance between the two tables of bone of which the plate is composed; and the upper table therefore separates the cranial cavity from part of the frontal sinus.

In an old adult skull the suture between the plate and the **small wing** may be obliterated, but if the suture is visible the outline of the wing can be made out—fairly broad at its medial end and tapering to a point at the lateral end. The posterior border of the small wing is the free, sharp margin of the floor of the lateral part of the fossa, and it ends *medially* in a prominent process, called the **anterior clinoid process**, that juts backwards behind the optic foramen.

Each lateral part of the floor of the anterior cranial fossa is convex, rather uneven, and slopes downwards towards the median portion, more so anteriorly than posteriorly, where both parts are smoother and more nearly horizontal. Together with the corresponding half of the median portion it supports the frontal lobe of the brain; the ridges and **digital impressions** on the lateral part correspond to the sulci and gyri on the orbital surface of the lobe, and therefore vary in the pattern they make; they are much better marked in some skulls than others.

The antero-lateral margin of the orbital surface of the frontal lobe, *i.e.* the superciliary margin of the brain, fits into the angle between the floor and the antero-lateral wall of the fossa, which corresponds, on the exterior, to a line drawn from the root of the nose upwards and then laterally along the superciliary arch and onwards to the root of the zygomatic process of the

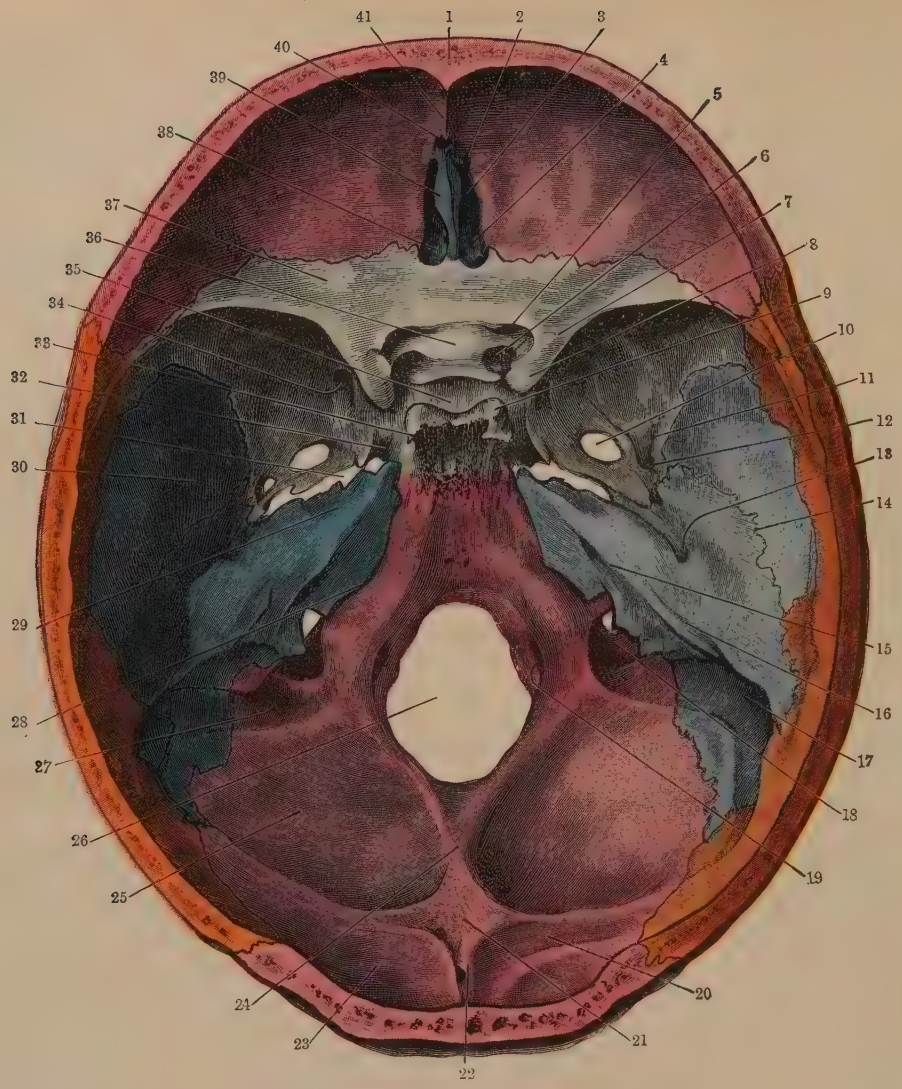

FIG. 138.—FLOOR OF CRANIAL CAVITY.

The frontal and occipital bones are coloured red ; the ethmoid and temporal bones, blue ; the parietal, orange ; and the sphenoid is left uncoloured.

1. Frontal bone.
2. Slit for anterior ethmoidal nerve.
3. Anterior ethmoidal foramen.
4. Lamina cribrosa of ethmoid.
5. Optic foramen.
6. Foramen for internal carotid artery formed by anterior and middle clinoid process.
7. Small wing of sphenoid.
8. Anterior clinoid process, in this case united on its medial side to the middle clinoid processes.
9. Posterior clinoid process.
10. Foramen ovale.
11. Groove for middle meningeal artery.
12. Foramen spinosum.
13. Hiatus canalis facialis.
14. Line of petro-squamosal suture.
15. Internal acoustic meatus.
16. Groove for superior petrosal sinus.
17. Groove for sigmoid part of transverse sinus.
18. Jugular foramen.
19. Canalis hypoglossi.
20. Groove for transverse sinus.
21. Internal occipital protuberance.
22. Ridge for attachment of falx cerebri.
23. Fossa for lodgment of left occipital lobe of brain.
24. Internal occipital crest.
25. Fossa for the lodgment of the left cerebellar hemisphere.
26. Foramen occipitale magnum.
27. Groove for the sigmoid sinus turning into the jugular foramen.
28. Groove for the inferior petrosal sinus between petrous temporal and basi-occipital.
29. Trigeminal impression for the semilunar ganglion.
30. Middle cranial fossa for lodgment of the temporal lobe of the brain.
31. Cleft between petrous temporal and great wing near foramen lacerum.
32. Carotid groove in front of foramen lacerum.
33. Dorsum sellæ of sphenoid.
34. Leads into foramen rotundum.
35. Fossa hypophyseos.
36. Tuberculum sellæ of the sphenoid.
37. Anterior cranial fossa for lodgment of frontal lobes of the brain.
38. Cribriform plate of ethmoid.
39. Crista galli of ethmoid.
40. Foramen cæcum.
41. Frontal crest for attachment of falx cerebri.

frontal bone, and then backwards to the pterion. The gyrus rectus, which is the most medial gyrus of the orbital surface, lies on the cribriform plate and the body of the sphenoid behind that; the olfactory tract and bulb, immediately lateral to the gyrus rectus, lie on the sphenoid and on the orbital plate at the edge of the cribriform plate; the nerve filaments, twenty or so, which constitute the olfactory nerve, come up from the nose through the small **foramina in the cribriform plate** (which are arranged in two irregular rows) and end in the olfactory bulb.

In the lateral part of the fossa, especially in front and at the side, there are narrow branching *grooves for the anterior meningeal vessels* derived from the middle meningeal and ethmoidal vessels.

The **crista galli** is the upper anterior part of the perpendicular lamina of the ethmoid projected upward into the cranial cavity. It is highest and thickest in front, where it may contain either spongy bone or an air cavity which opens directly into the nose or into the frontal sinus; and from its anterior part two processes, called *alar processes*, project forwards to articulate with the frontal bone and form the side boundaries of the **foramen cæcum**, which lies between the frontal bone and the crista galli.

The anterior end and anterior part of the convex border of the falx cerebri are attached to the sharp sloping border of the crista galli and to the frontal crest. The anterior part of the superior sagittal venous sinus lies on the frontal crest in the convex border of the falx, and its commencement is connected with the veins of the nose by the vein which passes through the foramen cæcum.

The **nasal slit** is a short and narrow cleft, often difficult to find, situated between the anterior part of the root of the crista galli and the anterior part of the cribriform plate; it leads down into the nasal cavity.

The **anterior** and **posterior ethmoidal canals** are narrow tunnels which begin at foramina of the same name between the roof and medial wall of the orbit, where they have been seen already, and run in a medial direction, between the labyrinth of the ethmoid and the medial part of the orbital plate of the frontal bone, to open into the cranial cavity; their openings are often hidden by overhanging lips of bone. The *posterior* canal transmits the posterior ethmoidal vessels and opens at the junction of the cribriform plate with the front of the sphenoid. The posterior ethmoidal nerve, also contained in the canal, does not reach its cranial end, being distributed to the mucous lining of the ethmoidal and sphenoidal sinuses. The *anterior* canal is larger; it opens at the side of the cribriform plate about the middle; it transmits the anterior ethmoidal vessels and the anterior ethmoidal nerve, which is a continuation of the naso-ciliary nerve; the nerve runs forwards on the cribriform plate and descends to the nose through the **nasal slit** or through a foramen alongside the slit.

The **small wing of the sphenoid**, triangular in outline and compressed from above downwards, lies in the roof of the orbit and superior orbital fissure, and in the floor of the anterior cranial fossa; posteriorly, it overhangs the middle cranial fossa. It arises by two roots separated by the optic foramen: the *anterior root*, broad and flat, is continuous with the anterior part of the upper surface of the body of the sphenoid; the *posterior root*, much smaller, springs from the side of the body of the sphenoid and stands between the optic foramen and superior orbital fissure. The spheno-parietal venous sinus lies in the dura mater on the lower surface of the overhanging posterior margin of the wing. The **anterior clinoid process**, projecting backwards from the postero-medial angle of the wing, gives attachment to the anterior end of the free margin of the tentorium cerebelli.

Fossa Cranii Media.

The **middle cranial fossa** is divided into a median part and a right and a left lateral part.

Median Part of Middle Cranial Fossa.

The median part is elevated above the level of the lateral parts. Its floor is formed by the body of the sphenoid, and is separated therefore from the cavity of the nose by the sphenoidal sinus enclosed within the bony shell of the body of the sphenoid (Fig. 146, 8, p. 170). The floor presents for examination the optic groove and foramina, the sella turcica, and the carotid grooves.

Sulcus Chiasmatis.—The **optic groove** or sulcus chiasmatis is situated in the most anterior part of the floor, immediately behind the anterior cranial fossa; it may be well defined or very shallow.

Foramen Opticum.—On each side the optic groove ends at the **optic foramen**, which opens into the medial side of the back of the orbit, where it has been seen already (pp. 134 and 136).

Sella Turcica.—**Sella turcica** is the name given to the middle part of the upper surface of the body of the sphenoid, from a resemblance to a Turkish saddle. The pommel is the transverse, oval elevation, called the **tuberculum sellæ**, situated directly behind the optic groove. The seat is the wide, smooth depression behind

the tuberculum; it is called the **hypophyseal fossa** (pituitary fossa) because a process of the brain called the hypophysis (pituitary body) lies in it. Behind the hypophyseal fossa there is an upstanding square plate of bone (broken off in many skulls) called the **dorsum sellæ** or back of the saddle. The upper corners of the dorsum sellæ are called the **posterior clinoid processes.** The anterior and posterior clinoid processes get their name from a fancied resemblance to the four posts of a bed [κλίνη (clinē) = a bed]. Low down on the side of the dorsum sellæ, where its root joins the body of the sphenoid, there is a narrow groove for the passage forwards of the abducent nerve; the groove is only the width of a thick pin, but can usually be seen even when the dorsum sellæ is broken off.

Sulcus Caroticus.—The *carotid groove* is a broad, shallow, ʃ-shaped groove on the upper part of the side of the body of the sphenoid. It begins at the medial side of the foramen lacerum, ascends for a short distance, then runs forwards on the side of the sphenoid body, and finally turns upwards to end medial to the anterior clinoid process. The internal carotid artery lies on it, and its sinuous bends indicate the course of the artery in the cranial cavity.

In many skulls there is a pair of **middle clinoid processes.** Each middle clinoid process, when present, is usually a small tubercle situated a little behind the lateral end of the tuberculum sellæ. In some skulls it is a large process and joins the anterior clinoid process (Fig. 138, 8), converting the termination of the carotid groove into a foramen, called the **carotico-clinoid foramen.** Occasionally it joins the posterior clinoid process instead, or it may branch and join both the anterior and the posterior clinoid process.

The **optic foramen** is a short, wide, nearly circular canal which passes in a lateral direction, forwards and slightly downwards from the cranial cavity into the orbit, and transmits the optic nerve and the ophthalmic artery. It is bounded by the body of the sphenoid and the two roots of the small wing, the thin bone of the body separating it from the sphenoidal sinus.

The **optic groove** or sulcus chiasmatis connects the two optic foramina. The optic chiasma, which connects the two optic nerves, does not, however, lie in the groove, but is situated a little distance above it; therefore "sulcus chiasmatis" is not an appropriate name.

The **hypophyseal fossa** lodges the hypophysis and is roofed over by a fold of dura mater called the diaphragma sellæ, which has a hole in the middle of it for the stalk that connects the hypophysis with the brain. The **posterior clinoid processes** give attachment to the anterior ends of the circumferential margin of the tentorium cerebelli.

The cavernous venous sinus lies at the side of the body of the sphenoid on the horizontal part of the **carotid groove**; its centre is opposite a point on the upper border of the zygomatic arch directly above the tubercle of the root of the zygoma; the carotid artery, lying in the carotid groove, is imbedded in the sinus, together with the carotid plexus, the oculo-motor, trochlear, ophthalmic, and abducent nerves, while the maxillary nerve runs forwards towards the foramen rotundum just below the carotid groove and cavernous sinus. Those structures are therefore all related to the body of the sphenoid—the cavernous sinus, the carotid artery, and the maxillary nerve being closely related to it and to the sphenoidal sinus within it. The two cavernous sinuses are connected by anterior and posterior inter-cavernous sinuses which, respectively, cross the back of the **tuberculum sellæ** and the front of the **dorsum sellæ.** The notch between the tuberculum sellæ and the anterior clinoid process is occupied by the carotid artery as it leaves the carotid groove.

Lateral Part of Middle Cranial Fossa.

Each lateral subdivision of the middle cranial fossa is a wide, deep hollow which sinks to the level of the zygomatic arch and lower surface of the body of the sphenoid; it contains the temporal lobe of the brain. The principal parts on the exterior of the skull to which it is related are the orbit *in front,* the temporal fossa *laterally,* and the infra-temporal fossa and the mandibular joint *below.*

The bones in the lateral part of the middle fossa are: (1) The petrous part of the temporal bone, *i.e.* the pyramidal mass of bone forming its posterior wall or boundary; (2) the squamous temporal, in front of the petrous, in the side wall of the fossa and slightly in the floor; (3) the great wing of the sphenoid, partly in the side wall in front of the squamous temporal and partly in the anterior wall and in the floor in front of the petrous temporal. Beyond the limits of the fossa the lower part of the parietal bone lies in the side wall of the cranial cavity above the squamous temporal, and its antero-inferior angle articulates with the top of the great wing.

The *anterior lip* of the hollow is the overhanging posterior margin of the anterior fossa, and it ends laterally, on the side wall, **opposite the pterion**. The *posterior lip* is the upper margin of the petrous temporal; it is channelled lengthwise by a groove, sometimes well defined, but sometimes poorly marked and interrupted, which lodges the superior petrosal venous sinus; close to its medial end there is a wide, very shallow notch, called the *trigeminal notch*, on which the trigeminal or fifth cerebral nerve lies.

Fissura Orbitalis Superior.—The noteworthy feature in the *anterior boundary* of the fossa is the large, oblique gap between the wings of the sphenoid, called the **superior orbital fissure**, which opens into the orbit, where it has been examined already (pp. 134, 135).

The points to be noted in the *floor* are the foramen rotundum, foramen ovale, foramen lacerum, foramen spinosum, and the grooves for the meningeal vessels.

Foramen Rotundum.—The **foramen rotundum** is the round hole situated almost directly below the medial end of the superior orbital fissure; it leads horizontally forwards into the upper part of the pterygo-palatine fossa, and transmits the maxillary nerve; if a pin is pushed forwards through the foramen, and the skull is looked at from the side, the point of the pin will be seen entering the pterygo-palatine fossa. The foramen is situated in the root of the great wing, close to the body of the sphenoid, and is separated only by thin bone from the sphenoidal sinus.

Foramen Ovale.—The **foramen ovale** is nearly half an inch behind the foramen rotundum, near the posterior border of the great wing of the sphenoid; it transmits the mandibular nerve, and has been seen already in the roof of the infra-temporal fossa (pp. 146, 147).

Foramen Spinosum.—The **foramen spinosum**, behind and lateral to the foramen ovale and quite close to it, also has been seen from the infra-temporal fossa; it transmits the middle meningeal vessels.

Sulci Arteriosi.—The **grooves for the middle meningeal vessels** are usually sufficiently distinct to enable one to trace the course of the main trunk of the artery and its branches on the walls of the cranial cavity; their whole course is seen in a skull split into halves without previous removal of the skull cap (Fig. 146, p. 170). The **main groove** begins at the foramen spinosum, runs forwards and in a lateral direction on the part of the squamous temporal that bears the articular tubercle of the lower surface of the skull; and at a varying point, but usually near the side of the skull opposite a point on the upper margin of the zygomatic arch about midway between the acoustic meatus and the margin of the orbit, it divides into an anterior and a posterior branch. The **anterior groove** extends from that point to the anterior inferior angle of the parietal bone *opposite the pterion*; in that region the groove is usually very deep and often roofed over and converted into a tunnel for a short distance; becoming a groove again, it extends upwards and backwards, branching over the parietal bone, the chief branch of the groove taking a line towards the point on the top of the skull midway between nasion and inion. The **posterior groove** extends backwards and upwards across the squamous temporal on to the parietal bone, branching as it goes, the chief branch taking a line towards the lambda. The meningeal vessels, since they are so closely related to the bone, are liable to be torn when the skull is injured during life, especially the veins, for they lie between the arteries and the bone. The chief point of danger is at the pterion where the anterior branch is lodged in a deep groove and may lie in a tunnel. The grooves are in the inner table of the skull bones, which is more brittle than the outer table, and is sometimes called the *vitreous* table on that account; in an injury to the head the brittle, inner table may be cracked and the vessels torn, though the outer table is not broken [*vitreus*=like glass].

Foramen Lacerum.—The **foramen lacerum** is a large hole, with ragged margins, already seen on the lower surface of the skull. Seen in the floor of the cranial cavity, it is situated between the petrous temporal and the sphenoid. The carotid canal opens into it laterally, and the carotid artery crosses it to reach the carotid groove on the sphenoid. A spur of bone, called the **lingula**, projects obliquely backwards from the lateral margin of the carotid groove. In some skulls the lingula is a mere spicule of bone; in others it is long enough to reach the petrous

temporal and form a complete lateral boundary for the foramen lacerum. In many skulls the roof of the carotid canal is deficient in bone, or has been partly broken away; in that case the jagged margins of the incomplete roof of the canal are continuous with the margins of the foramen lacerum. The posterior end of the **pterygoid canal** is found on the anterior margin of the foramen lacerum almost directly below the lingula.

The *posterior wall* or boundary of the lateral part of the middle cranial fossa is formed by the anterior face of the petrous temporal, and is nearly triangular in outline; the parts to be specially looked for in it are the trigeminal impression, the arcuate eminence, the tegmen tympani, and the hiatus of the facial canal.

Impressio N. Trigemini.—The **trigeminal impression** is a shallow depression, barely wide enough to accommodate a finger tip, situated on the anterior surface

Preparation to display the position and relations of the tympanic antrum. The greater part of the posterior wall of the external acoustic meatus has been removed, leaving only a bridge of bone at its medial extremity; under this a bristle (thick black) is displayed, passing from the tympanic antrum through the iter chordæ posterius to the cavity of the tympanum.

of the petrous temporal near its apex or medial extremity, below the trigeminal notch. The semilunar ganglion—the chief ganglion of the trigeminal nerve—lies in it.

Eminentia Arcuata.—The **arcuate eminence** is a smooth, rounded elevation on the anterior surface of the petrous temporal near its upper margin, a little lateral to a point midway between the apex of the petrous temporal and the side of the skull; sometimes it is diffuse and ill-defined. Underneath it, in the substance of the bone, there is one of the curved canals of the internal ear, called the *superior semicircular canal*, the convexity of whose curve produces the elevation.

Hiatus Canalis Facialis.—The **hiatus** of the **facial canal** is a small slit situated lower down on the anterior surface, and about midway between the apex of the petrous temporal and the side of the skull. It communicates with the facial canal in the interior of the bone, and transmits a small nerve, called the greater superficial petrosal nerve, which emerges from the hiatus and lies in a groove that runs in a medial direction and downwards and forwards to the foramen lacerum.

Tegmen Tympani.—The **tegmen tympani** is the fairly smooth area of bone forming the lateral part of the anterior surface of the petrous temporal, and is so

named because part of it forms the roof of the middle ear or tympanum. It is made of thin bone, and therefore disease in the middle ear has only a short way to travel to attack the membranes of the brain and the brain itself. The tegmen tympani is the roof not only of the tympanum but also of the musculo-tubal canal and the tympanic antrum. The **tympanum** has been seen already at the far end of the external acoustic meatus, and its position relative to the cranial cavity can be gauged from its position as seen through the meatus. The **musculo-tubal canal** runs in a medial direction and downwards and forwards from the tympanum, and it was located when the lower surface of the skull was examined. The **tympanic antrum** is a small but very important cavity, which lies in the substance of the temporal bone behind the tympanum and communicates with the tympanum; it is about half an inch medial to the suprameatal triangle; it communicates posteriorly with the air cells which pervade the mastoid portion of the temporal bone to a greater or lesser extent; the antrum is relatively large at birth; the mastoid cells grow as diverticula from the antrum, commencing at or shortly before birth, but not reaching full development till after puberty. If the student has a specimen of skull of his own, he would not be ill-advised to break through the tegmen tympani carefully and snip it away, in order to see the tympanic antrum and note its relation to the middle ear and to the exterior of the skull.

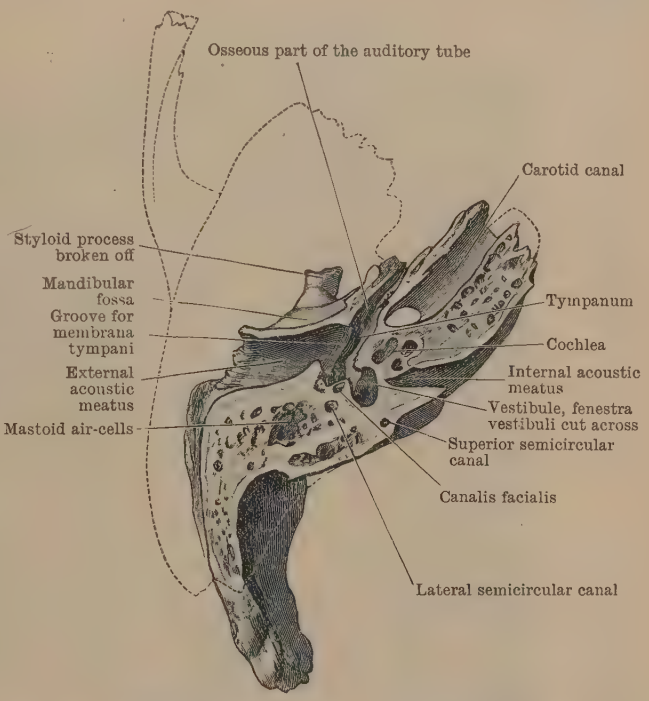

FIG. 140.—HORIZONTAL SECTION THROUGH THE LEFT TEMPORAL BONE (Lower Half of Section).

The overhanging *anterior lip* of the **lateral part of the middle cranial fossa** has a concave edge which begins medially at the anterior clinoid process and sweeps in a lateral direction and forwards and upwards to end at the side of the skull in the region of the pterion, the groove or tunnel for the anterior branch of the middle meningeal vessels being just behind, or even in, its lateral extremity. The lip is formed chiefly by the small wing of the sphenoid, and is completed laterally by the frontal bone. It fits into the stem of the lateral fissure of the cerebrum, *i.e.* the cleft between the frontal and temporal lobes; therefore the lateral end of the stem, where it breaks up into the rami of the fissure, is opposite the pterion.

The lower margin of the temporal lobe, *i.e.* the anterior part of the infero-lateral margin of the cerebrum, fits into the ill-defined groove that marks the junction of the side wall of the fossa with the floor and posterior boundary; and it corresponds, on the exterior, to a line which begins near the anterior end of the upper border of the zygomatic arch, runs backwards along the upper border of the arch and the posterior root, and is continued backwards a short distance beyond the root to a point which corresponds, in the living head, to the place where the skin of the back of the root of the ear joins the skin of the head.

The **foramen of Vesalius**, when present, is situated a little medial to the foramen ovale.

The **foramen lacerum** is a short wide canal seen both on the lower surface of the skull and in the floor of the middle cranial fossa; the carotid canal opens into it laterally, and the carotid groove begins on its antero-medial boundary. On the **lower surface** it is bounded *postero-laterally* by the petrous temporal, *medially* by the basilar part of the occipital bone and the body of the sphenoid, and *anteriorly* by the root of the great wing and pterygoid process of the sphenoid. **In the cranial cavity** it is bounded *postero-laterally* by the petrous temporal, *medially* and *anteriorly* by the carotid groove on the body and root of great wing of the sphenoid; and the lingula, if long, completes the *lateral* boundary, which is defective if the lingula is short. The foramen

transmits a meningeal branch of the ascending pharyngeal artery, some meningeal lymph vessels, and small veins connecting the cavernous sinus with the pharyngeal venous plexus. It *contains* (1) some cartilage, (2) the internal carotid artery, surrounded by the internal carotid plexus of sympathetic nerves and a plexus of tiny veins connecting the cavernous sinus and pharyngeal plexus, (3) the great deep petrosal nerve, the termination of the greater superficial petrosal nerve, and the beginning of the nerve of the pterygoid canal. The cartilage fills the lower part of the foramen, and is pierced by the structures transmitted. The internal carotid artery, after it

emerges from the carotid canal and as it bends up into the cranial cavity to enter the cavernous sinus, lies on the upper surface of the cartilage. While in the foramen the carotid nerve plexus gives off the great deep petrosal nerve. The greater superficial petrosal nerve, a branch of the facial, runs in a groove on the anterior surface of the petrous temporal from the hiatus canalis facialis to the foramen lacerum, and joins the great deep nerve to form the nerve of the pterygoid canal, which traverses that canal and joins the spheno-palatine ganglion.

The **pterygoid canal** is a narrow horizontal tunnel, about half an inch long, which traverses the combined root of the pterygoid process and great wing of the sphenoid, and transmits the nerve of the pterygoid canal and an artery of the same name derived from the third part of the

internal maxillary artery. The posterior end of the canal opens on the anterior margin of the foramen lacerum below the lingula and above the pterygoid tubercle. The anterior end opens on the posterior wall of the pterygo-palatine fossa below and medial to the foramen rotundum.

The motor and sensory roots of the trigeminal nerve cross the **trigeminal notch** and enter the **trigeminal impression** on the roof of the medial end of the carotid canal, where the sensory root joins the semilunar ganglion; the ganglion also lies partly in the impression and partly overlaps the carotid artery in the foramen lacerum. Three large nerves spring from the ganglion—the ophthalmic, which runs forwards towards the superior orbital fissure but divides into branches before it gets there; the maxillary, which runs forwards to the foramen rotundum; and the mandibular, which descends to the foramen ovale. The motor root runs under cover of the ganglion and is incorporated in the mandibular nerve either at the foramen ovale or just below it.

The **hiatus canalis facialis** transmits the greater superficial petrosal nerve and the petrosal branch of the middle meningeal artery. The nerve runs in a groove medially and forwards, and has to pass under cover of the semilunar ganglion or the mandibular nerve as it approaches the foramen lacerum.

Below the hiatus there is a small aperture through which the lesser superficial petrosal nerve issues from the substance of the temporal bone; continuous with the aperture there is a narrow groove which runs medially, forwards and downwards to the suture between the petrous temporal and the great wing of the sphenoid. The aperture and the groove are often very difficult to identify. The nerve lies in the groove and leaves the skull either through that suture or through the foramen ovale, or through the **canaliculus innominatus**, which, when present, is situated behind the foramen ovale.

Occasionally the remains of the *petro-squamous suture* can be seen in the adult near the side wall of the skull.

The **tympanum**; the **internal ear**, which lies in the substance of the petrous temporal medial to the tympanum; the **musculo-tubal canal**, which opens out of the anterior part of the tympanum and is divided by a septum into an *auditory tube* and a *canal for the tensor tympani* muscle; the **tympanic antrum**, situated behind the tympanum; and the **mastoid air cells**, which communicate with the antrum—are all described fully in the chapter on Sense Organs.

Fossa Cranii Posterior.

The **posterior cranial fossa** lies above the vertebral column and the muscles of the back of the neck. It is the largest and deepest of the cranial fossæ, and it lodges the hind-brain, *i.e.* cerebellum, pons, and medulla oblongata.

The **bones** which form the walls of the fossa are: (1) the posterior part of the body of the **sphenoid**, including the *dorsum sellæ*; (2) the posterior surface of the **petrous temporal**; (3) the cerebral surface of the **mastoid temporal**, in the side wall behind the petrous temporal; (4) the posterior inferior angle of the **parietal bone**, above the mastoid temporal; (5) the whole of the **occipital bone**, except the part of the squama that lies above the level of the external occipital protuberance and the superior nuchal lines: the **basilar part** of the occipital bone is situated in the anterior wall of the fossa, above and in front of the foramen magnum, which occupies the lowest part of the floor; the **lateral part**, including the jugular process, lies in the floor, at the side of the foramen magnum; the lower, larger part of the **squama** lies in the floor, in the side wall, and in the posterior wall, behind the foramen magnum, behind the lateral part and behind the mastoid temporal and inferior angle of the parietal bone. In an adult over 25 years the basilar part is fused with the body of the sphenoid, the line of fusion being barely half an inch below the root of the dorsum sellæ.

The **rim** of the fossa is formed by: (1) the **dorsum sellæ**, in the middle in front; (2) in the middle posteriorly, a prominent elevation, called the **internal occipital protuberance**, which is nearly opposite the external protuberance; (3) the **upper margin of the petrous temporal**, on each side in front; (4) on each side, posteriorly, a broad, shallow, horizontal groove, called the **transverse sulcus**, which begins at the side of the internal occipital protuberance, and passes laterally and forwards to the base or lateral end of the petrous temporal; at that point it leaves the rim to become continuous with a deeper groove, called the sigmoid sulcus, which extends sinuously to the jugular foramen; the horizontal part of a large venous sinus, called the transverse sinus, lies in the transverse groove, and the sigmoid part of that sinus lies in the sigmoid groove.

A wide fold of the inner layer of the dura mater, shaped like a tent and called the **tentorium cerebelli**, roofs over the posterior cranial fossa and keeps the weight

of the hinder part of the cerebrum off the cerebellum. The circumferential or basal margin of the tentorium is attached to the lips of the transverse groove and the lips of the groove for the superior petrosal sinus on the upper margin of the petrous temporal.

The fossa is divisible into a median part and a right and a left lateral part.

Median Part of Posterior Cranial Fossa.

The parts to be noted in the median subdivision are the foramen magnum, the hypoglossal canals, the jugular tubercles, the clivus, the grooves for the inferior petrosal sinuses, and the internal occipital crest.

Foramen Occipitale Magnum.—The **foramen magnum** is in the lowest part of the fossa. The medial surface of the occipital condyle can be seen at the anterior part of the margin on each side, and in many skulls the condyles encroach upon the foramen and reduce the width of its anterior part. (See also p. 148.)

Canalis Nervi Hypoglossi.—The internal opening of the **canal for the hypoglossal nerve** is situated a little above the part of the margin of the foramen magnum that is formed by the condyle. The opening is rather hidden unless the skull is tilted; and it is often double on one or both sides. The external opening has been seen already on the lower surface of the skull (p. 149).

Tuberculum Jugulare.—The **jugular tubercle** is the smooth rounded elevation situated above and in front of the internal opening of the hypoglossal canal.

Clivus.—The **clivus** is the broad sloping surface between the anterior margin of the foramen magnum and the root of the dorsum sellæ; it is formed by the upper surfaces of the basilar part of the occipital bone and of the posterior part of the body of the sphenoid; it is related to the pons and medulla oblongata of the brain [*clivus* = a slope].

Sulcus Petrosus Inferior.—The **groove for the inferior petrosal sinus** lies along the suture between the basilar part of the occipital bone and the petrous temporal, and is shared by both bones.

Crista Occipitalis Interna.—The **internal occipital crest** is the strong median ridge between the foramen magnum and the internal occipital protuberance.

The hypoglossal nerve pierces the dura mater as two bundles which unite in the **hypoglossal canal**. When the opening of the canal is double, the two bundles may enter the canal separate, or they may both enter through one of the openings, while the other transmits a meningeal artery.

The **jugular tubercle** overlies the hypoglossal canal; immediately behind and lateral to the tubercle there is a short, shallow groove in which the ninth, tenth, and eleventh cerebral nerves lie, as they pass towards the jugular foramen.

The **clivus** is concave from side to side. Its upper part is related to the pons and the basilar artery, its lower part to the medulla oblongata and the vertebral arteries, and, near the foramen magnum, it is roughened by the attachments of the membrana tectoria and the upper limb of the cruciate ligament. Between the two layers of the dura mater that cover the clivus there are some venous channels, called the basilar plexus, which connect the right inferior petrosal sinus with the left. The abducent nerve, on each side, pierces the inner layer of the dura mater near the lateral margin of the clivus, about half an inch below the dorsum sellæ, and runs upwards on the clivus, between the two layers of dura mater, to the groove on the side of the root of the dorsum sellæ, where it enters the cavernous sinus.

The **groove for the inferior petrosal sinus** begins at the apex of the petrous temporal, *i.e.* at the medial end of its upper border, where the sinus is connected with the posterior end of the cavernous sinus; it runs obliquely downwards, backwards, and in a lateral direction along the petro-occipital suture, to the jugular foramen, where the sinus, descending through the antero-medial part of the foramen, joins the commencement of the internal jugular vein.

The **internal occipital crest** gives attachment to a small fold of the inner layer of dura mater, called the falx cerebelli, which intervenes between the two hemispheres of the cerebellum. A small venous sinus, called the occipital sinus, lies along the edge of the crest between the two layers of the falx; sometimes the sinus is paired. The lower or anterior end of the crest sometimes divides into two parts which form the boundaries of a small depression called the **vermian fossa**, because a part of the cerebellum called the vermis is related to it.

The tentorium cerebelli, the falx cerebri, and the falx cerebelli are attached to the **internal occipital protuberance**; in its immediate neighbourhood the superior sagittal sinus and the straight sinus end, and the transverse sinuses and the occipital sinus begin; the posterior end of the cerebrum is immediately above and lateral to it. The internal occipital protuberance is seldom directly opposite the external protuberance, but there is so little difference in their levels that the external protuberance is usually taken as the surface guide to the position of structures

near the internal protuberance. Owing to the two protuberances, that region of the occipital bone is one of the thickest parts of the skull.

Lateral Part of Posterior Cranial Fossa.

The chief parts to be noted in each lateral subdivision of the posterior cranial fossa are the cerebellar fossa, the transverse and sigmoid grooves, the jugular foramen, the condyloid canal, the mastoid foramen, and the internal acoustic meatus. Points of less importance are the grooves for the meningeal arteries, the openings of the aqueduct of the cochlea and aqueduct of the vestibule, and the subarcuate fossa.

The **cerebellar fossa** is the wide concavity between the transverse groove and the foramen magnum. Faint grooves produced by meningeal arteries may be seen in its floor.

Sulcus Transversus.—The **transverse groove** begins at the side of the internal occipital protuberance and sweeps round the wall of the cranial cavity to the lateral end of the upper margin of the petrous temporal, where it joins the sigmoid groove.

Sulcus Sigmoideus.—The **sigmoid groove** curves downwards and descends along the side wall of the skull to the floor, extends in a medial direction on the floor for an inch, and, finally, curves forwards to end at the jugular foramen. Its curves resemble those of the letter S; hence the name "sigmoid" [*sigma* is the Greek name for the letter S].

The position of the two grooves corresponds, on the exterior of the skull, to a line (1) which begins at the side of the external occipital protuberance, and is drawn almost horizontally, but with a slight upward convexity, to a point a little behind the place where the posterior root of the zygoma joins the supramastoid crest, and that point, on the living head, is where the skin of the upper part of the back of the root of the auricle joins the skin of the head; (2) from that point the line is drawn almost vertically downwards to a point about a finger's-breadth behind the lower margin of the external acoustic meatus; (3) from there, forwards to the lower border of the meatus. The first or horizontal part of the line is opposite the horizontal part of the transverse sinus and the attachment of the tentorium; the posterior part of the infero-lateral border of the cerebrum is just above it; the margin of the cerebellum is just below it. The second and third parts of the line correspond to the sigmoid part of the transverse sinus.

The sigmoid groove is deeper than the transverse groove; in some skulls its upper part is especially deep, at the expense of the petrous temporal, so that it is quite close to the tympanic antrum, and the sigmoid sinus in such a case is in considerable danger in an operation on the antrum.

The **mastoid foramen** is an aperture of variable size that leads from the exterior of the skull (p. 136) into the sigmoid groove on the side wall of the fossa. The **condyloid canal,** when present, passes from the condyloid fossa (p. 149) into the posterior cranial fossa and opens into or near the sigmoid groove on the floor of the fossa.

Eminentia Cruciata.—The posterior part of each transverse groove is situated on a thick, blunt ridge that extends in a lateral direction from the internal occipital protuberance for some distance. Above that ridge, on the posterior wall of the cranial cavity, there is a wide, well-marked depression, called the *posterior cerebral fossa*, which lodges the posterior end of the occipital lobe of the cerebrum. The right cerebral fossa is separated from the left by a thick vertical ridge which descends to the internal occipital protuberance. Along that ridge the sagittal groove, seen already on the vault of the skull, runs down to the protuberance and becomes continuous with one or other of the transverse grooves, usually the right; occasionally it splits and becomes continuous with both transverse grooves. The transverse ridges, the sagittal ridge, and the internal occipital crest culminate and meet at the protuberance, and together with the protuberance are called the **eminentia cruciata.**

The **transverse groove** begins at the internal occipital protuberance, passes across the occipital squama to its lateral angle, and then passes on to the mastoid temporal and the truncated posterior inferior angle of the parietal, grooving only a small part of the parietal angle. There it becomes the **sigmoid groove**, which turns downwards grooving the mastoid temporal and the petrous temporal, where it is separated by very thin bone from the mastoid air cells and may be very close to the tympanic antrum; reaching the floor, it passes off the mastoid temporal on to the upper surface of the jugular process of the occipital bone, on which it passes first in a medial direction and then forwards to the jugular foramen.

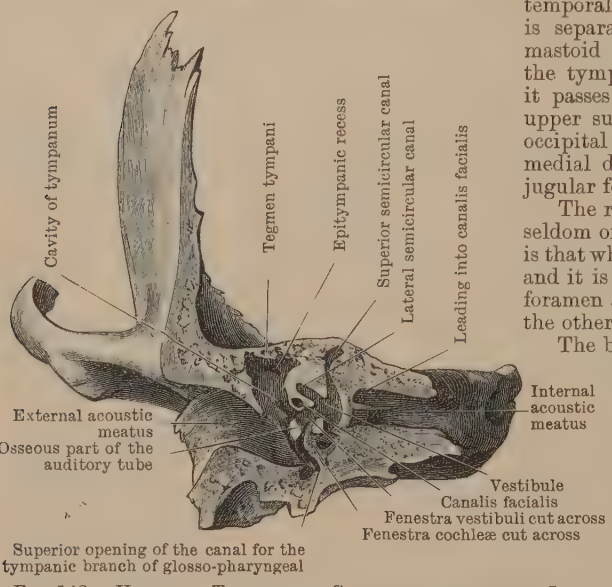

FIG. 142.—VERTICAL TRANSVERSE SECTION THROUGH THE LEFT TEMPORAL BONE (Anterior Half of Section).

The right and left transverse grooves are seldom of equal size; the wider of the two is that which is joined by the sagittal groove, and it is usually the right; and the jugular foramen also is wider on that side than on the other.

The basal margin of the **tentorium cerebelli** is attached to the internal occipital protuberance, to the lips of the transverse groove, to the lips of the narrow, ill-marked groove along the upper margin of the petrous temporal, and then is prolonged medially to be attached to the posterior clinoid process. Along the transverse groove it encloses the horizontal part of the transverse sinus; along the margin of the petrous temporal it encloses the superior petrosal sinus, which runs from the cavernous sinus to the transverse sinus; and at the trigeminal notch the trigeminal nerve crosses beneath the sinus and the margin of the tentorium. The internal margin of the tentorium, *i.e.*, the margins of the door of the tentorium, is continued forwards, on each side, across the attached, basal margin at the apex of the petrous temporal, to be fastened to the anterior clinoid process.

Sulci Arteriosi.—Faint narrow grooves are seen here and there in the walls of the posterior cranial fossa for the posterior meningeal vessels, which are derived from the vertebral, the occipital, and the ascending pharyngeal arteries; and some twigs of the posterior branch of the middle meningeal artery may descend into the fossa.

Foramen Jugulare.—The **jugular foramen** is the large aperture, with irregular margins, situated between the petrous temporal and the jugular process of the occipital bone, in the anterior and medial part of the floor of the lateral subdivision of the fossa. It leads downwards and slightly forwards to the lower surface of the skull, where it is opposite the lower margin of the external acoustic meatus.

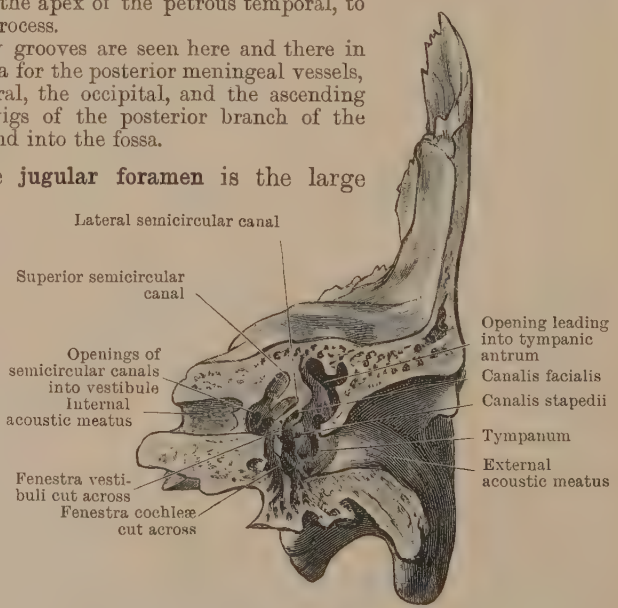

FIG. 143.—VERTICAL TRANSVERSE SECTION THROUGH THE LEFT TEMPORAL BONE (Posterior Half of Section).

The **jugular foramen** transmits three sets of structures, and small spicules of bone projecting from its margins may partly or completely divide it into corresponding compartments. By far the most important structures that pass through the foramen are the transverse sinus and the ninth, tenth, and eleventh cerebral nerves. The *antero-medial compartment* transmits the inferior petrosal sinus and a meningeal branch of the ascending pharyngeal artery. The *middle compartment* transmits the glosso-pharyngeal, vagus, and accessory nerves, in that order from before backwards. The *postero-lateral compartment* is larger than the other two, and transmits the sigmoid part of the transverse sinus as it becomes the internal jugular

vein, a meningeal branch of the occipital artery, a meningeal branch of the vagus, and lymph vessels from the meninges. (See also p. 151.)

Meatus Acusticus Internus.—The posterior surface of the petrous temporal forms the anterior wall of the lateral part of the fossa; the only conspicuous aperture in it is the oblique opening of the **internal acoustic meatus** (Fig. 146, 34, p. 170). The meatus is a short canal in the petrous temporal, nearly horizontal and nearly transverse; its lateral end is separated by thin bone from the internal ear.

The **internal acoustic meatus** is about 8 mm. long and 3 to 5 mm. wide. It transmits the motor and sensory parts of the facial nerve, the acoustic nerve, the internal auditory branch of the basilar artery and the internal auditory vein, which joins the inferior petrosal sinus. The lateral end of the meatus is called the **fundus** or bottom. The part of the petrous temporal bone that forms the fundus separates the meatus from the vestibule and cochlea of the internal ear, and is called the **lamina cribrosa**, because there are several apertures in it which transmit the auditory vessels and the facial and acoustic nerves. If the skull has been split into halves so that one can see into the meatus, the lamina cribrosa and the holes in it are visible at the far end. The position of the internal ear can be gauged by an examination of the meatuses. The lamina cribrosa, seen at the bottom of the internal meatus, is the medial wall of the internal ear. The lateral wall of the internal ear is the medial wall of the tympanum or middle ear; that wall can be seen through the external acoustic meatus, and the bulge called the promontory seen there is produced by the basal curve of the cochlea, which is coiled like a snail shell [κοχλίας (cochlias) = a snail, a spiral]. The arcuate eminence of the anterior surface of the petrous temporal also is a guide, for it overlies the superior semicircular canal, which stands up from the posterior part of the vestibule of the inner ear like the handle of a pail. At the bottom of the internal meatus the facial nerve passes through one of the holes in the lamina cribrosa and enters the facial canal, which conducts it through the temporal bone, passing first in a lateral direction, above the vestibule, to the anterior part of the upper border of the medial wall of the tympanum, then backwards along the upper border of the medial wall, and finally downwards behind the tympanum to appear as the stylo-mastoid foramen on the lower surface of the skull.

16. Squama of occipital bone.

Apertura Externa Aquæductus Vestibuli.—A narrow canal about 8 mm. long, called the **aqueduct of the vestibule**, passes backwards from the vestibule and opens on the posterior surface of the petrous temporal into a small slit seen about half an inch lateral to the opening of the internal meatus; the slit is overhung by a thin lip of bone. The canal transmits a tiny artery and vein and a delicate membranous tube called the ductus endolymphaticus, which emerges from the external aperture of the canal and dilates to form a blind bag, called the saccus endolymphaticus, which lies under cover of the dura mater.

Fossa Subarcuata.—The **subarcuate fossa** is a small ill-defined depression about midway

between the opening of the meatus and the aperture of the aqueduct, but at a higher level than either of them. It is larger and better defined in the skull of a child than of an adult (Fig. 168, c, p. 201). Small vessels pass through its floor into the bone.

Apertura Externa Aquæductus Cochleæ.—On the anterior margin of the jugular foramen, directly below the opening of the internal meatus, there is a small pit hidden under an overhanging lip of bone, but may in some specimens be seen from the lower surface of the skull. At the bottom of the pit there is the external opening of the **aqueduct of the cochlea**, a narrow canal about 15 mm. long, which leads from the cochlea and conducts a small vein to the inferior petrosal sinus and a tubular prolongation from the dura mater to the cochlea.

CAVUM NASI.

The term **Nose** includes not only the **external nose**, which juts from the face, but also the **cavity of the nose**, of which merely a small part lies in the external nose.

The **cavity of the nose** extends from the choanæ on the base of the skull to the apertura piriformis on the front, or to the nostrils, when the soft parts are in place. It lies above the cavity of the mouth, being separated therefrom by the hard palate; and it lies below the anterior and middle cranial fossæ and the frontal and sphenoidal air sinuses. In round numbers of millimetres, its length varies from 50 mm. at the floor to 75 mm. at the roof; its greatest height, about its middle, is 50 mm., and it diminishes to 30 mm. at the apertura piriformis and 25 mm. at the choana.

It is divided into **right** and **left halves** by a median partition or **septum**, and the term "cavity of nose" or "nasal cavity" is applied sometimes to the whole cavity and sometimes to one or other of the halves, the context interpreting which is meant. Each of the two cavities is narrow from side to side, the widest part, near the floor, measuring only about 10 mm., while near the roof, except in its posterior section, it is only 1 or 2 mm.

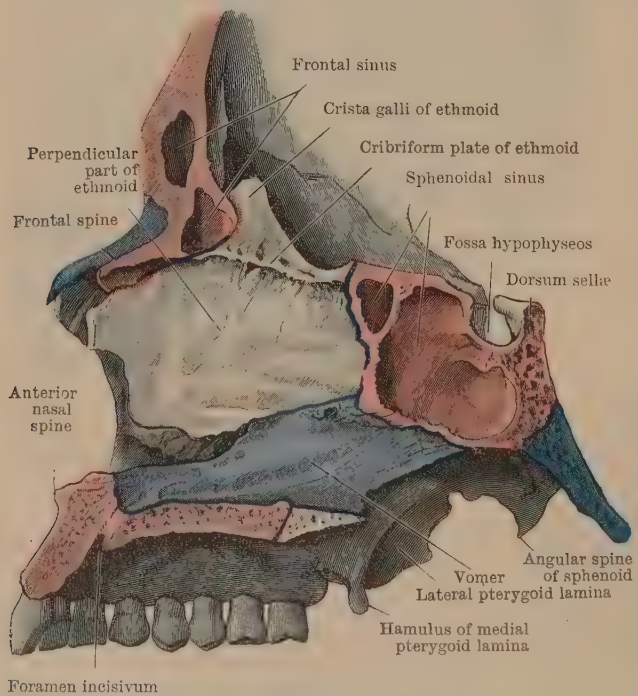

FIG. 145.—ROOF, FLOOR, AND SEPTUM OF NOSE.

The frontal, maxillary, and sphenoid bones are coloured red; the nasal, vomer, and basi-occipital blue; the perpendicular part of the ethmoid and the horizontal part of the palatine bone are left uncoloured.

Boundaries of Nasal Cavity.—Each of the two nasal cavities has a *roof*, a *floor*, a *lateral* wall, and a *medial* wall, which is the septum between the two cavities.

The **roof** is very narrow from side to side except at its posterior end. It is horizontal in the middle, but slopes downwards in front and behind, so that the anterior and posterior parts of the cavity are of lesser vertical depth than the middle part. The **middle**, horizontal part consists of the cribriform plate of the ethmoid. The **anterior** sloping part is formed by a small part of the frontal bone and by the nasal bone below that; and, still lower down, when the soft parts are in place, by the cartilages of the nose. The **posterior** sloping part—a very steep slope—is formed by the anterior and inferior surfaces of the body of the sphenoid.

The **roof of each nasal cavity**, in nearly the whole of its length, is only 1 or 2 mm. in width, but its most posterior part, which is formed by the lower surface of the body of the sphenoid, measures about 10 mm. across; in a dried skull, that is also the lowest part of the roof, being on a level with the zygomatic arch at the side of the skull. Though the anterior part of the lower surface of the body of the sphenoid is reckoned as part of the roof, yet the ala of the vomer and the sphenoidal process of the palatine bone, which are closely applied to it, shut it off from the nasal cavity, and are the actual bones clothed with the muco-periosteum of the posterior part of the roof. The **pharyngeal canal** is situated in that part of the roof, between the sphenoidal process and the body of the sphenoid.

The part of the roof formed by the anterior surface of the body of the sphenoid looks forwards rather than downwards, and diminishes to 2 mm. in width as it is traced upwards and forwards, for the greater part of each half of the front of the body of the sphenoid articulates with the labyrinth of the ethmoid, leaving the smaller part alongside the median plane free to form a boundary for the nasal cavity. In that area there is a round opening of considerable size which leads back into the *sphenoidal sinus*.

The anterior surface and anterior part of the lower surface of each half of the body of the sphenoid is formed by bone which in early life is separate and is called the *sphenoidal concha*.

The part of the nasal cavity which is highest, and also nearest the cranial cavity, is the middle part; it is roofed by the cribriform plate, which is at the level of the nasion, and is perforated by the olfactory nerves; infection from a diseased nose has, at that part, only a very short distance to travel to reach the brain and its membranes.

The small nasal surface of the frontal bone appears in the roof of the nose in front of the cribriform plate and separates the nasal cavity from the frontal sinus; it slopes downwards and forwards to the nasal bone, those two bones forming the anterior sloping part of the roof, along which the anterior ethmoidal nerve, with companion vessels, runs downwards and forwards to emerge between the nasal bone and cartilage, under the name of the external nasal nerve, for the supply of the skin of the lower half of the external nose; the nerve leaves a narrow groove on the surface of bone on which it runs.

The **floor** is smooth, nearly horizontal from before backwards, and slightly concave from side to side. It is considerably wider than the roof, measuring 10-12 mm. across, and is slightly wider in the middle than at either end. It is shorter than the roof, for the choanæ slope from above downwards and forwards, while the apertura piriformis slopes downwards and backwards. Its posterior fourth or third is formed by the horizontal part of the palatine bone, and the remainder by the palatine process of the maxilla. Near the front, close by the septum, is the opening of the incisive canal, which is covered over with mucous membrane before maceration. The **incisive canal** passes downwards through the bone and divides into the foramina of Stensen and Scarpa, which open into the incisive foramen on the hard palate.

The three chief constituents of the **septum** are: (1) the perpendicular lamina of the ethmoid, situated above and behind; (2) the vomer, situated below and behind; (3) the septal cartilage of the nose, which, in a dried skull, is destroyed; it is situated anteriorly, and fills in the wide, angular interval between the other two. The superficial area of the septum is too great for the height of the cavity, and it is therefore bent to one side near its middle, or it is bent first to one side and then to the other.

The **osseous septum** is composed almost entirely of the perpendicular lamina of the ethmoid superiorly and the vomer below and posteriorly, but it is completed by the following small projections: (1) The *sphenoidal crest*, which projects forwards from the median line of the front of the body of the sphenoid to articulate with the perpendicular lamina. (2) The *frontal spine*, which projects from the nasal part of the frontal bone downwards and forwards between the perpendicular lamina and the nasal crest. (3) A *nasal crest* is formed by the lips of the margins of the nasal bones that articulate with each other; that crest articulates, from above downwards, with the frontal spine, the perpendicular lamina, and the septal cartilage. (4) A *nasal crest*, to articulate with the lower edge of the vomer, is formed by sharp ridges that stand up from the horizontal part of the palatine bone and the palatine process of the maxilla, where they articulate with their fellows of the other side. (5) A thicker and higher *incisor crest* stands up from the junction of the alveolar processes of the maxillæ; it articulates posteriorly with the vomer and superiorly with the vomero-nasal cartilage.

The upper part of the perpendicular lamina of the ethmoid shows numerous small branching grooves which lodge olfactory nerves. Indistinct grooves for vessels may be seen on the vomer, and one long groove for the naso-palatine nerve and spheno-palatine vessels, which enter the nose through the spheno-palatine foramen in the lateral wall, cross the roof and run downwards and forwards, grooving the vomer, to reach the incisive canal.

The *cartilaginous septum* is formed almost wholly by the septal cartilage, which, however, is aided by (1) the vomero-nasal cartilage, a small strip along its lower margin; and (2) the medial part of the greater alar cartilage, at the tip of the nose.

The **lateral wall** is very uneven and is composed of several bones, namely, the *nasal*, the *maxilla* and its *frontal process*, the *lacrimal*, the *labyrinth* of the

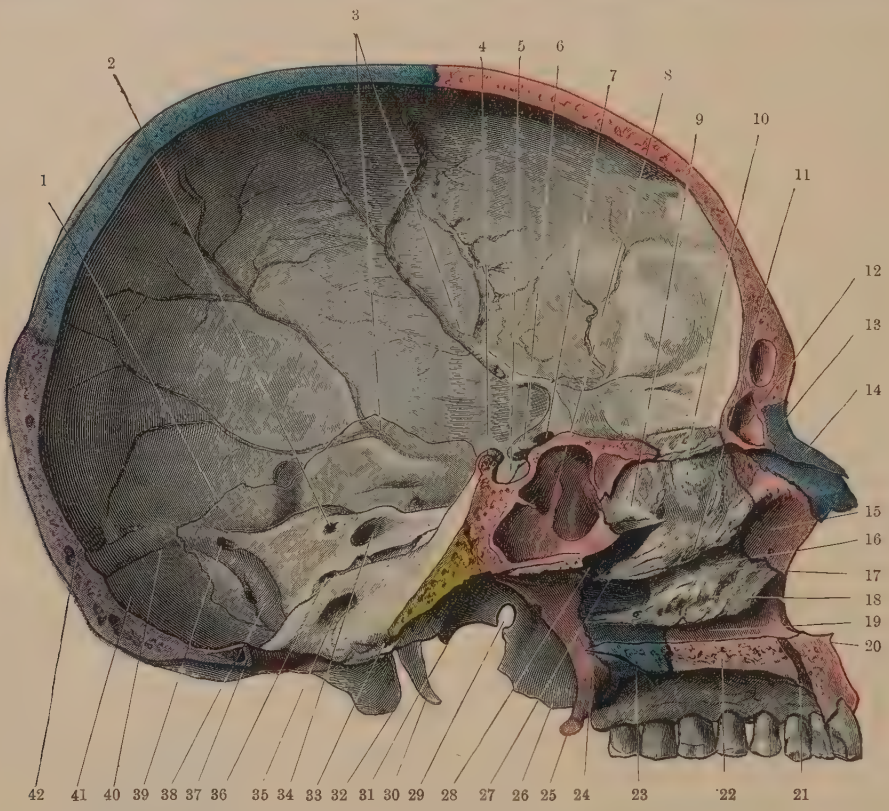

FIG. 146.—MEDIAL ASPECT OF THE LEFT HALF OF THE SKULL SAGITTALLY DIVIDED.

The frontal, maxillary, and sphenoid bones are coloured red ; the parietal, nasal, and palatine bones, blue ; the basilar part of occipital, yellow, and squama occipitalis, purple. The ethmoid and inferior concha, together with the left ala of the vomer, are left uncoloured.

ethmoid and its *conchæ*, the *inferior concha*, the perpendicular part of the *palatine*, and the *medial lamina of the pterygoid process*.

The conchæ should be identified at once. The **inferior nasal concha** is the rough plate of bone that projects from the side wall into the lower part of the nasal cavity for a little distance and then curves downwards ; it is a separate bone,

and if it has been broken away the line along which it was attached is seen as an irregular broken ridge about half an inch above the floor of the nose. The **middle nasal concha** is situated about an inch above the inferior concha, which it resembles; it is not a separate bone, but projects from the ethmoid labyrinth a little way into the nasal cavity and then turns downwards. The **superior nasal concha** also is a projection from the labyrinth. It is much smaller than the other conchæ; it is the small ridge of bone situated a little above the posterior half of the middle concha. If a pair of forceps is passed into the nose and opened vertically, it must be kept close to the septum to prevent the upper leg being intercepted by the conchæ.

The **nasal bone** lies in the anterior and upper part of the lateral wall, as well as in the roof. The **frontal process of the maxilla** lies immediately behind and below the nasal bone. Those two bones form also the bony skeleton of the external nose. The **lacrimal bone**, already seen in the orbit, lies behind the frontal process; only its lower and anterior part appears in the nose.

The **medial lamina of the pterygoid process** is the most posterior bone in the lateral wall of the nose. It forms the lateral boundary of the choana, and has been often referred to already.

The medial surface of the **body of the maxilla** lies in the lower part of the side wall of the nasal cavity, extending from the lower part of the apertura piriformis backwards almost to the medial pterygoid lamina. It is to a large extent concealed by other bones, among which two openings are seen leading into the maxillary sinus.

The **perpendicular part of the palatine bone** lies in the posterior part of the lateral wall in front of the medial pterygoid lamina. The horizontal part is easily identified in the floor. The perpendicular part lies directly above the lateral margin of the horizontal part and extends upwards to the body of the sphenoid in the roof. It is wider, as well as longer, than the horizontal part. It separates the nasal cavity from the pterygo-palatine fossa. Behind that, it overlaps the medial pterygoid lamina; anteriorly, the greater part of it is applied to the posterior part of the medial surface of the maxilla, shutting off that part from the nasal cavity.

The smooth lateral surface of the **labyrinth of the ethmoid** has been seen already in the orbit, behind the lacrimal bone; its rough **medial surface** is now seen in the nose below the cribriform plate, extending from the frontal process of the maxilla to the body of the sphenoid, forming the greater part of the upper half of the lateral wall of the nose. The superior and middle conchæ project from its medial surface; and hidden under cover of the middle concha there is a rounded bulging part of the labyrinth, called the **bulla ethmoidalis,** which can partly be seen when examined from the front [*bulla* = a bubble]. The bulla is bounded in front and below by a curved groove or slit called the **hiatus semilunaris.**

Meatuses of the Nose.—The cavity of the nose is divided into the *common* meatus, the *superior*, *middle*, and *inferior* meatuses, the *naso-pharyngeal* meatus, the *spheno-ethmoidal recess*, and the *atrium* of the middle meatus; and, when the soft parts are in place, the portion above the nostril is called the *vestibule* of the nose.

The **common meatus** is the narrow cleft that separates the septum from the conchæ; it extends from the roof to the floor. The **naso-pharyngeal meatus** is the portion of the cavity behind the conchal region. The **spheno-ethmoidal recess** is the small space above and behind the superior concha. The **superior meatus** is an oblique, cleft-like space in the posterior half of the labyrinth of the ethmoid; its slit-like orifice is below the superior concha and above the middle concha. The **middle meatus** is much larger than the superior; part of it is lateral to the middle concha and part of it is below, extending down to the inferior concha; the lower part is roomy; the part that lies under cover of the middle concha is greatly contracted by the bulging bulla ethmoidalis. The **atrium** of the middle meatus is the wide region in front of the middle meatus [*atrium* = an entrance hall]. The **inferior meatus** is the space lateral to and below the inferior concha.

The **lateral wall** is more uneven and complicated than the other boundaries of the nose;

it is also the most variable and most liable to injury in the dried skull, so that the student may have difficulty in applying any given description to the specimen he is using for study.

The groove made by the anterior ethmoidal nerve may be on the part of the **nasal bone** that lies in the lateral wall, rather than on the part in the roof.

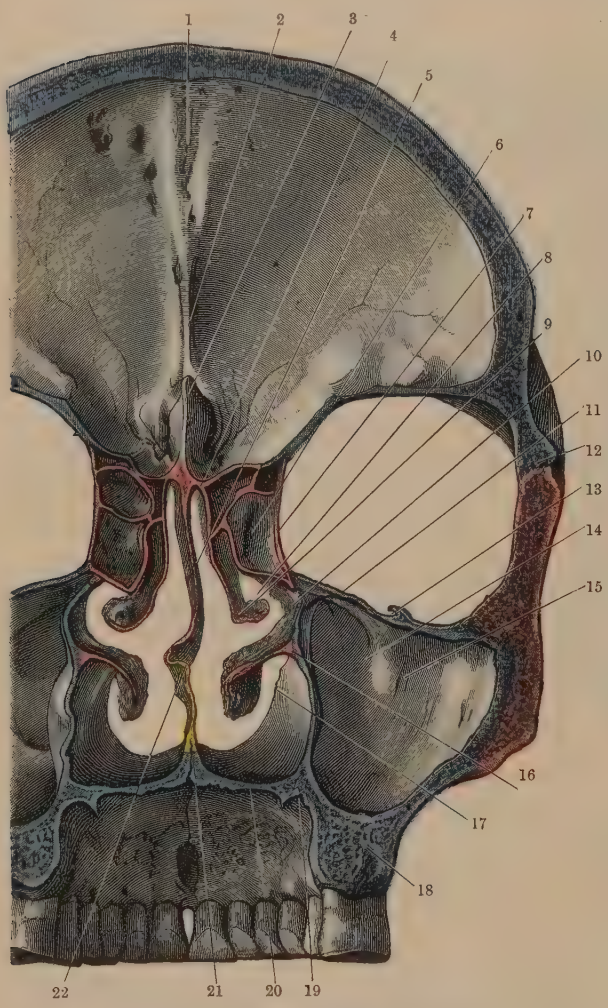

FIG. 147.—FRONTAL SECTION PASSING INFERIORLY THROUGH THE INTERVAL BETWEEN THE FIRST AND SECOND MOLAR TEETH.

The frontal and maxillary bones, where cut, are coloured blue; the ethmoid, inferior conchæ, and zygomatic red; the vomer yellow.

18. Alveolar process of maxilla.
19. Groove for greater palatine nerve and vessels.
20. Palatine process of maxilla.
21. Nasal crest of maxillæ.
22. Vomer.

The **frontal process of the maxilla** presents a wide area which forms the side wall of the *atrium* of the middle meatus. At the lower boundary of that area, where the frontal process joins the body of the maxilla, there is a horizontal ridge, called the *conchal crest*, which articulates with the anterior part of the inferior concha. At the upper boundary of the area there is a ridge called the *ethmoidal crest*. The anterior part of that ridge produces the elevation, called the *agger nasi*, in the un-macerated head. The posterior part articulates with the anterior end of the middle concha; the portion of the frontal process above that articulation is applied to the front of the labyrinth of the ethmoid and helps to close in the anterior ethmoidal cells.

The **lacrimal bone** also is applied to the labyrinth, forming a boundary to anterior ethmoidal cells; but its antero-inferior portion appears in the side wall of the nose, and its lowest part projects downwards and helps to close the large opening of the maxillary sinus.

The **labyrinth of the ethmoid**, situated between the orbit and the nasal cavity, bulges into the cavity and greatly reduces the width of its upper part. It is composed of exceedingly thin, fragile bone. The upper half of its medial aspect is a wide area which, though far from smooth, is relatively even, and shows narrow grooves for the lateral group of olfactory nerves leading up to the holes in the cribriform plate. Inferiorly the posterior half of the area ends in the projecting ridge called the **superior concha**; the anterior half is continuous with the medial surface of the anterior part of the middle concha.

The **spheno-ethmoidal recess** is situated above and behind the posterior part of the superior concha, in front of the body of the sphenoid, and the sphenoidal sinus opens into it.

The **middle concha** forms the roof and medial wall of the upper, narrow part of the middle meatus, and its rough medial surface is the lower and lesser half of the medial aspect of the labyrinth. It extends forwards to the frontal process of the maxilla, and backwards to the perpendicular part of the palatine bone, its anterior end being at a considerably higher level than the posterior end. The lower border is convex from before backwards, its lowest point being about the level of the floor of the orbit, and the border is thickened and curled in a lateral direction, so that the lateral surface of the concha is concave and the medial surface is convex.

The **superior meatus** is bounded inferiorly by the posterior half of the middle concha, and superiorly by the superior concha and the walls of posterior ethmoidal cells, which open into

it by two or three orifices in the dried skull, but mucous membrane covers one or two of the openings during life. The **spheno-palatine foramen** also opens into it at its posterior part, but is covered over with mucous membrane before maceration.

The rounded, bulging **bulla ethmoidalis**, which lies in the lateral wall of the upper part of the middle meatus, hidden under cover of the middle concha, varies considerably in size; it encloses some of the middle ethmoidal sinuses.

From the labyrinth, in front of the bulla, there springs a long, thin process, called the **uncinate process**, which curves downwards and backwards, first in front of the bulla and then below it, and has a considerable share in covering the large opening of the maxillary sinus.

The curved interval between the bulla and the uncinate process is the **hiatus semilunaris**, into which the mucous lining dips as it passes from the bulla to the process. In some cases, however, the uncinate process is closely applied to the bulla, and the hiatus is then a gutter-like groove on the process, the margins of which are curled to form the margins of the groove. The **infundibulum** [=a funnel], which leads downwards through the anterior part of the ethmoid labyrinth from the frontal sinus, opens into the hiatus, and the upper or anterior portion of the hiatus is sometimes described as part of the infundibulum.

The **middle meatus** extends from the attached margin of the middle concha down to the inferior concha, and is therefore of considerable height. The middle concha constitutes a medial wall for the upper, narrow part of the meatus, which is at the level of the orbit, and is separated from the orbit by the lower part of the labyrinth, including the bulla. The lower, wide part of the meatus is open medially, and is situated below the labyrinth, opposite the upper part of the maxillary sinus, from which it is separated by the bones that close the opening of the sinus.

The *sinuses* leading into the meatus open into its upper part. The *middle ethmoidal* sinuses open into it on the surface of the bulla; the *maxillary* sinus opens into the lower part of the hiatus semilunaris; the infundibulum, leading from the *frontal* sinus, opens into the upper part of the hiatus; the *anterior ethmoidal* sinuses also open into the upper part of the hiatus and into the infundibulum. In the dried skull there are, in addition, one or more openings into the lower part of the meatus, out of the maxillary sinus, but they are closed with mucous membrane when the soft parts are in place.

The **perpendicular part of the palatine bone** is a very thin plate of bone situated in the posterior part of the side wall of the nose. Its posterior edge articulates with the medial pterygoid process and often overlaps it. Anteriorly, it is applied to the medial surface of the maxilla and takes a considerable share in closing the opening of the maxillary sinus. Between the upper parts of the maxilla and pterygoid process, it forms the medial wall of the pterygo-palatine fossa, from which the **greater palatine canal** descends to the hard palate; the canal is situated in the side wall of the nose between the palatine bone and the maxilla. Two processes project upwards from the upper end or margin of the palatine bone, namely, the sphenoidal and orbital processes; they are separated by the spheno-palatine notch, which, with the body of the sphenoid, forms the **spheno-palatine foramen**. The *sphenoidal process* inclines medially to form part of the roof of the nose. The *orbital process* is wedged in between the body of the sphenoid, the labyrinth of the ethmoid, and the body of the maxilla, and forms the posterior corner of the floor of the orbit; it often contains a cavity, called the palatine sinus, which may open into the sphenoidal sinus or into a posterior ethmoidal sinus. At the root of the orbital process, a ridge called the *ethmoidal crest* articulates with the posterior end of the middle concha; about 10 mm. from the lower end of the palatine bone, a ridge called the *conchal crest* articulates with the posterior end of the inferior concha.

The **inferior concha** extends between the conchal crests of the palatine bone and the maxilla, and its anterior attachment is the higher. It reaches a little further forward and a little further back than the middle concha. Its lower border is slightly thickened, curled laterally, convex from before backwards, and is only a little distance above the level of the lower margin of the apertura piriformis. The inferior concha passes across the lower part of the opening of the maxillary sinus and sends off processes which assist in closing the opening.

The **inferior meatus** extends from the attached margin of the inferior concha to the hard palate; the medial surface of the lower part of the maxilla forms its lateral wall; and the concha provides it with a roof and a partial medial boundary. It is related laterally to the maxillary sinus and inferiorly to the mouth. The **naso-lacrimal canal** opens into it under cover of the anterior part of the inferior concha.

The junction of the middle meatus and its atrium is opposite the fossa for the lacrimal sac in the orbit, and the mucous lining of the nose is separated from the sac by the lacrimal bone and the frontal process of the maxilla. The **naso-lacrimal canal** is situated in the side wall of the nose between the nasal cavity and the maxillary sinus. It is 10 or 12 mm. in length, and is bounded laterally and antero-medially by the walls of a deep groove in the maxilla, while postero-medially it is bounded by the lower part of the lacrimal bone and the inferior concha.

The apertures leading into or out of the nose are the following: The *choana*; the *apertura piriformis*, or, when soft parts are present, the *nostril*; the *naso-lacrimal canal*; and the *openings of the sinuses*, namely, sphenoidal, ethmoidal, frontal, and maxillary. The **sphenoidal sinus** opens into the spheno-ethmoidal recess; the **posterior ethmoidal sinuses** open into the superior meatus; the **middle** and **anterior ethmoidal sinuses**, the **frontal sinus** *via* the infundibulum,

and the **maxillary sinus** open into the middle meatus. The *naso-lacrimal canal* opens into the inferior meatus.

Besides the foregoing there are certain apertures in the dried skull which are covered over with mucous membrane before maceration, viz.: The *spheno-palatine foramen* opens out of the pterygo-palatine fossa into the posterior part of the superior meatus; there is an additional opening out of the maxillary sinus into the middle meatus; the *incisive canal* leads down from the anterior part of the floor of the nose into the incisive foramen; and the *foramina in the lamina cribrosa* in the roof transmit the olfactory nerves from the nose to the median part of the anterior cranial fossa.

General Relations of the Nose (Fig. 147, p. 172).—**Superior,** from before backwards: the frontal sinus; the anterior or ethmoidal part of the median subdivision of the anterior cranial fossa; the sphenoidal sinus, separating the nose from the posterior part of that fossa and from the median subdivision of the middle cranial fossa. **Inferior**: the mouth. **Posterior**: the nasal part of the pharynx. **Lateral**: the pterygoid fossa, the pterygo-palatine fossa, and the greater palatine canal (canalis pterygo-palatinus) opposite the posterior section of the cavity; further forward, the ethmoidal sinuses, the infundibulum, and the orbit, opposite the upper half of the middle section of the cavity, while opposite the lower half there are the maxillary sinus and the naso-lacrimal canal; the anterior section is situated in the external nose and is related laterally to the exterior.

SINUS PARANASALES.

The **para-nasal air sinuses** (Figs. 147, 148, pp. 172, 175) are cavities in the interior of certain of the skull bones, namely, the *frontal*, the *ethmoid*, the *sphenoid*, the *palatine*, and the *maxilla*. They all communicate either directly or indirectly with the cavity of the nose. Those communicating directly with the nose are the sphenoidal, ethmoidal, and maxillary; those communicating indirectly are the frontal and the palatine. They are all lined with mucous membrane which is continuous, round the lips of the apertures of communication, with the mucous lining of the nose, and disease can readily spread from the nose to the sinuses. During a severe cold in the head, the inflammation often extends from the nasal mucous lining to the mucous lining of sinuses, giving rise to frontal headaches (frontal sinus), pain in the cheek (maxillary sinus), pain between the eyes (ethmoidal sinuses), deep-seated pain at the back of the eyes (sphenoidal sinus).

The walls of the sinuses are composed of compact bone and are lined with endosteum which is blended with the mucous lining.

At birth the ethmoidal sinuses are present but are very small; the maxillary sinus is a mere groove; the frontal and sphenoidal appear during childhood. They all enlarge gradually till puberty, and rapidly after puberty.

The sinuses act as resonating chambers for the voice; and by means of them the bones containing them, without increase of weight, gain increase of bulk and superficies necessary for the formation of the walls of the cavities of the nose, mouth, and orbits.

Sinus Maxillaris (Figs. 141, 147, 148, pp. 162, 172, 175).—The **maxillary sinus** (Antrum of Highmore) is a large cavity occupying the body of the maxilla. It is situated *lateral* to the lower half of the nasal cavity, *below* the orbit, *in front of* infra-temporal fossa, and *above* the molar and premolar teeth, its deepest part being above the first molar and second premolar tooth. The opening out of it is on the medial side; in a separated maxilla the opening is very wide, but when in position in the skull, that large opening is overlapped by adjoining bones and reduced to two, or perhaps three, small apertures; when the mucous membrane is in place, only the uppermost of those apertures is left uncovered, and it opens out of the **uppermost** part of the sinus into the lower or posterior part of the hiatus semilunaris of the middle meatus.

The **maxillary sinus** is the largest of the sinuses; it is variable in size and may differ in the two sides of the same skull. Average measurements, in round numbers, are 35 mm. in height,

30 mm. in antero-posterior depth, and 25 mm. in width. In shape it resembles a pyramid. The **apex** is situated in the zygomatic process of the maxilla. The **base** or **medial wall** separates it from the inferior meatus and lower, wide part of the middle meatus, and is formed by the medial or nasal surface of the maxilla and the bones which almost completely close the large opening in the upper part of that surface, namely, portions of the uncinate process of the ethmoid, the palatine, the lacrimal, and the inferior concha.

The secretions of the mucous lining of the sinus are swept towards the orifice in the medial wall by the cilia of the epithelium covering the mucous membrane; in inflammatory conditions,

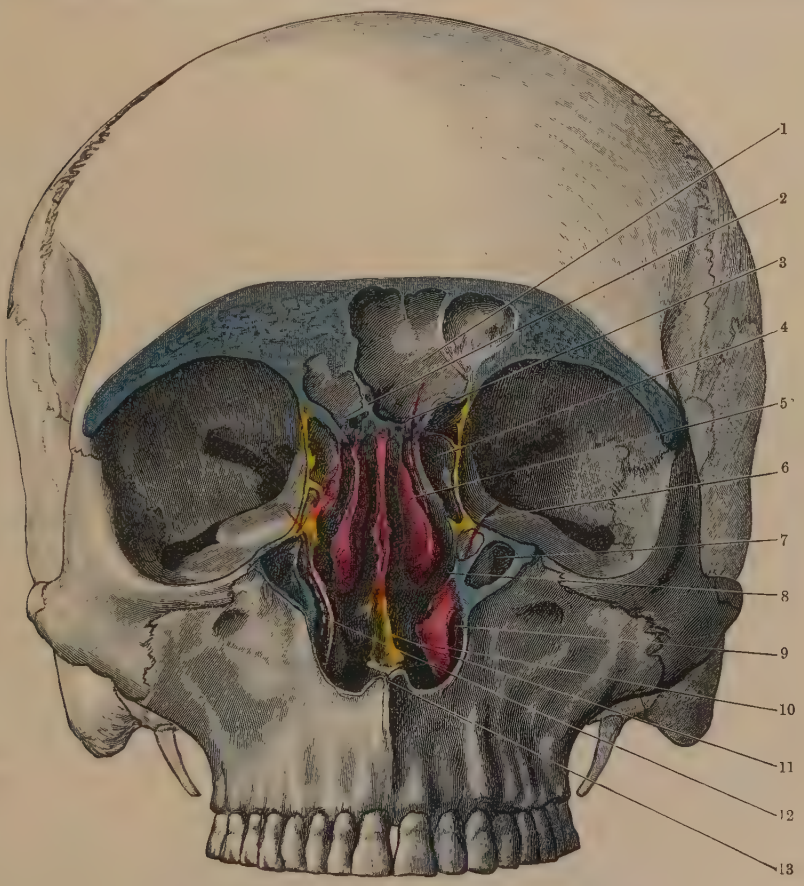

FIG. 148.—PART OF THE FRONTAL, NASAL, AND MAXILLARY BONES REMOVED IN ORDER TO DISPLAY THE RELATION OF THE VARIOUS CAVITIES EXPOSED.

The frontal and maxillary bones, where cut, are coloured blue; the ethmoid and the inferior concha red; the lacrimal and vomer yellow.

when the quality of the secretion clogs the action of the cilia or the quantity is too great for them to cope with, the sinus fills up, since the orifice is at its uppermost part.

The **floor** of the sinus is formed by the alveolar process of the maxilla, and is the thickest wall of the sinus, though the process is excavated by the alveoli of the teeth. The teeth whose roots are in relation to the floor vary from the three molars as a minimum to the molars, premolars, and the canine as a maximum. The roots of the first two molars produce eminences in the floor, and, though usually covered with thin bone, they may perforate the floor. Incomplete septa springing from the intervals between teeth may partially divide the sinus into compartments. The floor is below the level of the floor of the nose; the lowest part is about 10 mm. below the level of the nose, and overlies the roots of the first molar and second premolar teeth. The **posterior wall** is formed by the posterior or infra-temporal surface of the maxilla, which separates the sinus from the infra-temporal and pterygo-palatine fossæ. The **posterior alveolar canals,** conveying the vessels and nerves to the molar teeth, are situated in the lower

part of the posterior wall. The **roof** is formed by the orbital surface of the maxilla, which separates the sinus from the orbit. The **infra-orbital groove and canal** are situated in the roof and may produce a ridge, especially at the angle between roof and anterior wall. The anterior or **antero-lateral wall** is formed by the facial surface of the maxilla. The branches of the infra-orbital vessels and nerve to the premolar, canine, and incisor teeth descend through canals in the antero-lateral wall, but occasionally one or more of the canals may be defective, so that the corresponding vessels and nerve lie between the bone and the mucous lining. The upper and anterior part of the sinus extends far enough forwards to be in front of the naso-lacrimal canal as well as lateral to it.

Sinus Frontalis.—The **frontal sinus** is a cavity in the frontal bone; it is separated from its fellow by a complete bony septum which is usually bent to one or other side. It is situated immediately above the supra-orbital margin and above the root of the nose. If large, it extends backwards in the roof of the orbit between the two tables of the orbital plate. The frontal sinus may open directly into the nasal cavity through an opening in the nasal part of the frontal bone, but more commonly one of the anterior ethmoidal cells is converted into a passage, called the **infundibulum**, by means of which the sinus drains into the middle meatus, for the upper end of the infundibulum opens into the sinus and its lower end opens into the upper or anterior end of the hiatus semilunaris. The mucous lining of the infundibulum is sometimes called the *fronto-nasal duct.*

Cellulæ Ethmoidales.—The **ethmoidal sinuses** or cells are numerous small thin-walled, intercommunicating cavities occupying the labyrinth of the ethmoid. They are situated between the orbit and the nasal cavity, and below the cranial cavity, from which they are separated by the medial part of the orbital plate of the frontal bone. They are divided into three groups—anterior, middle, and posterior. The **posterior sinuses** open into the superior meatus of the nose by one or more apertures. The **middle sinuses** open into the middle meatus on the surface of the bulla ethmoidalis by one or two apertures. The **anterior sinuses** open into the hiatus semilunaris of the middle meatus.

The **frontal sinus** varies greatly in size in different skulls, and may vary on the two sides of the same skull, the left being usually the larger. Average measurements are 30 mm. in height, 25 mm. in transverse width, and 20 mm. in antero-posterior depth. The configuration of the brow in the living person gives no indication of its size; in a well-formed skull it may be absent, or may extend laterally as far as the temporal fossa and backwards in the roof of the orbit as far as the optic foramen. The septum between the right and left sinuses is usually median inferiorly and bent to one side above. The sinus is related *inferiorly* to the orbit, the nose, and the anterior ethmoidal cells; *postero-superiorly* to the cranial cavity and the brain.

The walls of the **ethmoidal sinuses** are completed by the bones with which the ethmoid labyrinth articulates—the body of the sphenoid, the orbital process of the palatine bone, the orbital plate of the frontal bone, the lacrimal bone, the frontal process and the medial margin of the orbital surface of the maxilla. They are related *laterally* to the orbit; *medially* to the upper half of the cavity of the nose; *posteriorly* to the sphenoidal and palatine sinuses; *superiorly* to the sphenoidal sinus, the frontal sinus, the anterior cranial fossa, and to the ethmoidal canals which are situated between the orbital plate and the ethmoidal labyrinth; *inferiorly* the posterior sinuses are related to the superior meatus, into which they open, and the middle and anterior sinuses are related to the lower part of the middle meatus.

Sinus Sphenoidalis.—The **sphenoidal sinus** is a large cavity occupying the body of the sphenoid bone. It is situated above the cavities of the naso-pharynx and nose, and below the median part of the cranial cavity. It is divided completely into right and left halves by a median bony septum, which, however, is usually bent to one or other side: each half may be referred to as a sphenoidal sinus, and it opens into the spheno-ethmoidal recess of the nose by a round aperture 4 or 5 mm. in diameter.

The **sphenoidal sinus** may be small and limited to the anterior part of the body of the sphenoid; or it may occupy the whole of the body and extend into the roots of the lesser wings, greater wings, and pterygoid processes, and backwards into the basilar part of the occipital bone. Its average dimensions are about 20 mm. each way.

Inferiorly it is related to the cavity of the naso-pharynx and the naso-pharyngeal meatus; *anteriorly*, to the upper part of the middle section of the cavity of the nose and the posterior ethmoidal cells. *Laterally* it is related: (1) to the optic nerve in the optic foramen, and to the apical part of the orbit; (2) behind that, to the cavernous venous sinus, in the walls of which the internal carotid artery, the third, fourth, sixth, and ophthalmic nerves are imbedded; (3) to the maxillary nerve, as it runs forwards along the lower border of the cavernous sinus and as it passes through the foramen rotundum. *Superiorly* it is related: (1) to the frontal lobes of the

brain and the olfactory tracts, lying on the anterior part of the body of the sphenoid; (2) more remotely, to the optic chiasma, which lies above the optic groove; (3) to the hypophysis cerebri (pituitary body), lying in the hypophyseal fossa; (4) to the pons and the basilar artery, lying on the clivus. The relation of the sinus and the nose to the hypophysis is of special interest because the hypophysis is subject to tumour growth and the operator approaches it through the nose and the sphenoidal sinus. The hypophysis is 60 mm. behind the nasion and at almost the same horizontal level. A line connecting the hypophysis with the lower margin of the apertura piriformis is 75 mm. long and forms an angle of 45° with the floor of the nose.

The **palatine sinus**, when present, occupies the orbital process of the palatine bone, and opens into either the sphenoidal sinus or a posterior ethmoidal sinus.

Mandibula.

The **mandible** or lower jaw bone lies below the anterior part of the cranium, and is the skeleton of the lower part of the face. It consists of a horseshoe-shaped **body** and two flat, broad **rami**, which stand up from the posterior part of the body, one on each side. Each ramus is surmounted by two processes, the anterior of which is named the **coronoid process**, and the posterior is named the **condyloid process**; the condyloid process consists of an articular part, called the **head**, supported on a more constricted part called the **neck**.

Corpus Mandibulæ.—The **body** of the mandible consists of a right and a left half fused together in the median plane in front, but widely separated behind. The junction between the two halves is called the **symphysis menti** [σύν (syn) = together; φύω (phyō) = grow; *mentum* = the chin]. The halves are joined together by fibrous tissue at birth, but are fused together into one bone during the second year.

On the front of the mandible, along the line of the symphysis, there is a faint, vertical ridge, which swells out inferiorly into a triangular elevation, of varying prominence, called the **mental protuberance**; the lower angles of the triangle are called the *mental tubercles*; in the region of the protuberance, the bone is bent forwards to produce the prominence of the **chin**. The forward projection of the lower part of the middle of the mandible to make the chin is a Human characteristic: among lower animals, not even the Anthropoid apes (Gibbon, Gorilla, Orang-utan, and Chimpanzee) have chins as an outstanding feature; and the prominence of the chin is not so marked in the primitive races of Men as in the higher, though the mandible as a whole may be a heavier bone.

7. Angle.
8. Oblique line.
9. Mental foramen.

Each half of the body of the mandible has a medial and a lateral surface and an upper and a lower border. The surfaces slope so that the lower border of the whole bone makes a wider arch than the upper border.

The **upper border** is called also the **alveolar margin**, because it is occupied by a row of pits or **alveoli**, which are the sockets for the teeth, and are visible if the

teeth have fallen out after death. On each side the sockets for the two incisors, the canine, and the two premolars are single, but those for the three molars are double, for each mandibular molar has two roots—an anterior and a posterior. When teeth are removed during life the walls of the alveoli are gradually absorbed until no evidence of them is left; the upper border of the mandible in the region of the lost teeth is smooth, and the vertical diameter of the bone is reduced.

The **lower border** is sometimes called the *base* of the mandible. On the lower border, or behind the border, at the side of the symphysis, there is a broad, rough mark or depression called the **digastric fossa.** The rest of the lower border is smooth and rounded and has a slight fulness or downward convexity about its middle.

The **lateral surface** is slightly convex, but on its anterior part, alongside the symphysis, below the incisor teeth, there is a broad, shallow depression called the *incisive fossa.* About an inch from the symphysis, below the second premolar or the interval between the premolars, there is an oblique opening called the **mental foramen,** situated about midway between the upper and lower borders if the alveoli are present, but nearer the upper border if the alveolar walls have been absorbed. Below the mental foramen there is an ill-defined ridge called the *oblique line*; it extends from the mental tubercle to the anterior border of the ramus, but is not well marked till it approaches the ramus.

The **medial surface** is undulating, being convex and concave at different parts. Low down on the back of the symphysis there is a rough mark, which may be divided into a right and a left half, each of which is called a **mental spine**; and the mental spine may be subdivided into an upper and a lower **genial tubercle** [γένειον (geneion) = the chin].

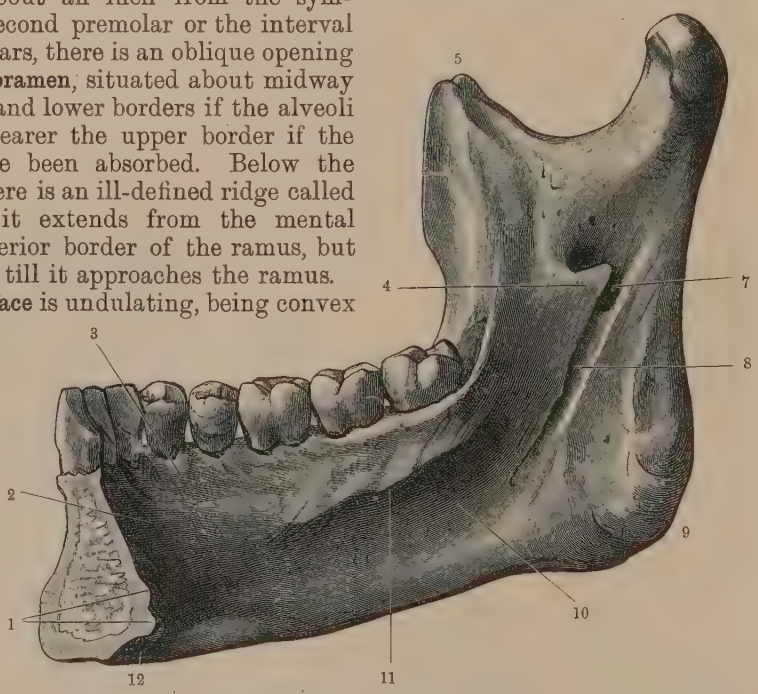

Fig. 150.—The Medial Side of the Right Half of the Mandible.

7. Mandibular foramen.
8. Mylo-hyoid groove.
9. Angle.
10. Submaxillary fossa.
11. Mylo-hyoid line.
12. Digastric fossa.

At the side of the symphysis, a little above the digastric fossa, there is a smooth, shallow depression, about the width of a thumb-print, called the **sublingual fossa.** Farther back there is an elongated, shallow depression called the **submaxillary fossa,** which extends on to the ramus; inferiorly it reaches the lower border of the mandible; superiorly it is bounded by an oblique ridge, called the **mylo-hyoid line,** which begins at the level of the root of the last molar tooth and passes downwards and forwards to the posterior margin of the digastric fossa; the lower or anterior part of the line is faint, and separates the submaxillary and sublingual fossæ from each other.

Ramus Mandibulæ.—The **ramus** of the mandible is, properly, the broad, flattened plate which rises up above the level of the posterior part of the body; but for the sake of simplifying the description of the attachment of muscles it is convenient to include the bone down to the lower border under the term *ramus*; at the same time it is not necessary to subdivide the lower border: it is the lower border of the mandible, irrespective of subdivision into body and ramus. Each

ramus has a lateral and a medial surface, an anterior and a posterior border, and an upper end or border surmounted by the coronoid and condyloid processes, which are separated by a wide gap called the **mandibular notch.**

The **lateral surface** is fairly flat, and rather rough. Where the lateral surfaces of ramus and body join, at the lower border of the bone, a faint groove may be detected; if the finger tip is placed on the corresponding point in a living person the pulsing of an artery can be felt; that is, the external maxillary artery—the chief artery of the face—as it crosses the lower border of the mandible and enters the face. The **medial surface** is more uneven. About its centre there is an oblique opening called the **mandibular foramen**; it leads into a canal which runs downwards and forwards in the substance of the bone and carries the vessels and nerves for the teeth; the spur of bone that overlaps the foramen anteriorly is called the **lingula.** A narrow groove, called the **mylo-hyoid groove,** begins at the lower margin of the foramen, runs downwards and forwards and fades away in the submaxillary fossa. The **anterior border** of the ramus is sharp, and is continuous with the oblique line of the body. The **posterior border** is smooth and rounded; the point where it meets the lower border is called the **angle of the mandible**—a point easily felt in the living and much used as a landmark.

Processus Coronoideus.—The **coronoid process** is flattened and pointed; it is triangular in outline, and is named from its resemblance, when looked at sideways, to the beak of a bird [κορώνη (corōnē) = a sea crow]. Its anterior border is continuous with the anterior border of the ramus, and both can be felt inside the mouth, above and behind the last molar tooth. Its posterior border bounds the mandibular notch anteriorly. Its surfaces are continuous with those of the ramus.

Processus Condyloideus.—The **condyloid process** consists of an articular head or condyle supported on a constricted neck.

The **head** of the mandible is elongated transversely. It includes only the part that is smooth and coated with cartilage; it has therefore an upper and a posterior aspect and a small, negligible anterior aspect. The head articulates with the mandibular fossa and articular tubercle of the temporal bone—but not directly: an articular disc of fibro-cartilage, which is placed within the joint and is attached by its circumference to the fibrous capsule of the joint, separates the head from the temporal bone and divides the joint cavity into an upper and a lower compartment. When the mandible is at rest, with the mouth shut, the upper surface of the head is in contact with the disc, below the mandibular fossa; when the mouth is opened, the mandible rotates so that the back of the head is brought into articulation, and at the same time the head travels downwards and forward till it comes to lie beneath the articular tubercle. The head can be felt in front of the ear, and the finger can follow its movements as the mouth is opened and shut.

The **neck** of the mandible is obliquely compressed from before backwards. The narrow *medial* and *lateral surfaces* widen out inferiorly as they merge into the surfaces of the ramus. The smooth *posterior surface* is continuous with the back of the head and the posterior border of the ramus. The *anterior surface* is rough and hollowed out, forming a depression which is overhung by the anterior margin of the head and is continuous inferiorly with the medial surface of the ramus; the sharp margin between the anterior and lateral surfaces bounds the mandibular notch posteriorly.

The **alveolar margin** is thicker behind than in front; it gives attachment to the gums, around the mouths of the alveoli. The socket of the canine tooth may produce a vertical eminence on the labial surface of the bone, and the incisor sockets may do so also.

The mucous membrane of the mouth covers the **lateral surface** of the body down to a line drawn from the last molar socket to the apex of the mental protuberance. The lower part of the buccinator arises from the lateral surface opposite the *molar sockets*; the incisive muscle, from the lower part of the **incisive fossa**; the mentalis, from a point opposite the bottom of the *canine socket*; the quadratus labii inferioris, from a line joining the mental tubercle and foramen; the triangularis, from the anterior part of the **oblique line**, below the mental foramen. The **mental foramen,** which may be double on one or both sides, opens obliquely in a lateral direction and upwards, and transmits the mental vessels and nerve. The external maxillary artery lies on the mandible at the junction of body and ramus. The **lower border** of the mandible gives attachment to the deep fascia of the neck; and the platysma is inserted into the anterior half.

The mucous membrane covers the **medial surface** of the body down to a line drawn from the

posterior end of the mylo-hyoid line to a point just above the mental spine. A small vascular foramen is situated opposite the interval between the incisor sockets on each side; and another is placed in the symphysis above the mental spines; the genio-glossus arises from the upper part of the **mental spine**, and the genio-hyoideus from the lower part; or from the upper and lower **genial tubercles**, respectively; the anterior belly of the digastricus, from the **digastric fossa**; the mylo-hyoideus, from the **mylo-hyoid line**, the posterior end of which gives attachment also to fibres of the superior constrictor and the buccinator and to the lower end of the pterygo-mandibular raphe. The two mylo-hyoid lines form the sides of an arch which is smaller than the arches formed by the upper border and the lower border; for the surface above the lines slopes upwards and outwards, and the surface below slopes, to a still greater degree, downwards and outwards. The sublingual gland lies in the **sublingual fossa**; and the submaxillary gland lies in the **submaxillary fossa** (they should be named *submandibular* gland and fossa).

The **mandibular foramen** transmits the inferior alveolar vessels and nerve; their mylo-hyoid branches run along the **mylo-hyoid groove**, which may be partly converted into a tunnel. The pterygoideus internus is inserted into the rough patch that separates the foramen and groove from the angle of the mandible. The spheno-mandibular ligament is attached to the **lingula**; the stylo-mandibular ligament is attached to the **posterior border** *of the ramus* and also to the **angle**, which is usually everted, and is slightly obtuse in a well-formed adult jaw, more obtuse in childhood, and still more in old age after the teeth have been lost. In a young adult the slope of the jaw from angle to chin expresses almost the whole degree of obtuseness of the angle, for the posterior border of the ramus is nearly vertical; but not so in old edentulous persons, for in them the posterior border of the ramus slants downwards and forwards, chiefly owing to the backward tilt of the condyloid process. In mandibles of old people the increase of obtuseness is not so much in the angle proper as in the angle between the anterior margin of the ramus and the upper margin of the body.

The masseter is inserted into the **lateral surface** of the ramus and covers the ramus and the coronoid process, leaving the head and neck without a covering of muscle; the temporalis is inserted into the medial surface and the margins of the **coronoid process**, and also into the anterior margin of the ramus. In some specimens an oblique canal traverses a blunt, low, vertical ridge that begins near the tip of the coronoid process and extends downwards towards the posterior end of the mylo-hyoid line; the canal transmits the buccinator nerve. The coronoid process varies considerably in length, but its tip usually lies under cover of the anterior part of the zygomatic arch.

The long axis of the **head** is nearly horizontal and is directed latero-medially and backwards. The posterior surface is slightly convex; so also is the upper surface, which overhangs the front of the neck, and ends in little tubercles that overhang the sides of the neck. The articular capsule of the mandibular joint is attached to the margins of the articular surfaces of the head; a thickened part of the capsule, called the temporo-mandibular ligament, is attached to the lateral aspect of the **neck**. The pterygoideus externus is inserted into the front of the neck and the capsule. If the finger is placed in the acoustic meatus, the meatus can be felt widening as the mouth is opened, for when the mouth is shut the back of the head exerts pressure on the meatus, though it is separated by a portion of the parotid gland; the lateral aspect of the head and neck also is overlapped by the parotid gland and is crossed by the temporal branches of the facial nerve, which may be rolled between the finger and the bone. The external carotid artery ends behind the neck; the superficial temporal artery, accompanied at that level by the posterior facial vein, runs upwards behind the lateral end of the head; the internal maxillary artery passes forwards medial to the root of the neck; the auriculo-temporal nerve winds round the medial side and the back of the neck and joins the superficial temporal artery. The vessels and nerves to the masseter pass in a lateral direction, through the **mandibular notch**, in front of the neck.

Differences due to Age.—**At birth** the two halves are united by fibrous tissue; the body is a mere shell enclosing the rudimentary *teeth*, which are imperfectly separated from one another; the *mandibular canal* is near the lower border; so also is the *mental foramen*, which is opposite the cavity for the first milk molar tooth. The *ramus* is relatively short; the *condyloid process* is almost in line with the body, so that the angle is very obtuse; the *head* is relatively large, and the *coronoid process* rises to a higher level than the head.

During the first year the halves unite from below upwards, and union is completed during the **second** year. As the teeth erupt and the child begins to chew, the depth of the body increases by the growth of the alveoli, the lower part thickens, the rami enlarge and the angle becomes less obtuse, being about 140° in the fourth year. As growth advances the depth increases, and the body elongates, especially behind the mental foramen to provide room for the permanent molars; the mental foramen assumes its adult position and the angle is reduced to 110°.

In **old age** after teeth are lost the alveoli are absorbed, so that the chin appears more prominent, and the mental foramen is near the upper border. The angle opens out to 140° and the condyloid process is bent back so that the mandibular notch is wider.

Structure.—The body of the mandible is thicker than the rami, and is thickest near the rami at the level of the mylo-hyoid and oblique lines, for there the mandible is subject to the greatest strain when the elevating muscles bring it into contact with the resisting upper jaw. The tables of compact bone are exceptionally dense and are very thick where they join together at the lower border. The lingual walls of the alveoli are considerably thicker than the labial walls, except in the case of the **third molar** socket, where the labial wall is the thicker. The spongy substance is open-meshed below, but finer and more condensed in the walls of the

alveoli. The *canal* of the mandible lies in the spongy substance, about the level of the mylo-hyoid ridge, and does not have a definite wall; the mental foramen, and the canals which carry blood-vessels and nerves to the teeth branch off the mandibular canal.

Development and Ossification.—The **mandible** begins to ossify during the sixth week of fœtal life before any other bone in the body, except the clavicle. Each half is developed from (1) the membrane overlying Meckel's cartilage, (2) the ventral portion of Meckel's cartilage, (3) certain accessory cartilages which appear between the eleventh and fourteenth weeks. The greater part of the mandible is developed from the membrane. The extreme ventral end of Meckel's cartilage disappears, but a part of it is incorporated in the mandible from a point near the symphysis backwards to the level of the mental foramen. One of the accessory cartilages forms the head and a narrow wedge-like part in the ramus; another forms a narrow strip along the front of the coronoid process; and some accessory nodules take a share in forming the symphyseal part of the bone. Those different structures are not ossified from separate centres. Each **half** of the mandible is ossified from **one** centre, which appears in the membrane overlying the ventral part of Meckel's cartilage. The ossifying process spreads through the membrane and envelops and invades the cartilages. Some small nodules, called *ossicula mentalia*, which appear at the symphysis shortly before birth and fuse with the mandible shortly after birth, may be derived from independent ossific centres in the accessory cartilages.

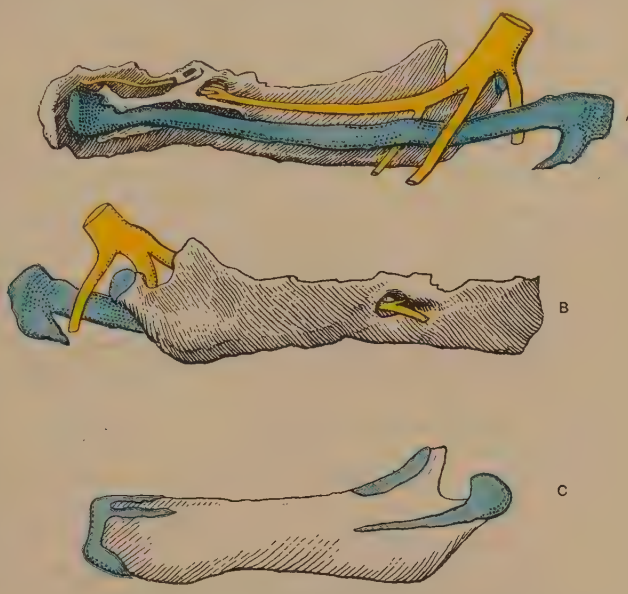

Fig. 151.—Development of the Mandible.

A, As seen from the medial side; B, from the lateral side; C, showing accessory (metaplastic) cartilages (blue).

(In A and B Meckel's cartilage is coloured blue.)

Meckel's cartilage is the cartilage of the first or **mandibular** arch of the embryo. Its dorsal end is in the region of the ear; its ventral end almost meets its fellow of the other side. The dorsal end ossifies to form two of the auditory ossicles, namely, *incus* and *malleus*; part of its ventral end is included in the mandible. The rest disappears; but the mylo-hyoid groove is the remains of the furrow in which part of it lay; and the *spheno-mandibular ligament* is derived from the fibrous sheath around it, though it has been argued that that ligament is the remnant of a muscular slip.

Dentes.

There are two sets of **teeth**: the *deciduous* or milk teeth, which are shed during childhood; and those that are potentially *permanent*.

The **deciduous teeth** are 20 in number, 5 on each side of the upper and the lower jaws, namely, 2 incisors, 1 canine, and 2 molars, in that order from before backwards. There are 32 adult or **permanent teeth**, 8 on each side above and below, namely, 2 incisors, 1 canine, 2 premolars, and 3 molars. The permanent incisor and canine teeth replace those of the same name in the milk dentition; the premolar teeth replace the milk molars. There are no teeth in the first dentition corresponding to the adult molars.

Each tooth is divided into—(1) a **crown**, above the level of the gum, (2) a **neck**, surrounded by the gum, (3) a **root** or **roots**, imbedded in the jaw. The **crowns** are chisel-shaped in *incisor* teeth; peg-shaped in *canine* teeth; have two tubercles or cusps in *premolar* teeth, one tubercle medial and the other lateral; have several tubercles in *molar* teeth. The crown of the first upper incisor is considerably wider than that of any other incisor, and the crown of the first lower incisor is usually the narrowest; the crown of the third lower molar is larger than that of the third upper molar; therefore, with the exception of the first lower incisor and the last upper molar, each tooth meets two teeth of the opposing jaw.

Each **root** or pang tapers to a point. The roots of the incisors, the canine, and the premolar teeth are single, except in the case of the first upper premolar, which may be bifid at its tip; each upper molar has three roots, two lateral and one medial, but those of the third molar may be clumped together; each lower molar has two roots, an anterior and a posterior, and both of those may be bifid at the point. If the teeth have all fallen out after death, those characters can be ascertained from the alveoli in the jaws.

The milk teeth are distinguished from adult teeth by their small size, their constricted necks, and, in the case of the molars, from the fact that the roots of the milk molars are more spread apart.

The bulk of each tooth is composed of an exceedingly hard substance called **ivory** or dentine. The crown is covered with a thin layer of still harder substance called **adamantine** or enamel. The root is covered with a crust of modified bone. A layer of fibrous tissue, called **alveolar periosteum**, lines the wall of the alveolus and surrounds the root, and is attached by Sharpey's fibres to both of them, binding them together. In the interior of each tooth there is a cavity, called the **pulp cavity**, containing connective tissue, vessels, and nerves. The vessels and nerves enter the tooth through a foramen at the tip of each root, and traverse a canal in the root to reach the pulp cavity.

The first **deciduous** tooth to **erupt** is one of the **incisors**, and it should appear about *six* **months** after birth; all the milk teeth should have appeared by the end of the *second* year. The first **permanent** tooth to **erupt** is one of the **first molars** and it should appear during the *sixth* **year**. By the *twelfth* year all the permanent teeth should have erupted, except the third molar (dens serotinus or wisdom tooth), which appears at any time between 17 and 25, and may not erupt at all.

See Figures in the chapter on the Digestive Organs, where the teeth are described fully.

Os Hyoideum.

The **hyoid bone** lies in the front of the neck, at the root of the tongue, between the mandible and the larynx. It is named from its resemblance to the letter U [the Greek letter υ aspirated thus $\acute{\upsilon}$ = hy; $\epsilon\tilde{\iota}\delta o\varsigma$ (eidos) = shape]. It does not articulate with any other bone. It consists of a *body*, a pair of *greater horns*, and a pair of *lesser horns*.

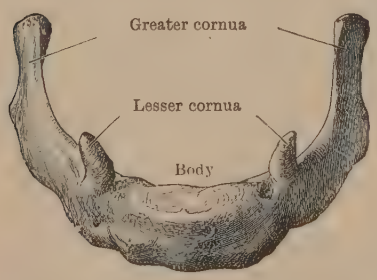

FIG. 152.—THE HYOID BONE AS SEEN FROM THE FRONT.

Corpus Ossis Hyoidei.—The **body** is the middle part or bottom of the U. It can be felt in the middle line of the neck about a finger's-breadth above the laryngeal prominence or "Adam's apple," when the chin is held up. When the chin is depressed the hyoid bone is at or above the level of the point of the chin and is closer to the larynx. If one swallows or gulps while the finger is placed on the hyoid bone, the bone is felt rapidly ascending, for the tongue, the hyoid bone, and the larynx are all suddenly jerked upwards in the movement of swallowing.

Cornua Majora.—The **greater horns** are the limbs of the U. They spring from the body about a finger's-breadth from the median plane and extend backwards in the sides of the throat; they can be gripped between finger and thumb, but the tip of the greater horn, though often referred to as a landmark, is overlapped by the anterior edge of the sterno-mastoid muscle, and cannot always be felt easily.

Cornua Minora.—The **lesser horns** are small pointed nodules of bone that project upwards from the junction of the body with the greater horns.

The **body** is compressed from before backwards and is curved from side to side with the convexity forwards. It has an upper and a lower border, and an anterior and a posterior surface. The anterior surface is divided into an upper and a lower part by a transverse ridge on which there is sometimes a small median tubercle; the upper part looks upwards rather than forwards and is divided by a median ridge into right and left halves. The genio-hyoideus is inserted into the upper part and a small adjoining area of the lower part. The anterior fibres of the hyo-

glossus arise at the side of the genio-hyoid; part of the mylo-hyoid is inserted below the genio-hyoid. The deep fascia of the neck is attached below the mylo-hyoid. The levator glandulæ thyreoideæ, when present, arises just below the attachment of the fascia, near the middle line.

The **lower border** gives insertion to the sterno-hyoideus. The median thyreo-hyoid ligament passes upwards behind the body to be attached to the **upper border**, which gives attachment also to the hyo-epiglottic ligament, and, occasionally, to some fibres of the genio-glossus. The **posterior surface** is smooth and concave; it is separated by some fat and a *bursa* from the median thyreo-hyoid ligament, which, in turn, is separated by a pad of fat from the stem of the epiglottis. When the larynx is pulled up during swallowing, the posterior surface of the hyoid bone overlaps the thyreoid cartilage of the larynx, and the bursa prevents friction between them.

The **greater horns** pass not only backwards, but have an upward and lateral inclination as well; they taper as they pass backwards, but each ends in a slightly swollen **tip**, to which the lateral thyreo-hyoid ligament is attached. They are compressed, so that each has a lateral and a medial surface and an upper and a lower border, but the compression is oblique, so that the surfaces are sometimes named upper and lower respectively, and the borders medial and lateral.

The **medial surface** is related to the thyreo-hyoid membrane, which passes upwards between it and the mucous membrane of the pharynx to be attached to the **upper border.** The **lateral surface** is continuous with the front of the body. It gives origin to the middle constrictor near the upper border, and to the hyo-glossus below that; the attachment of the fascial sling of the digastric tendon and the insertion of the stylo-hyoideus are close to the junction with the body. The deep fascia of the neck is attached near the lower border. The **lower border**, in its anterior two-thirds, gives insertion to the thyreo-hyoideus; the anterior belly of the omo-hyoideus is inserted into the anterior third, superficial to the thyreo-hyoid, and overlaps the insertion of the sterno-hyoid on the body.

The **lesser horn** is situated on the upper aspect of the junction of the body and the greater horn, and is often in line with the transverse ridge on the front of the body. It projects backwards and slightly in a lateral direction as well as upwards; usually it is only a few millimetres in length, but may be 10 or 12 mm. A few fibres of the middle constrictor arise from its lateral aspect, and the stylo-hyoid ligament is attached to its tip.

Development and Ossification.—The hyoid bone is developed from the cartilages of the second and third branchial or visceral arches, the ventral ends of which are fused together. On each side, the greater horn and the lateral part of the body are derived from the cartilage of the third arch. The lesser horn and the median part of the body are derived from the cartilage of the second or hyoid arch, which gives rise also to the stylo-hyoid ligament, the styloid process, and one of the auditory ossicles, namely, the *stapes*. Occasionally the stylo-hyoid ligament is ossified, and may be mistaken for a foreign body in the wall of the pharynx.

The hyoid bone is **ossified** from six centres. A pair (which soon unite into one) for the body, and one for each greater horn appear shortly before birth, and one for each lesser horn appears during the first year. The greater horn is united to the body by a plate of cartilage which ossifies at middle age. The lesser horn is united by a diarthrodial joint, which may disappear in old age.

The Skull at Birth.

At birth the skull, compared with other parts of the skeleton, is large, especially the vault. The facial region, however, compared with the rest of the skull, is small; in the adult the facial region, including the mandible, accounts for about one-half of the whole skull, but in the new-born child it is only one-eighth, for the teeth and the air sinuses are only rudimentary, and therefore the mandible, the maxillæ, and the nasal cavities are relatively small. A boy's head at birth is larger than a girl's, but so also is his body.

In the **vault**, the edges of the bones are not yet serrated, and are separated by linear intervals filled with strips of fibrous tissue continuous with the pericranium on the outer surface of the bones, and with the dura mater on the inner surface. Owing to the presence of those intervals, the bones of the vault have a certain degree of mobility, so that the head can be moulded into the required shape during the birth of the child. The bones are very thin, but, in addition to their mobility, they are less brittle than in an adult, and the pericranium is very tough, so that they are little liable to fracture.

In certain situations there are areas, rather than linear intervals, between the bones of the vault. Those areas are called **fonticuli** or fontanelles. They are seven in number—frontal, sagittal, occipital, right and left sphenoidal, right and left mastoid.

Fonticulus Frontalis.—The **frontal** or **antero-median fontanelle** is much the largest, and is easily felt in the fore part of the top of the head in the new-born child. It is lozenge-shaped, and measures about an inch and a half antero-posteriorly and an inch across. It is situated between the two halves of the

frontal bone and the two parietal bones. The ossifying process going on in those bones spreads into the fibrous membrane of the fontanelle; the bones meet and the fontanelle is closed during the second year.

The **sagittal fontanelle** is a small unossified space in the region of the sagittal suture at the *obelion*; it extends like a cleft into the upper part of each parietal bone. The parietal foramina in the adult are derived from it and indicate its position. The fontanelle is often quite closed at birth; in such cases the parietal foramina are absent.

The **occipital** or **postero-median fontanelle** is situated at the apex of the occipital bone between the two parietal bones. It is closed two months after birth.

The **sphenoidal** or **antero-lateral fontanelle** is situated at the anterior inferior angle of the parietal bone. It is closed three months after birth.

The **mastoid** or **postero-lateral fontanelle** is situated at the postero-inferior angle of the parietal bone. It is closed at the end of the first year.

From irregularities in ossification **sutural bones** may be developed in various sutures, and at

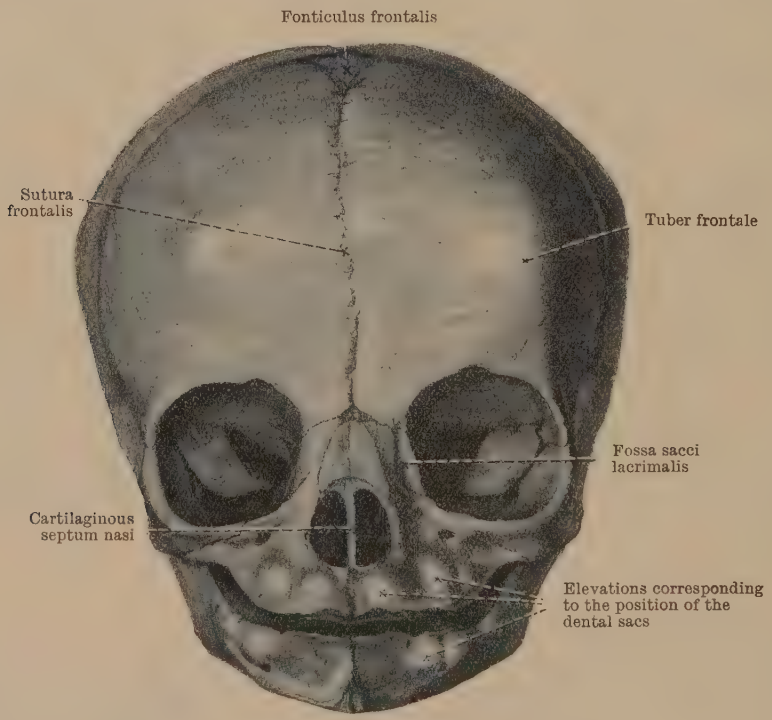

Fig. 153.—Frontal Aspect of the Skull at Birth.

the fontanelles. Those formed at the sphenoidal fontanelle, being in the region of the pterion, are called **epipteric bones.**

At birth the *occipital* bone is in four separate pieces, and on each side of the squama there is a cleft partially separating the upper, interparietal part of the bone from the rest; occasionally the two clefts meet. The *sphenoid* bone is in three separate parts—a median and two lateral—in addition to the sphenoidal conchæ. The *temporal* bone is in four parts—petro-mastoid, squamous, tympanic, and the styloid process. The mastoid process has not begun to develop. There is no *osseous* part of the external acoustic meatus, for the tympanic part of the temporal bone is not a plate as yet, but is a mere ring, incomplete superiorly. The tympanic membrane is therefore near the surface of the head; the obliquity of the membrane is greater than in the adult; it looks downwards and forwards more than in a lateral direction. The mandibular fossa is relatively large, and looks in a lateral direction as well as downwards.

The *mandible* is in two halves. The ramus is relatively short but wide, the angle is very obtuse, and the coronoid process is at a higher level than the head. The body has little substance beyond the walls of a wide groove incompletely divided into compartments for the dental sacs; the mental foramen is near the lower border. (See also p. 180.)

The *maxilla* is vertical and of small height, for the maxillary sinus is a mere groove in the lateral wall of the middle meatus; the distance between palate and orbit is therefore short. The alveolar process is small, reaching only a little below the level of the zygomatic arch; and it is hollowed out for the dental sacs.

The *nasal bones* are nearly flat. The *nasal cavity* is low, but the apertura piriformis is

relatively large and is a broad ovoid in outline; its lower margin is not far below the inferior orbital margin; for the nasal cavity is situated almost entirely between the orbits.

The *orbital opening* is large and nearly circular, and has sharp margins; the orbital fissures are wide; the fossa for the lacrimal gland is deep, and the fossa for the sac looks forwards rather than in a lateral direction.

The *frontal* bone is divided into halves by the frontal suture. The frontal tuberosities or

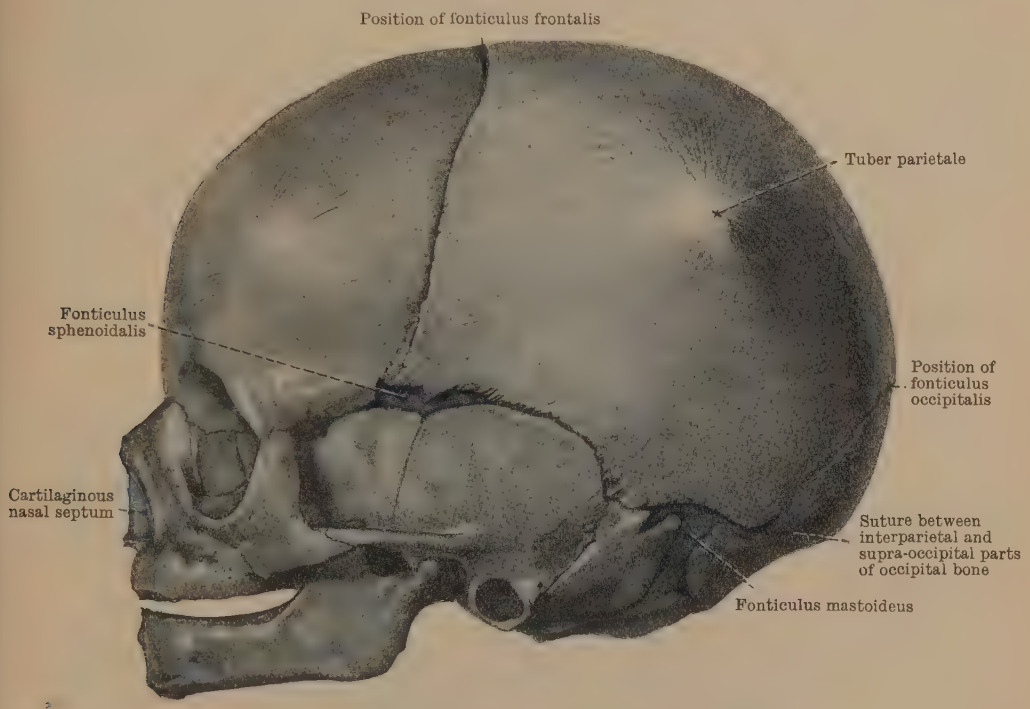

FIG. 154.—LATERAL ASPECT OF THE SKULL AT BIRTH.

eminences are very prominent; their prominence, combined with the absence of superciliary arches, gives the bulging appearance to the child's forehead. The *parietal eminences* or tuberosities are even more prominent and convex, and are situated at the widest part of the head, which is not always the case in the adult. The frontal and parietal eminences are more convex in the child than in the adult because the child's head is a smaller sphere.

Growth and Age Changes of Skull.

The skull grows rapidly from birth till the seventh year. At that age the orbits are almost as large as in the adult; the laminæ cribrosæ of the ethmoid, the body of the sphenoid, the petrous parts of the temporal bones and the foramen magnum have reached their full size; the jaws have enlarged in preparation for, as well as coincidently with, the eruption of the teeth, the chief enlargement in them being in the alveolar processes. For some years after the seventh growth is slower, but at puberty a rapid increase in the rate of growth takes place in all directions, especially in the frontal and facial regions, owing to the great increase of size of the air sinuses.

Growth in the thickness of bones takes place under the periosteum; growth in the area of the flat bones, and consequently growth in the capacity of the cranial cavity, takes place at the articulating margins of the bones; therefore, in order that increase may take place in the three dimensions, the sutures are arranged in three planes.

Up to maturity the age of the person can be ascertained approximately from the skull and the teeth.

A deciduous incisor erupts at the *sixth month* after birth, and all the incisors, except the lower lateral, appear during the *first year*; during that year the portions of the temporal bone and of the sphenoid unite. During the *second year*, the rest of the deciduous teeth erupt; the two halves of the mandible unite; the frontal fontanelle closes up; and the mastoid process appears. The lateral parts of the occipital bone unite with the occipital squama during the *third year*, and with the basi-occiput during the *fourth or fifth year*. The two halves of the frontal bone have almost completely united at the *sixth year*, and during that year the first of the permanent teeth—a first molar—erupts. The permanent incisors erupt during the *seventh and eighth years*, the premolars during the *ninth and tenth*, the canines during the *eleventh*, and the second molars during the *twelfth year*.

When the third molar is present the *seventeenth year* has been passed. If that tooth is present, and also the plate of cartilage between the body of the sphenoid and the occipital bone, the age is between 17 and 25. If the sphenoid and occipital are fused the age is over 25, for about that time the synchondroses of the skull disappear, *i.e.*, the synchondroses uniting the body of the sphenoid to the ethmoid and to the occipital, and the synchondrosis, on each side, between the lateral part of the occipital bone and the petrous part of the temporal bone.

After maturity, the wear of the teeth and the degree of obliteration of the sutures may give a rough indication of the age. Obliteration of sutures in the cranial vault—first in the coronal, next in the sagittal, and third in the lambdoidal—begins on the inner surface about ten years sooner than on the outer surface, and may begin between the *thirtieth and fortieth years*; but the order, the time, and the rate are all very variable, and complete obliteration does not take place till an advanced age.

In old age the skull vault may be thicker owing to deposit of bone on the inner surface; but in nearly all cases the skull bones are thinner, and the skull is lighter owing to absorption of diploë; associated with the absorption there are extension and enlargement of the sinuses. Consequent on loss of teeth there is diminution of the size of the jaws owing to absorption of the walls of the alveoli; the chin protrudes and the angle of the mandible becomes more obtuse. Less obvious changes are diminution of height and increase of breadth of the skull, transverse flattening of the base and the back of the head, and increase of the slope of the front and the back of the head; those changes may be due to the interaction of gravity and the support given to the skull by the vertebral column.

Sex Differences in the Skull.

There is little difference between the skulls of boys and girls till the age of puberty; but the skull of a woman is, as a whole, smaller than that of a man, and the air sinuses are small relatively to the size of the skull. The capacity of the cranial cavity is one-tenth less than in a man of the same race, and that is more or less in conformity with the relative size of the whole body of women and men of respective average build; the frontal and occipital regions of the cranial cavity are said to be relatively less capacious than the parietal region. Very often it is not possible to say with certainty whether a given adult skull is that of a man or of a woman, but the sex may be determined if the following differences are well marked.

The skull of a *woman* is lighter than that of a man and retains more of the character of a young skull; the muscular ridges are less pronounced; the mastoid processes are relatively small. The glabella and superciliary arches are less prominent; the forehead is therefore more vertical, and the frontal eminences appear to bulge more; the upper margin of the orbital opening is sharper—a fact appreciated better by touch than by sight; the parietal eminences are more convex. The facial region is rounder, and the jaws and teeth are smaller. The lower edge of the tympanic plate is said to be thicker and more tubercular. The vertex is said to be more flattened and the relative height of the skull to be less.

Development and Morphology of the Skull.[1]

At an early stage of development, the cerebral vesicles are enclosed in a membranous envelope, called the **primordial membranous cranium**, which is derived from the mesoderm. In certain lower vertebrates, *e.g.*, sharks and other *elasmobranch* fishes, a complete, thick-walled cartilaginous capsule, called the **primordial cartilaginous cranium**, is developed in the membranous envelope; but in mammals cartilage is developed only in the basal part; the roof, the greater part of the sides, and even part of the base of the skull remain membranous till bone is formed in them.

The **notochord** or chorda dorsalis [νῶτον (nōton) = the back] is imbedded in the basal part of the membranous envelope, but does not extend through the whole length of the base; its cephalic extremity reaches only to a point beneath the anterior end of the middle cerebral vesicle; and in the mammalian cartilaginous base it is related to that part which extends from the foramen magnum to the root of the dorsum sellæ. The cartilaginous base can therefore be divided into a **chordal** part and a **prechordal** part.

What is regarded as the typical occurrence of the chondrifying process in the mammalian skull is the appearance of a pair of elongated **parachordal cartilages** alongside the notochord, and a pair of elongated, curved **prechordal cartilages** or trabeculæ cranii, one at each side of the cranio-pharyngeal canal, *i.e.* the passage through which the pharyngeal part of the hypophysis enters the cranial cavity; those pairs of cartilages enlarge to form the cartilaginous base. But the process, so far as it has been observed, is not quite the same in the human embryo.

In the **human embryo** chondrification of the base of the cranium begins early in the second month and has almost attained its maximum about the end of the third month. Cartilage appears in the following situations.

(1) A pair of **parachordal cartilages** appear and fuse together around the notochord, to form a cartilaginous bar in which the *basi-occiput* ossifies. Extensions grow from its sides to form the

[1] Within the limits of a general text-book it is not possible to do more than glimpse at this abstruse and complicated subject. The reader who is interested is referred to the works of Gegenbauer, Froriep, Keibel and Mall, Hertwig, and Bardeen; and to the more recent writings of Gaupp, *Hertwig's Handbuch*, 1906; Viot, *Anat. Hefte*, 1909; H. Fuchs, *Anat. Anz.*, 1911; and Edward Fawcett, *Jour. Anat.*

cartilaginous precursors of the *lateral parts of the occipital bone*; and they grow backwards to form the thin plate of cartilage in which the part of the *occipital squama* below the superior nuchal lines ossifies; the two halves of the plate are tardy in uniting, so that the part immediately behind the foramen magnum remains membranous till shortly before birth, and is the commonest site for a cerebral meningocele.

(2) Chondrification takes place in the mesoderm around the developing internal ear, giving rise to what is called the **auditory capsule**, in which the *petrous* and *mastoid* parts of the *temporal* bone ossify.

(3) In front of the parachordal cartilages a small transverse strip of cartilage appears, which gives rise to the *dorsum sellæ*.

(4) At a more ventral level, in front of and ventral to the end of the notochord, a nodule of cartilage appears, which gives rise to the cartilaginous *body of the sphenoid* bone. It enlarges and grows forwards as two extensions which pass one on each side of the cranio-pharyngeal canal; they join together in front of the canal to form the anterior part of the cartilaginous body of the

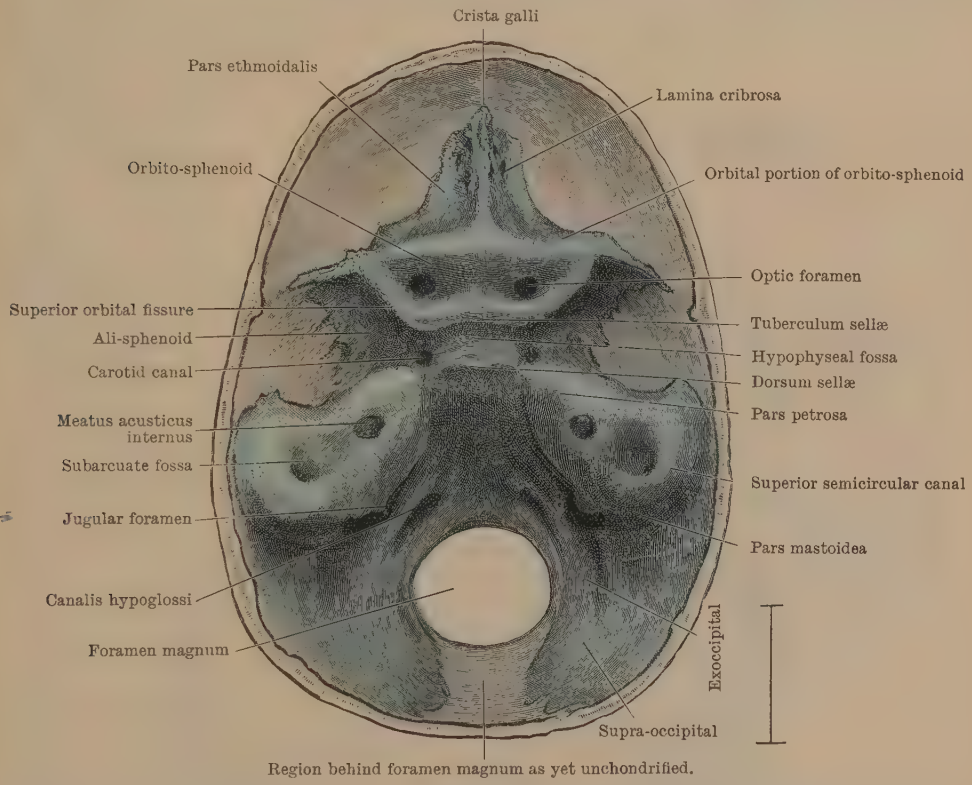

FIG. 155.—VIEW OF THE CHONDRO-CRANIUM OF A HUMAN FŒTUS 5 CM. IN LENGTH FROM VERTEX TO COCCYX (about the middle of the third month); the cartilage is coloured blue. The line to the right of the drawing shows the actual antero-posterior length.

sphenoid, and so provide the canal with cartilaginous boundaries, which grow inwards and usually occlude the canal during the third month, though occasionally it may remain open.

(The parachordal cartilages do not fuse together in such a way that the notochord traverses the basi-occipital bar lengthwise. The notochord lies in a groove on the posterior part of the cerebral surface of the bar, then pierces it to reach its pharyngeal surface, whence it runs upwards, between the basi-occipital and sphenoidal cartilages, to the root of the dorsum sellæ.)

(5) Chondrification occurs in the region that corresponds to the root of the *pterygoid process* and the root of the *great wing* of the sphenoid, including the *lingula* and the part around the *foramen rotundum*.

(6) Chondrification occurs in the whole of the region of the small wing, so that in the cartilaginous state it is bigger than the great wing.

(7) Chondrification occurs in the region of the nose to form a cartilaginous **nasal capsule** during the third month. A cartilaginous plate, called the **paranasal cartilage**, appears in the lateral wall of the cavity and gives rise to the *labyrinth* of the ethmoid, including *its conchæ*, to the *inferior concha*, and the *sphenoidal concha*, while part of it is included in the maxilla, and part persists through life as the *cartilages of the side* of the nose. Chondrification in the primitive septum takes place partly by extension from the cartilaginous sphenoid, and partly by the development of independent **para-septal cartilages** in each side of the ventral part of the septum. The perpendicular lamina of the ethmoid ossifies in the cartilaginous septum, but a great part of

the cartilaginous septum persists throughout life. The cartilaginous roof is formed partly by fusion of the cartilage in the side wall with that in the septum, and partly by independent chondrification of the mesoderm around the filaments of the olfactory nerve. Chondrification in the floor is very incomplete.

All the various chondrified areas of the mesoderm fuse together and form a cartilaginous platform in the base of the skull from which the cartilages of the branchial or visceral arches are suspended. Most of the cartilage is ossified; part is replaced by bone ossified in the surrounding membrane; parts persist as the cartilages in the *sides* and *septum* of the nose and in the *foramina lacera*; and parts survive till maturity in the *synchondroses* of the skull.

Some of the bones of the skull are ossified in the cartilage of the base, namely: the occipital bone, except the part of its squama above the nuchal lines; the petrous and mastoid parts of the temporal bone; the body of the sphenoid, the small wings, the roots of the great wings and of the pterygoid processes; the ethmoid; the inferior concha.

Some of them are ossified in the membrane overlying the cartilages of the nose, namely, the vomer, the lacrimal, the nasal, and the upper part of the maxilla.

Some are ossified from the membrane underlying the mucous lining of the bucco-pharyngeal cavity, namely, the lower part of the maxilla, the palatine, and the greater part of the pterygoid process.

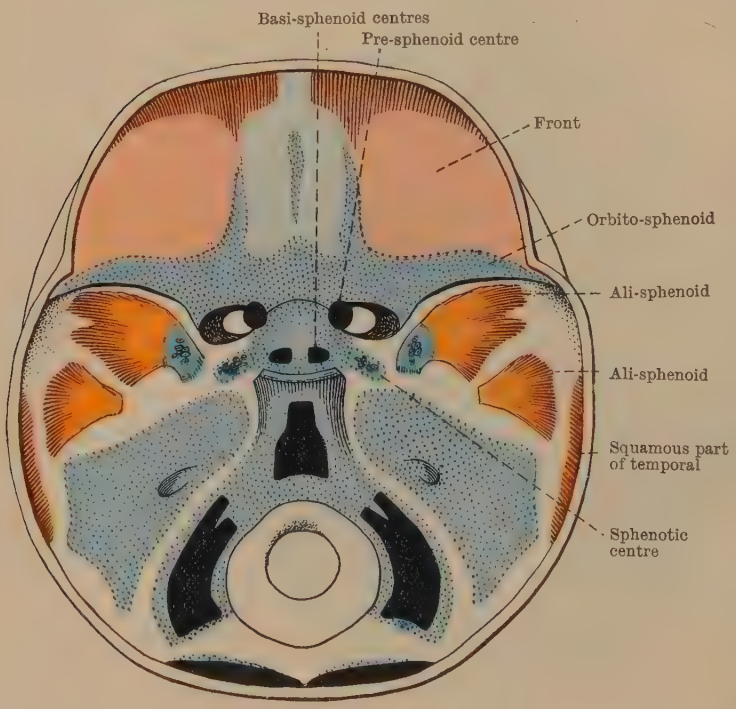

Fig. 156.—Ossification on Base and Side Walls of Skull of a four and a half Months' Fœtus (Schultze's method). Cartilage, blue; cartilage-bone, black; membrane-bone, red.

The frontal, the parietal, the squamous temporal, the upper part of the occipital squama, and the great wing of the sphenoid, all but its root, are ossified in the membranous brain envelope. The zygomatic bone ossifies in membrane which is continuous with the brain-case round the lateral margin of the orbit. The tympanic plate ossifies in membrane overlying the cartilaginous auditory capsule.

Skull bones therefore have been divided into two classes according to their method of ossification—cartilage or **primordial** bones and membranous or **secondary** bones. The distinction may be of not much importance, for the persisting osseous substance of every bone, whether its ossification began in cartilage or in membrane, is produced by ossification in the periosteum, *i.e.* in membrane; and some of the individual bones, *e.g.*, the temporal and the sphenoid, are ossified partly in cartilage and partly in membrane. It has been suggested, however, that the mammalian skull is derived from the two envelopes which have become modified and fused during the process of evolution. The inner envelope is the primordial chondro-cranium. The outer is of membranous origin, and is the more extensively evolved in the mammal; it appears first in certain fishes as ossified dermal plates overlying the primordial skull.

Although the skull never shows evidence of segmentation, probably owing to the need of stability even in the early evolutionary forms, it is assumed that the chordal part of the base has arisen by the fusion of segments equivalent to vertebræ, because—(1) of the presence of myotomes in the head region, (2) of the connexion with the series of branchial arches, and (3) of the segmental arrangement of nerves. The guide to the disposition of the nerves is their points of exit through the dura mater, for that is derived from the inner part of the primitive brain envelope; owing to the evolutionary changes that have taken place in the outer parts of the mammalian brain envelope, the apertures through which the nerves leave the skull, though very constant in position, do not in every case correspond to the points where they pierce the dura, *e.g.*, the oculo-motor and the abducent nerves in the human head.

The mammalian occipital bone is regarded (Froriep) as the equivalent of four fused vertebræ, and there is reason to believe that in some vertebrates the occipital region of the

primordial cranium is increased by inclusion of vertebræ from the cephalic end of the vertebral column. Gegenbauer concluded, from a study of the metameric arrangement of cerebral nerves, that the chordal part of the primordial cranium—and that is the part to which the cerebral nerves are primitively related, excepting the olfactory and the optic nerves, which are metamorphosed portions of the brain—consisted of the equivalents of nine fused vertebræ, and he called the chordal part the **vertebral** part of the cranium. The prechordal part he called **evertebral** or non-vertebral, and regarded it as a new formation developed to contain and protect the enlarging brain and the organs of smell and sight.

The outstanding features that distinguish the human skull are the large size of the brain-case, the small size of the face, and the fact that the skull is poised on the end of the backbone. Its position on the vertebral column reacts on its outward configuration; the occipito-vertebral joints are placed so that the fore and hind parts of the head nearly balance each other; therefore the prominent ridges and crests for the attachment of the muscles and ligaments required in lower mammals to hold the head in position are absent. The small size of the face is due chiefly to reduction of the bulk and length of the jaws and of the size of the teeth. Diminution of the mandible reacts on the form of the skull, for the muscles of mastication do not need to be so large, and there is corresponding reduction in the fossæ that lodge them, and in the surfaces and crests that give origin to them.

OSSA CRANII.

Os Frontale.

The **frontal bone** is situated in the front of the skull. It is divisible into—a **frontal part**, which lies in the forehead; two **orbital parts**, which lie in the roofs of the two orbits; and a **nasal part**, which lies in the roof of the nose.

Pars Frontalis.—The **frontal part** is the shell-like portion situated above the orbital openings. Its *external surface* is rounded from side to side and from above downwards. The convexity is

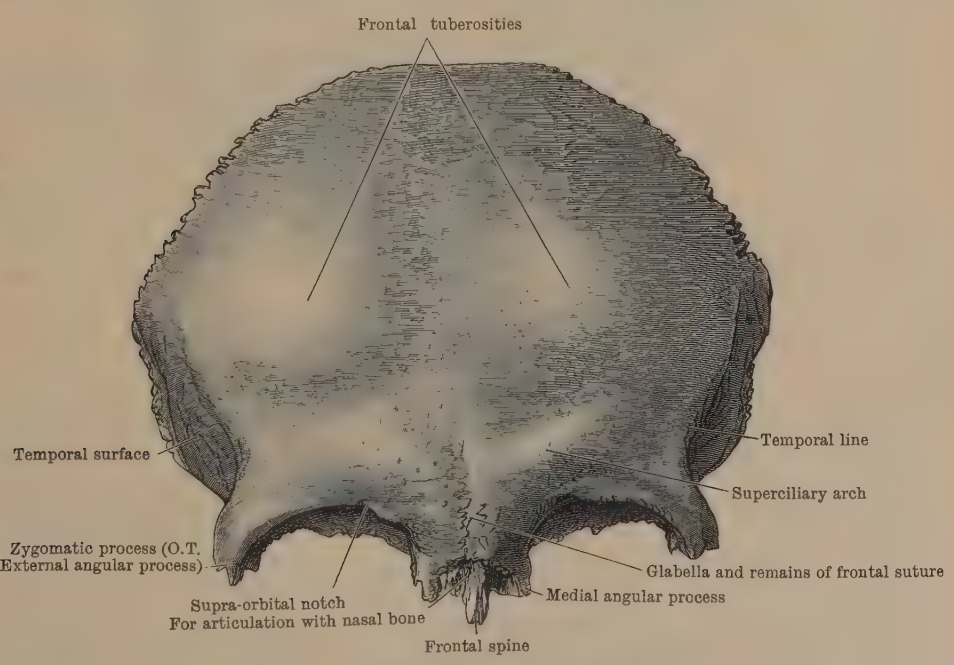

FIG. 157.—THE FRONTAL BONE (Anterior View).

most pronounced, on each side, about 35 mm. above the orbit, constituting what are known as the **frontal tuberosities** or eminences; they mark the original sites of the centres from which the bone ossifies. On each side, the lower border of the frontal part is the curved **supra-orbital margin**. The margin ends laterally in the prominent **zygomatic process**. The medial end descends to a slightly lower level and is called the **medial angular process**; it is separated from its fellow by a rough articular area called the **nasal notch**. The curve of the supra-orbital margin varies in different persons and races. Between its medial and intermediate thirds it is crossed by a groove, often (25 per cent., Krause) converted into a foramen—the **supra-orbital notch** or **foramen**, for the supra-orbital nerve. Sometimes (16 per cent., Loja) a series of grooves, radiating upwards and laterally, indicate the course of the nerve (Dixon). Above the supra-orbital margin the character of the bone displays marked differences in the two sexes: in the male, above the

interval between the two medial angular processes, there is usually a well-marked prominence, called the **glabella**; from this, the fulness extends laterally above the supra-orbital margin, varying in degree and extent, and forming the elevations known as the **superciliary arches**. Their prominence reacts on the character of the supra-orbital margins, which are thicker and more rounded in the male than in the female. The remains of the frontal suture can usually be seen in the glabella.

Extending from the **zygomatic process** is a well-marked ridge, called the **linea temporalis**, which curves upwards and slightly medially, and then, turning backwards, it arches across the lateral aspect of the bone. The line separates the anterior surface of the frontal portion of the bone from its *temporal surface*.

The *cerebral surface* of the frontal part is concave; it is marked by **digital impressions** for the gyri of the brain, and by narrow grooves for meningeal vessels, while on each side of the median plane there are **granular foveolæ**, varying in number and size, for the lodgment of arachnoid granulations. On the lower part of the surface there is a median ridge, called the **frontal crest**, which fades away as it is traced upwards. A groove called the **sagittal sulcus** begins on the crest and extends upwards to the articular margin of the bone, widening as it proceeds. A small hole, called the **foramen cæcum**, which is situated usually between the ethmoid and the lower end of the frontal crest, may be seen in its entirety on the separate frontal bone.

Pars Orbitalis.—Each **orbital part** or **plate** is a thin, brittle, curved plate which is convex upwards and has the outline of a sextant. Its upper or *cerebral surface* is convex and uneven,

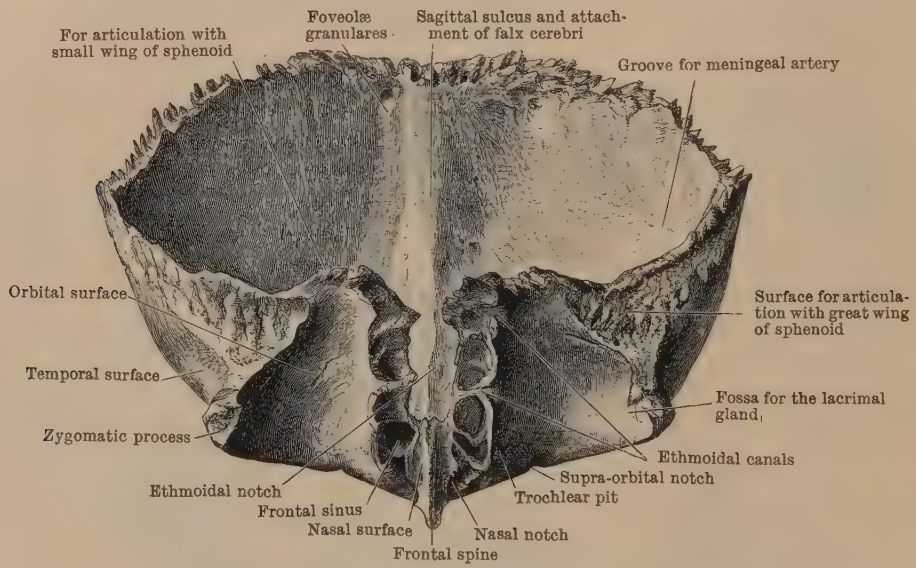

FIG. 158.—THE FRONTAL BONE AS SEEN FROM BELOW.

showing ridges and depressions corresponding to the sulci and gyri of the frontal lobe, which lies on it; it shows also narrow grooves for meningeal vessels.

The larger, lateral part of the *inferior surface* is smooth and concave, and forms the greater part of the roof of the orbit, extending forward to the supra-orbital margin. Near that margin, about midway between the medial angular process and the supra-orbital notch, there is either a very small depression **(fovea trochlearis)**, or a spicule of bone **(spina trochlearis)**, or both, for the attachment of the trochlea or pulley of the superior oblique muscle of the eyeball. Laterally the surface is overhung by the supra-orbital margin and the zygomatic process, so that a wide depression or **fossa for the lacrimal gland** is formed. The medial part of the inferior surface is a wide strip which overlies the labyrinth of the ethmoid, roofing in ethmoidal air-cells, so that it presents a number of irregular depressions corresponding to those cells. Anteriorly the opening from the frontal sinus is seen. Further back there are two narrow, nearly transverse, grooves which, with corresponding grooves on the ethmoid labyrinth, form the **anterior** and **posterior ethmoidal canals**. The medial margin of the orbital plate is parallel with its fellow of the other side. Their posterior halves, or more, are separated by an interval, called the **ethmoidal notch** because it is occupied by the laminæ cribrosæ of the ethmoid when the bones are articulated. The anterior halves of the margins are united to the nasal part of the bone.

Pars Nasalis.—The **nasal part** is the small portion of bone that lies in front of the ethmoidal notch. From its centre the **frontal spine** projects downwards and forwards into the nasal septum between the nasal crest of the nasal bones and the perpendicular lamina of the ethmoid, articulating with both. On each side of the root of the spine the nasal part presents a smooth, grooved surface that slopes from above downwards and forwards, and forms part of the roof of the nasal cavity.

Articulations.—The zygomatic process articulates with the frontal process of the zygomatic bone. Behind that, a rough, triangular area articulates with the great wing of the sphenoid. Above that, the whole serrated posterior margin of the frontal part articulates with the two

parietal bones. The posterior margin of the orbital plate articulates with the small wing of the sphenoid. The medial part of the inferior surface articulates with the labyrinth of the ethmoid. The medial angular process articulates with the lacrimal bone. The nasal notch articulates with the upper ends of the nasal bone and frontal process of the maxilla on each side. The frontal spine articulates with the nasal bones and the perpendicular lamina of the ethmoid.

Ossification.—Ossification begins in membrane from one centre for each half. Each centre appears about the sixth or seventh week in the region above the zygomatic process. From them the two halves of the frontal part of the bone are ossified, and by extension medially and backwards from their lower part the orbital parts also are ossified. Serres, Rambaud and Renault, and v. Ihering describe the occurrence of three pairs of secondary centres somewhat later: one pair for the frontal spine, on each side of the foramen cæcum; a centre on each side in the position of the trochlear pit; and a centre for each zygomatic process. Fusion between those secondary and the primary centres is usually complete about the sixth or seventh month of fœtal life. At birth the two symmetrical halves of the bone are separated by the *frontal suture*, obliteration of which, commencing as a rule on a level with the frontal tubera, gradually takes place, so that about the fifth or sixth year it is more or less completely closed, traces only of the suture being left above and below. In about 8 per cent. of Europeans the suture persists in the adult. At birth the supra-orbital notches lie near the middle of the supra-orbital margins.

Traces of the frontal sinuses may be met with about the second year, but it is only about the age of 7 that they can be definitely recognised. They increase in size slowly till the age of puberty and rapidly after puberty.

Structure and Variations.—Like other bones of the skull vault the frontal bone is made of two tables of compact substance enclosing a layer of spongy substance called the **diploë**. The diploë disappears from the part above the nose and the orbital openings to form the frontal air sinuses. The zygomatic process is dense in structure and is shaped so as to meet the pressure transmitted through the zygomatic bone from the closed jaws.

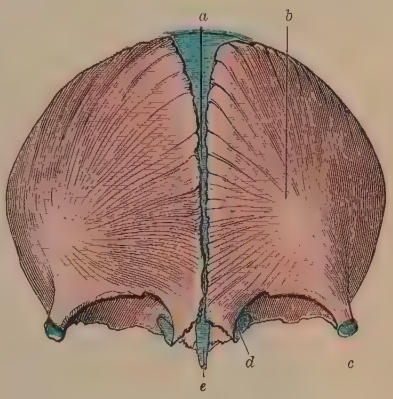

Fig. 159.—Ossification of the Frontal Bone.

a, Frontal suture still open. *b*, Position of primary centre. *c*, Centre for zygomatic process. *d*, Centre for region of trochlea. *e*, Centres for frontal spine.

The commonest variation is a persistence of the frontal suture: skulls displaying this peculiarity are termed **metopic**. The researches of various observers point to the more frequent occurrence of the metopic suture in the higher than in the lower races of man; and Calmette asserts its greater frequency in the brachycephalic than in the dolichocephalic type. Sutural bones may occur in the region of the frontal fontanelle; their fusion with one or other half of the frontal explains how the metopic suture is not always in line with the sagittal suture (Stieda, *Anat. Anz.* 1897); occasionally they coalesce to form a *bregmatic bone* (G. Zoja, *Bull. Scientifico*, xvii.). Turner (*Challenger Reports*, part xxix.) records an instance of direct articulation of the frontal bone with the orbital surface of the maxilla in a Bush skull; other examples of the same condition, which obtains normally in the skulls of the chimpanzee and gorilla, have been observed (*Jour. Anat. and Physiol.* vol. xxiv.). There is sometimes a small arterial groove just medial to the supra-orbital notch or foramen, and occasionally that foramen is double, the lateral aperture appearing in the orbital margin wide of its middle point. Frequently the bone corresponding to the floor of the lacrimal fossa displays a cribriform appearance. Schwalbe (1901) records the presence of small independent ossicles (supra-nasal bones) in the anterior part of the metopic suture. He has directed attention also (*Zeit. f. Morph. und Anthr.* vol. iii.) to the existence of the metopic fontanelle, first described by Gerdy, and the occurrence of *metopic ossicles* (ossa interfrontalia) and *canals*.

Ossa Parietalia.

The **parietal bones** are placed one on each side of the vault of the cranium. Each articulates with its fellow of the opposite side, with the frontal *anteriorly*, with the occipital *posteriorly*, and with the temporal and the sphenoid *inferiorly*. Each bone possesses a parietal and cerebral surface, four borders, and four angles.

The **parietal surface**, convex from above downwards and from before backwards, displays towards its centre a more or less pronounced elevation called the **parietal tuberosity** or **eminence**. The eminence marks the position of the ossific centre, and not infrequently corresponds to the point of maximum width of the head. At a variable distance from the inferior border of the bone, and more or less parallel to it, two curved lines can usually be distinguished. They are the two branches into which the temporal line, seen already on the frontal bone, divides, and they are named the **superior** and **inferior temporal lines**. The area below the lines forms part of the floor of the **temporal fossa**, and is called the **planum temporale**; it is often faintly marked by grooves for branches of the middle temporal artery. Near the upper border of the bone, and about an inch from its postero-superior angle, is the small **parietal foramen**.

The **cerebral surface** is concave. It is moulded over the surface of portions of the frontal, parietal, occipital, and temporal lobes of the cerebrum, and displays digital impressions for the gyri of the brain. It presents also well-marked grooves for the branches of the middle meningeal vessels; the grooves radiate from the antero-inferior angle and the lower margin of the bone, the best marked running upwards at some little distance behind and parallel to the anterior border. Close to the superior margin there is a series of pits for arachnoideal granulations, and there also the bone is channelled so as to form a groove (**sulcus sagittalis**), which is completed by articulation with its fellow of the opposite side. Close to the postero-inferior angle there is a short curved groove called the **transverse sulcus**.

The *anterior*, *superior*, and *posterior borders* are deeply serrated. The **anterior border** articulates with the frontal bone, forming with it the *coronal suture*. In the upper part of the suture the frontal bone overlaps the parietal, while the parietal overlies the frontal below. The **posterior border** is united with the occipital bone to form the *lambdoid suture*. The **superior border** articulates with its fellow of the opposite side to form the *sagittal suture*; in the interval between the two parietal foramina this suture is usually simple in its outline. The **frontal** or **antero-**

superior angle is almost rectangular; the **occipital** or **postero-superior angle** is usually more or less rounded. The **inferior border** (**margo squamosus**) is curved, and shorter than the others. Sharp and bevelled at the expense of its outer table, it displays a fluted arrangement, and articulates with the squamous part of the temporal bone. The **sphenoidal** or **antero-inferior angle**, pointed and prominent, articulates with the great wing of the sphenoid. It is wedged into the angle between the great wing and the frontal bone, and is bevelled at the expense of its inner table anteriorly, whilst inferiorly it is thinned at the expense of its outer table. The **mastoid** or **postero-inferior angle** is a truncated angle lying between the inferior and posterior borders. It is deeply serrated, and articulates with the mastoid part of the temporal bone.

Ossification.—Ossification takes place in membrane by two centres which appear, one above the other, in the eighth week of fœtal life; they gradually unite during the fourth month and correspond in position to the future parietal tuberosity; from that region ossification spreads in a radial manner towards the edges and angles of the bone, where, however, the membranous condition persists for some time, constituting the fontanelles. Ossification is also somewhat delayed in the region of the parietal foramina, so that a membranous interval, called the sagittal fontanelle, is not infrequently apparent even at birth.

Structure and Variations.—The parietal bone is thin towards its lower part, and is thickest along the upper border.

A number of cases have been recorded in which the parietal bone is divided into an upper and lower part by an antero-posterior suture. Coraini records a case in which the parietal was incompletely divided into an anterior and posterior part by a vertical suture. A tripartite condition of the bone has also been observed (Frasetto). The parietal foramina vary greatly in size, and to some extent in position. They are sometimes absent on one or other side,

or both. They correspond in position to the sagittal fontanelle. Sometimes the ossification of the sagittal fontanelle is incomplete and a small transverse fissure remains. Occasionally in

FIG. 161.—THE RIGHT PARIETAL BONE (Cerebral Surface).

the region of the frontal fontanelle an ossicle of variable size may be met with. According to its fusion with adjacent bones it may disturb the direction of the sagittal suture.

Os Occipitale.

The **occipital bone**, placed at the posterior and lower part of the cranium, consists of four parts, arranged around a large ovoid hole, called the foramen magnum. The expanded, curved plate behind the foramen is the **squama occipitalis**. The thick rod-like portion anterior to the foramen is the **basilar part**. On each side the foramen is bounded by the **lateral** or **exoccipital parts**.

Squama Occipitalis.—The **squamous part** in shape somewhat resembles a Gothic arch, and is curved from side to side and from above downwards. It forms inferiorly a small portion of the middle of the posterior boundary of the foramen magnum, and unites, on each side of that, with the lateral parts of the bone.

About the centre of the *external surface* of the squama there is a prominence, varying in distinctness, called the **external occipital protuberance**. On each side, a curved line, called the **superior nuchal line**, extends from the protuberance towards the lateral angle of the bone; immediately above it there is often another curved ridge called the **highest nuchal line**. The right and left superior nuchal lines divide the external surface of the squama into an upper part called the occipital plane and a lower part called the nuchal plane. The **occipital plane** bulges backwards beyond the protuberance, but in exceptional cases the protuberance is the most posterior part of the skull. The **nuchal plane** is rough and uneven. It is divided into a right and a left half by a median ridge, called the **external occipital crest**, which extends from the protuberance to the foramen magnum. From the middle of the crest a curved line, called the **inferior nuchal line**, extends towards the lateral margin of the bone on each side.

The *internal surface* of the squamous part is concave, and is subdivided into four fossæ by a crucial arrangement of grooved ridges called the **eminentia cruciata**. In the upper pair of fossæ are lodged the occipital lobes of the cerebrum, whilst the hemispheres of the cerebellum occupy the lower pair. Near the centre of the eminence is the **internal occipital protuberance**, an irregular elevation, the sides of which are variously channelled according to the disposition of the grooves; the internal protuberance is usually at a slightly higher level than the external. Leading from the protuberance to the posterior margin of the foramen magnum is a sharp and well-

defined ridge called the **internal occipital crest**. Passing upwards from the protuberance there is usually a well-marked ridge, to one or other side of which, more frequently the right, there is a well-defined groove called the **sulcus sagittalis**. A pair of **transverse sulci** extend horizontally from the protuberance, and separate the upper pair of fossæ from the lower. Commonly the right transverse groove is confluent with the groove on the right side of the median ridge, but exceptions are not infrequent.

The **superior angle**, more or less sharp and pointed, is wedged in between the two parietal bones. Each **lateral angle** articulates with the posterior extremity of the mastoid portion of the corresponding temporal bone. The **superior borders**, much serrated, articulate with the parietal bones, forming the **lambdoid suture**; and the **lateral borders**, extending from the lateral angles to the jugular processes inferiorly, are connected with the medial margins of the mastoid portions of the temporal bones.

Pars Lateralis.—Each **lateral part** of the occipital bone is placed at the side of the foramen magnum; on their inferior surfaces they bear the **occipital condyles**, by means of which the skull articulates with the atlas. The condyles are elongated and oval; they are situated at the side of the anterior half of the foramen magnum; their anterior ends are closer together than their

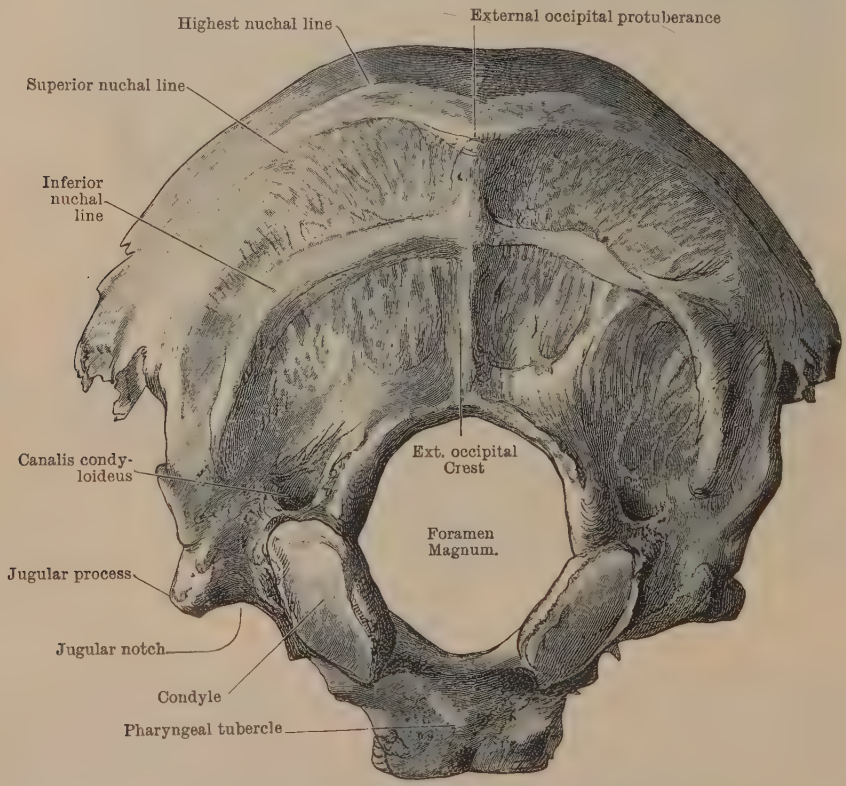

FIG. 162.—THE OCCIPITAL BONE AS SEEN FROM BELOW.

posterior ends; their articular surfaces are convex from before backwards and look in a lateral direction as well as downwards. Each articular surface is supported on a boss of bone through which the **canal for the hypoglossal nerve** passes. The canal opens externally into a depression just lateral to the anterior part of the condyle; its internal opening is a little above the margin of the foramen magnum. Behind the condyle there is a wide depression called the **condyloid fossa**, into which there opens a canal called the **condyloid canal**; the canal, however, is not always present. The edge of the foramen magnum immediately behind the condyle is often grooved by the vertebral artery. The bone which lies lateral to the posterior half of the condyle is called the **jugular process**. The *anterior* border of the process is free, rounded, and forms the posterior boundary of the jugular foramen; the border is concave from side to side, and the concavity is called the **jugular notch**. *Laterally*, the jugular process articulates by a synchondrosis with the jugular surface of the petrous part of the temporal bone. Its *posterior* border is confluent with the occipital squama, and its *lower* surface is rough.

The *superior aspect* of the lateral part displays, at the side of the foramen magnum, a smooth, oval elevation, called the **jugular tubercle**, which overlies the hypoglossal canal; in many cases there is a shallow oblique groove, on or behind the tubercle, which lodges the vagus, accessory and glosso-pharyngeal nerves. The upper surface of the jugular process presents a wide, deep, groove for the lower part of the transverse sinus; the condyloid canal, when present, opens into, or near, the groove.

Pars Basilaris.—The **basilar part** of the occipital bone extends forwards and upwards from the foramen magnum. Its anterior extremity is usually sawn across, as, after the twenty-fifth year, it is fused with the body of the sphenoid bone. The sawn surface is quadrilateral in outline; but posteriorly, where the basilar part bounds the foramen magnum, it is broad and thin. On its *inferior surface* some little distance anterior to the foramen magnum, there is a small elevation called the **pharyngeal tubercle**. The *superior surface* forms a broad and shallow groove which slopes upwards and forwards from the foramen magnum. *On each side* its lateral edge is faintly grooved for the inferior petrosal venous sinus, below which the lateral aspect of the bone is rough for the cartilage which unites it to the sides and apex of the petrous part of the temporal bone.

Foramen Occipitale Magnum.—The **foramen magnum** is variable in size and outline, but is usually ovoid, with the long axis antero-posterior. The plane of its outlet varies in different skulls, but usually it is directed downwards and slightly forwards. Anteriorly the condyles encroach upon it, and narrow its transverse diameter to some extent.

Ossification.—The major part of the bone ossifies in cartilage, the upper part of the

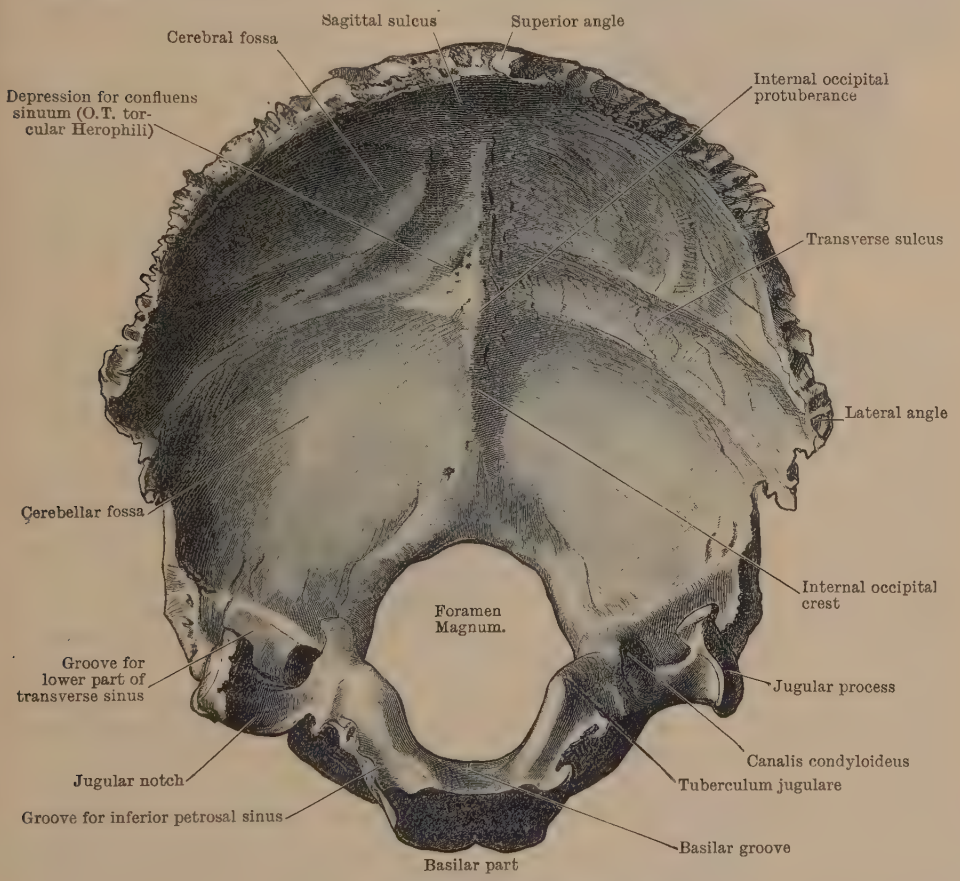

FIG. 163.—OCCIPITAL BONE (Cerebral Surface).

squama (interparietal) alone ossifying in membrane. The **basilar part** begins to ossify about the sixth week of fœtal life by the appearance of two centres, one in front of the other; the anterior, according to Albrecht, constitutes the *basiotic* (p. 196), the posterior the *basi-occipital*. Those two centres—which there is some reason to believe may themselves be formed by the fusion of pairs—rapidly unite, so that the occurrence of one centre alone is frequently described. From it the anterior part of the margin of the foramen magnum is ossified, together with the anterior ends of the occipital condyles. It helps also to close up the front of the hypoglossal canal. Union with the condylic parts is complete about the fourth or fifth year. Ankylosis between the basi-occipital and the sphenoid takes place about the twenty-fifth year.

The **lateral part**, including the posterior three-fourths of the condyle, begins to ossify in the eighth week of fœtal life from a single centre. The lateral part is usually completely fused with the squamous part by the third year or earlier.

As already noted, the squama consists of two parts, an upper and a lower. The part above the nuchal lines ossifies in membrane; the part below ossifies in cartilage. In a three-months fœtus this difference is very characteristic. The cartilaginous part (*supra-occipital*) begins to ossify in the sixth or seventh week from two centres (four according to Mall), which rapidly join to form an elongated strip placed transversely in the region of the occipital protuberance. The

centres for the superior part (*interparietal*) appear later. According to Maggi (*Arch. Ital. Biol.* tom. 26, fasc. 2), they are four in number, of which two, placed on each side of the median plane, appear in the eighth week. The other pair, placed laterally, are seen in the ninth week; fusion between them takes place early. Union between the supra-occipital and the interparietal elements occurs about the third or fourth month; but evidence of their separation is frequently met with, even in the adult, by the persistence of a transverse suture running medially from each lateral angle of the squama. The supra-occipital forms a small part of the median part of the posterior border of the foramen magnum, though there a small independent centre, known as the *ossicle of Kerkring*, is occasionally met with. Other independent centres are sometimes seen between the supra-occipital and the lateral parts of the bone.

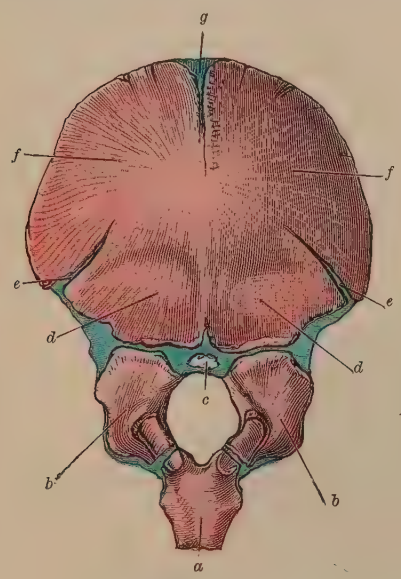

FIG. 164.—OSSIFICATION OF THE OCCIPITAL BONE.

a, Basilar centre; *b*, Lateral part; *c*, Ossicle of Kerkring; *d*, Supra-occipital (from cartilage); *e*, Fissure between supra-occipital and interparietal; *f*, Interparietal (from membrane); *g*, Fissure between interparietals.

At birth the occipital bone is in four pieces: the interparietal and supra-occipital combined; the basilar part; and the lateral parts.

Structure and Variations.—The squama shows thickenings of compact bone at the ridges and crests, and it is thickest at the protuberances; the floors of the lower pair of fossæ are thinner than the upper pair and their lower parts have no diploë. The basilar part is made of spongy substance surrounded by compact substance which is thickest on the lower surface. In the condyles the spongy substance is arranged radially to the convex articular surfaces. The hypoglossal canal is surrounded by very dense bone.

The *torus occipitalis transversus* is the term applied to an occasional elevation which includes the external occipital protuberance and extends laterally along the superior nuchal line. Occasionally an emissary vein pierces the bone opposite the occipital protuberance. In about 15 per cent. of cases the hypoglossal canal is double; much rarer, three or even four foramina may be met with. The most striking of the many variations to which the occipital bone is subject is the separation of the upper part of the squama to form an independent bone—the *interparietal bone*, called also, from the supposed frequency of its occurrence in Peruvian skulls, the *os Incæ*. By a reference to the account of the ossification of the bone, the occurrence of this anomaly is explained developmentally, an independent bone being formed from one or more of the interparietal centres. In place of forming a single bone the interparietal is occasionally met with in two symmetrical halves, and instances have been recorded of its occurrence in three or even four pieces. In the latter cases the two upper parts form the *pre-interparietals*. Not uncommonly the lower end of the internal occipital crest divides to enclose a depression, called the *vermiform fossa*, which lodges the vermis of the cerebellum. Instances are recorded of the presence of a separate epiphysis between the basi-occipital and the sphenoid, called the *os basioticum* (Albrecht) or the *os pre-basi-occipitale*. An oval pit, called the *fovea bursæ* or *pharyngeal fossa*, is sometimes seen in front of the tuberculum pharyngeum; it marks the site of the bursa pharyngea. Occasionally the basilar part is pierced by a small venous canal. The so-called **third occipital condyle** is a process which arises from the anterior border of the foramen magnum, and articulates with the dens of the epistropheus. Guerri has recorded a case in which, in a fœtal skull, there were two projecting tubercles in the position of the third occipital condyle, independent of the basi-occipital portions of the condyles, apparently supporting the view of Macalister that there are two different structures included under this name, one ossified in the sheath of the notochord, the other in the vertebral bow of the lowest occipital vertebra. On the lower surface of the jugular process, a rough or smooth elevated surface, or else a projecting process, the extremity of which may articulate with the transverse process of the atlas, is sometimes met with. This is the paroccipital or *paramastoid process*. The size and shape of the foramen magnum varies much in different individuals and races, as also the disposition of its plane. Elliot Smith has called attention to the asymmetry of the cerebral fossæ, which is correlated with asymmetry of the occipital poles of the cerebral hemispheres. Numerous instances of fusion of the atlas with the occipital bone have been recorded. Many are, no doubt, pathological in their origin; others are associated with errors in development. Interesting anomalies are those in which there is evidence of the intercalation of a new vertebral element between the atlas and occipital, constituting what is termed a **pro-atlas**.

Ossa Temporalia.

The **temporal bone** lies about the middle of the lower half of the side of the skull, and enters largely into the formation of the cranial base. It is placed between the occipital behind,

the parietal above, the sphenoid in front, and the occipital and sphenoid medially and below. It has four main parts—squamous, petrous, mastoid, and tympanic.

Squama Temporalis.—The **squamous part** is a thin scale-like plate of bone placed vertically in the side of the skull. It has a semicircular upper border, a cerebral or medial surface, a temporal or lateral surface and a small inferior surface; the zygomatic process projects forwards from the lower part of its lateral surface; most of its inferior surface is occupied by a hollow called the mandibular fossa, and an eminence called the articular tubercle, in front of the fossa.

The anterior part of the **upper border** is nearly vertical and articulates with the great wing of the sphenoid. The remainder of the border is bevelled at the expense of the inner table, overlaps and articulates with the parietal bone, and ends posteriorly by joining the upper border of the mastoid part at an angle, called the **parietal notch** because the posterior inferior angle of the parietal bone fits into it.

The **cerebral surface** is limited below by the petro-squamous suture, the remains of which can often be seen in the adult skull. The surface is marked by *digital impressions* for gyri of the brain, and is crossed by a groove or grooves for branches of the middle meningeal vessels.

The **temporal surface**, smooth and slightly convex, is larger than the cerebral surface; it

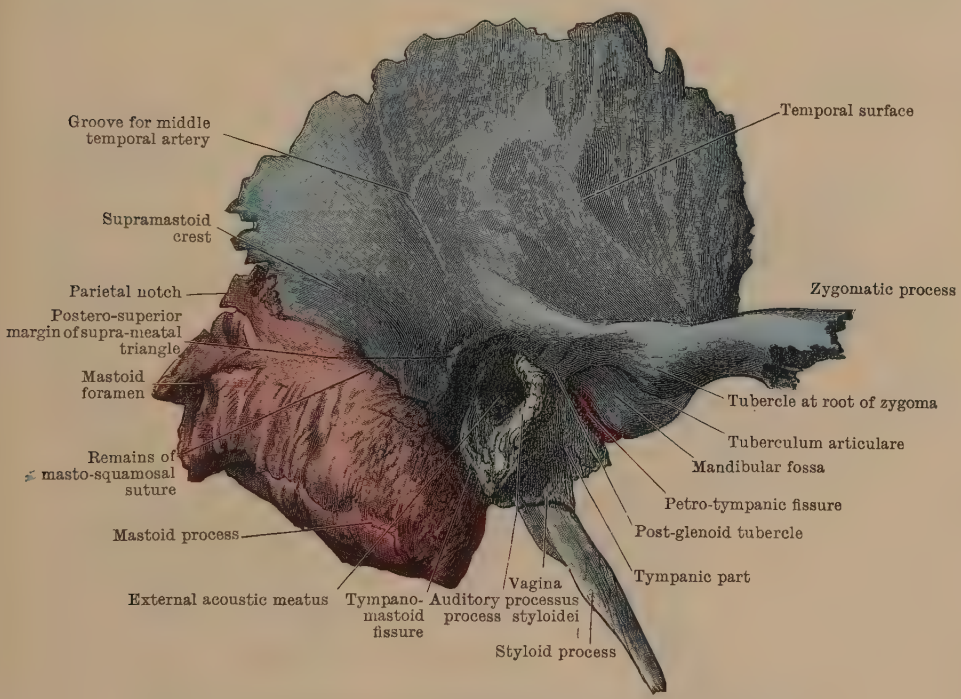

FIG. 165.—THE RIGHT TEMPORAL BONE SEEN FROM THE PARIETAL SIDE.

The squamo-zygomatic part is coloured blue; the petro-mastoid, red.
The tympanic part and styloid process are left uncoloured.

forms a considerable part of the floor of the temporal fossa. Near its posterior part it is crossed by one or more ascending grooves for the branches of the middle temporal artery.

The **zygomatic process** or **zygoma** springs from the lower and anterior part of the temporal surface by two roots, and curves forwards to end in an oblique, serrated edge which articulates with the temporal process of the zygomatic bone. The *upper border* of the process is sharp and is continuous with the posterior root. The *posterior root* is a salient ridge that extends backwards above the external acoustic meatus and becomes continuous with a blunt low ridge, called the **supra-mastoid crest**, which curves upwards, forming the lower part of the posterior boundary of the temporal fossa, and becomes continuous with the temporal line of the parietal bone. The *lower border* of the zygomatic process is continuous with the *anterior root*, which is a broad, thick bar of bone that turns abruptly in a medial direction to join the side of the skull. The lateral end of the root is prominent and is called the **tubercle** of the root of the zygoma; the medial end is continuous with a smooth transverse elevation on the lower surface of the squama, called the **articular tubercle**, the lower surface of the root forming part of the tubercle.

In front of the medial part of the tubercle, and medial to it, there is a small triangular area, called the **infra-temporal surface** because it forms part of the roof of the infra-temporal fossa; it articulates medially with the great wing of the sphenoid.

Behind the articular tubercle there is a smooth concavity called the **mandibular fossa**. The fossa and the tubercle articulate with the head of the mandible. At the lateral part of the posterior boundary of the fossa, just in front of the opening of the external acoustic meatus,

there is a small smooth projection called the **post-glenoid tubercle**; it is sometimes called the *middle root* of the zygoma.

Immediately behind the mandibular fossa there is a narrow cleft called the **petro-tympanic fissure**; its posterior boundary is the upper edge of the tympanic plate. In some skulls the lower edge of the tegmen tympani appears in the medial part of the fissure (p. 152).

Behind the external acoustic meatus, and below the supramastoid crest, the squamous element extends downwards as a pointed process, which assists in forming the posterior wall of the external acoustic meatus, where it unites inferiorly with the tympanic part and forms the lateral wall of a cavity in the interior of the temporal bone called the tympanic antrum. In the adult this process is occasionally sharply defined posteriorly by an oblique irregular fissure, the remains of the masto-squamosal suture, which is often not closed till puberty. Immediately above and behind the external acoustic meatus there is a small depression called the **supra-meatal triangle**; in rare cases there is a little spur of bone, called the *spina supra meatum* on the antero-inferior margin of the triangle.

Pars Tympanica.—The **tympanic part** of the temporal bone is a curved plate the concave **upper surface** of which forms the anterior, lower, and part of the posterior wall of the external

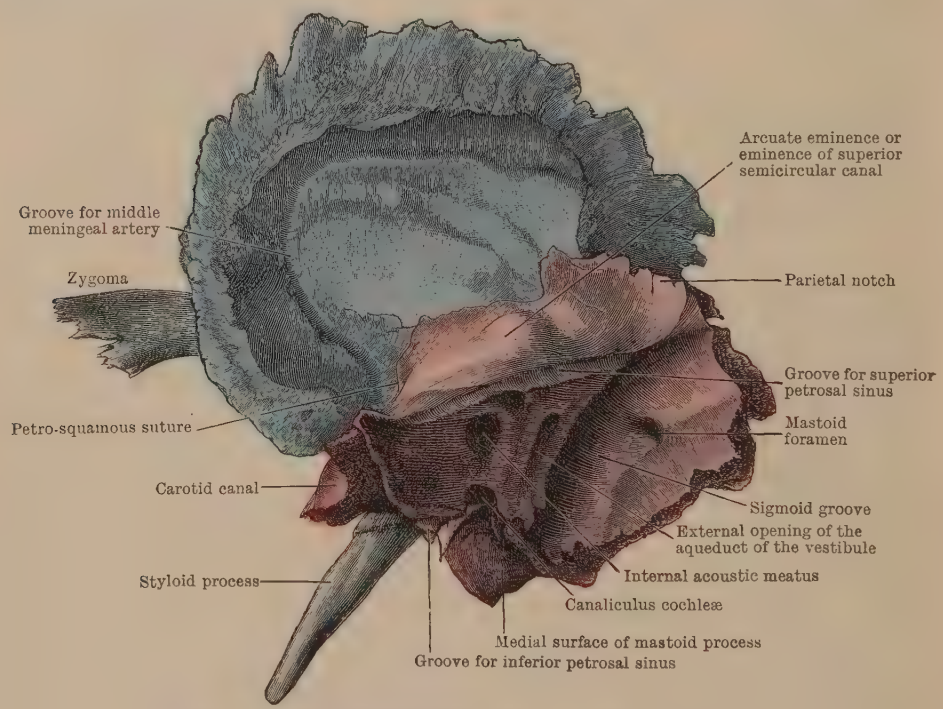

FIG. 166.—THE RIGHT TEMPORAL BONE (Cerebral aspect).

The squamous part is coloured blue; the petro-mastoid part, red. The styloid process and the zygoma are left uncoloured.

acoustic meatus. *Medially* it is fused with the petrous temporal. Its **anterior surface** is free and concave and has three borders. The *upper border* forms the posterior boundary of the petro-tympanic fissure. The *lower border* is sharp and uneven, and partly ensheathes the root of the styloid process, forming what is called the **vagina** or **sheath** of the styloid process. The *lateral border*, curved, thick, and rough, gives attachment to the cartilage of the auricle and is sometimes called the **auditory process.** The part of the plate that curves upwards in the posterior wall of the meatus is united with the mastoid temporal and with the descending process of the squamous temporal; but between it and the mastoid there is a narrow cleft, often very indistinct, called the **tympano-mastoid fissure.**

Meatus Acusticus Externus.—The **external acoustic meatus** is a canal about 15 mm. long; it is directed obliquely medially and a little forwards, and describes a slight curve, the convexity of which is directed upwards. It is oval in outline, the long axis of the oval being nearly vertical near the lateral end, but oblique from above downwards and backwards near the medial end. The upper margin of the *porus* or lateral orifice of the meatus overhangs the lower margin, but the medial orifice, which is closed by the tympanic membrane, is so oblique that the lower wall of the meatus is almost, or quite, as long as the upper wall.

Pars Mastoidea.—The **mastoid part** lies behind the squamous and tympanic parts. *Anteriorly* it is fused with those parts, and more deeply with the petrous part. Its *upper border* articulates with the parietal bone, forming the parieto-mastoid suture; its *posterior border* articulates with the occipital squama to form the occipito-mastoid suture. *Inferiorly* it sends down a blunt projection,

called the *mastoid process*, the root of which is bounded medially by a well-marked **mastoid notch**. Between the notch and the lower part of the occipito-mastoid suture there is an uneven strip of bone, on which there may be a shallow groove made by the occipital artery; the groove is nearly parallel to the notch. The *lateral surface* is convex and slightly roughened; the **mastoid foramen** opens on it near its posterior border; the foramen is variable in size and position and may open into the occipito-mastoid suture. The *medial surface* of the mastoid portion forms, in part, the side wall of the posterior cranial fossa. Coursing over this aspect of the bone there is a broad curved groove, called the **sigmoid sulcus**, the convexity of which is directed forwards and lies in the angle formed by the base of the petrous part and its fusion with the mastoid portion.

Pars petrosa (pyramis).—The **petrous part** of the temporal bone is shaped like a three-sided pyramid. By its base it is partly united obliquely to the other parts of the bone, and is partly free, forming the medial wall of the tympanic cavity. Its apex is directed medially, forwards, and a little upwards. Its three surfaces are arranged as follows: The **anterior** looks upwards, slightly forwards, and a little laterally, and forms part of the posterior wall of the middle cranial fossa. The **posterior** is directed backwards and medially, and forms part of the anterior wall of the posterior cranial fossa. The **inferior** is seen on the lower surface of the skull, and is directed downwards. The margins or angles are named anterior, superior, and posterior.

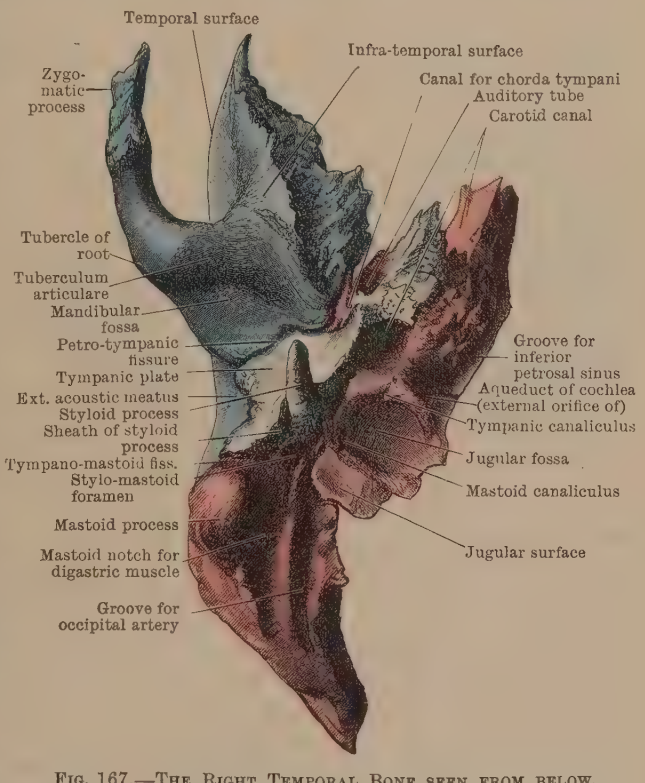

FIG. 167.—THE RIGHT TEMPORAL BONE SEEN FROM BELOW.

The squamo-zygomatic part is coloured blue; the petro-mastoid, red. The tympanic portion and styloid process are left uncoloured.

The **anterior margin** is short and articulates with the posterior border of the great wing of the sphenoid; it forms an acute angle with the anterior border of the squamous part; within the angle is wedged the posterior corner of the great wing. At the apex of the angle there is seen the opening of the **musculo-tubal canal**, which leads backwards and laterally to the tympanic cavity; the canal is divided by a thin bony septum into an upper part called the *semi-canal for the tensor tympani* muscle, and a larger, lower part which is the *osseous part* of the **auditory tube**.

The **posterior margin** is in part articular and in part non-articular. Posteriorly and laterally it corresponds to the upper margin of an area on the inferior surface which articulates with the jugular process of the occipital. Medial to that it is irregularly notched, and forms the free anterior edge of the jugular foramen. The remaining antero-medial part, which extends from the jugular foramen to the apex of the bone, articulates with the margin of the basilar part of the occipital bone; the inferior petrosal sinus runs along the articulation, grooving both bones.

The **superior margin** is a sinuous edge which is grooved lengthwise for the superior petrosal sinus, while near the apex it is crossed by the trigeminal nerve, which produces a shallow notch on the margin.

The inferior surface of the petrous part is bounded in front by the anterior border medially and the tympanic plate laterally, and behind by the posterior border. On it the following parts are to be noted: A slender process, about an inch long, called the **styloid process**, projects downwards, forwards, and medially from behind the lower edge of the tympanic plate. The **stylo-mastoid foramen** is the opening behind the root of the styloid process and in front of the mastoid notch. Medial to the root of the styloid process there is a smooth, deep concavity, called the **jugular fossa** because it lies in the antero-lateral wall of the jugular foramen. Behind and lateral to the jugular fossa there is a small area, called the *jugular surface*, which is united by cartilage to the jugular process of the occipital bone. On the lateral part of the wall of the fossa there is a very small aperture; that is the medial end of the **mastoid canaliculus**, which opens laterally in the tympano-mastoid fissure. In front of the jugular fossa there is an oval or circular aperture which is the lower end of the **carotid canal**; the canal passes upwards for a short distance, and then, becoming horizontal, it passes medially and forwards, and ends at the apex as

an oblique opening with jagged margins. On the lateral wall of the ascending part of the canal there are two or more small openings of **carotico-tympanic canaliculi**, which communicate with the tympanum. On the ridge between the carotid canal and the jugular fossa, there is the lower opening of the **tympanic canaliculus**, which leads up to the tympanum. Medial to the interval between the carotid canal and jugular fossa there is a small angular depression at the bottom of which there is the external aperture of the **aqueduct of the cochlea**. Medial to and in front of the lower opening of the carotid canal there is a rough **quadrate area**; a strip along its antero-lateral border articulates with the posterior margin of the great wing of the sphenoid and helps to form the groove for the lodgment of the cartilage of the auditory tube; its postero-medial border is united to the occipital bone by dense fibrous tissue or cartilage, the gutter between the two bones being called the *petro-basilar fissure*.

The **anterior surface** of the petrous part bears the impress of gyri of the temporal lobe of the cerebrum; in addition, there is a distinct but shallow depression, called the **trigeminal impression**, near the apex, on the roof of the carotid canal; it lodges the semilunar ganglion. Lateral to the middle of the anterior surface, and close to its superior border, there is an elevation called the **eminentia arcuata**, more or less pronounced, which marks the position of the superior semicircular canal within the substance of the bone. A little in front of this, and in line with the angle formed by the anterior border and the squamous part, is the slit-like opening of the **hiatus canalis facialis**. Leading forwards and medially from the hiatus towards the anterior border there is a groove for the greater superficial petrosal nerve, which passes out of the hiatus. A little lateral to the hiatus there is another small opening (**apertura superior canalis tympanici**), often difficult to see; from it a groove runs forwards which channels the upper surface of the roof of the semi-canal for the tensor tympani muscle. Through the aperture and along the groove passes the lesser superficial petrosal nerve. The bone forming the lateral part of the anterior surface, lateral to and in front of the arcuate eminence, is called the **tegmen tympani**, for it roofs over the tympanic cavity and antrum; it forms the roof of the semi-canal for the tensor tympani also. The line of fusion between the petrous and squamous parts of the bone is often indicated by a faint, irregular **petro-squamous fissure** along the lateral margin of the anterior surface of the petrous temporal.

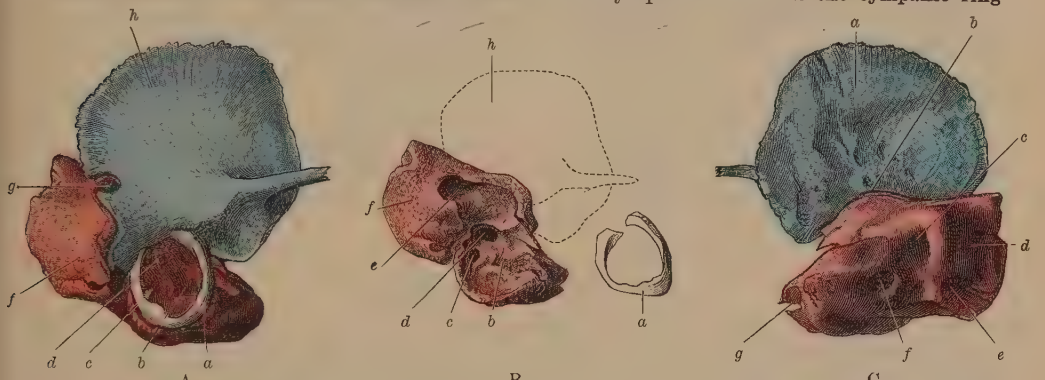
The most conspicuous feature on the **posterior surface** of the petrous part of the bone is an oblique, oval aperture which leads into the internal acoustic meatus. The **internal acoustic meatus** is a canal about 10 mm. long which passes laterally and slightly downwards into the bone, and ends blindly, except that the bony substance at the **fundus** or far end has a number of small holes in it. That bone is therefore called the **lamina cribrosa**, and it separates the meatus from the internal ear. It is crossed by a ridge, called the **transverse crest**, which divides it into two unequal parts. In the *upper*, smaller *part*, posteriorly, there is a small spot, called the **area vestibularis superior**, with a few holes in it for the transmission of branches of the vestibular nerve; in front of that there is the **area facialis**, with one large aperture through which the facial nerve enters the **facial canal**. In the *lower part*, posteriorly, there is a small spot called the **area vestibularis inferior**; branches of the vestibular nerve pass through small holes in it and through the **foramen singulare**, which is a small aperture situated immediately below and behind the area; in front of the area the branches of the cochlear nerve pass (*a*) through a small opening that leads into the **central canal of the cochlea**, and (*b*) through a number of smaller holes which are arranged in a spiral curve around the opening of the central canal and are named collectively the **tractus spiralis foraminosus**. Lateral to the internal acoustic meatus and above it, close to the superior border, there is an irregular depression called the **subarcuate fossa**, with one or two small foramina opening into it. It is often faintly marked; it is seen best in young bones (see Fig. 168, C), where it forms a distinct recess, which is bounded above by the bulging caused by the superior semicircular canal, within the concavity of which it is placed. About half an inch lateral to the meatus there is the **apertura externa aquæductus vestibuli**, often concealed in a narrow curved fissure overhung by a sharp scale of bone. The ridge above it corresponds to the upper half of the posterior semicircular canal.

Ossification.—The temporal bone of man represents the fused periotic, squamosal, and tympanic elements; the squamosal and tympanic are membrane bones, whilst the periotic is ossified in the cartilaginous auditory capsule. The cartilages of the first and second visceral arches are also intimately associated with its development. The human temporal bone is characterised by the large proportionate size of the squamosal, the comparatively small size of the tympanic, the absence of an auditory bulla, and the large size of the mastoid process.

Ossification commences in the ear capsule in the fifth month, and proceeds so rapidly that by the end of the sixth month the individual centres are more or less fused. Of these, one, the **Pro-otic** (Huxley), which appears in the vicinity of the eminentia arcuata, is the most definite in position and form; from it a lamina of bone of spiral form is developed, which covers in the medial limb of the superior semicircular canal, and forms the roof of the internal acoustic meatus, together with the commencement of the facial canal. Reaching forwards, it extends to the apex of the petrous part; whilst laterally it forms part of the medial wall of the tympanum, surrounds the fenestra vestibuli, and encloses within its substance portions of the cochlea, vestibule, and superior semicircular canal. Another centre, the **Opisthotic**, appears in the vicinity of the promontory on the medial wall of the tympanum, surrounds the fenestra cochleæ, forms the floor of the vestibule, and extends medially to complete the floor of the internal acoustic meatus. Surrounding the cochlea inferiorly and laterally, it completes the floor of the tympanum, and ultimately blends with the anterior and inferior part of the tympanic ring. The carotid canal at first grooves it, and is then subsequently surrounded by it. According

to Lambertz the lamina spiralis of the cochlea ossifies in membrane. The roof of the tympanum is formed from a separate centre, the **Pterotic**, which extends backwards towards the superior semicircular canal, and encloses the tympanic part of the facial canal; laterally it unites by suture with the squamosal, and sends down a thin process, which appears between the lips of the petro-tympanic fissure, and forms the lateral wall of the auditory tube. Nuclei, either single or multiple, **Epiotic**, appear in the base of the petrous part, envelop the posterior and lateral semicircular canals, and extend into the region of the mastoid process. The **styloid process**, an independent development from the upper end of the cartilage of the second visceral arch, is ossified from two centres. The upper or basal appears before birth, and rapidly unites with the petro-mastoid, the tympanic plate encircling it in front. This represents the **tympanohyal** of comparative anatomy. At or after birth another centre appears in the lower part of the cartilage to form the **stylohyal**. Ankylosis usually occurs in adult life between the tympanohyal and stylohyal portions.

The centre for the **squamo-zygomatic** appears in membrane about the end of the second month near the root of the zygoma; it extends forwards and laterally into the zygoma, medially into the roof of the infra-temporal fossa, and upwards into the squamosal. From the squamosal, ossification extends downwards and backwards to form the post-auditory process between the mastoid and tympanic parts. It forms the lateral wall of the tympanic antrum, and is the area above the anterior part of the root of the mastoid process in the adult. About the third month a centre appears in the lateral membranous wall of the tympanum: from it the **tympanic ring**



The squamo-zygomatic part is coloured blue; the petro-mastoid red. The tympanic ring is left uncoloured.

FIG. 168.—A. THE PARIETAL SURFACE OF THE RIGHT TEMPORAL BONE AT BIRTH. B. THE SAME WITH THE SQUAMO-ZYGOMATIC PORTION REMOVED.

(The lettering is the same in both A and B.) *a*, Tympanic ring. *b*, Medial wall of tympanum. *c*, Fenestra cochleæ. *d*, Fenestra vestibuli. *e*, Tympanic antrum. *f*, Mastoid process. *g*. Masto-squamosal suture, with foramen for transmission of vessels. *h*, Squamo-zygomatic, removed in figure B to show how its descending process forms the lateral wall of the tympanic antrum.

C. CEREBRAL SURFACE OF THE RIGHT TEMPORAL BONE AT BIRTH.

a, Squamo-zygomatic. *b*, Petro-squamosal suture and foramen (just above the end of the lead line). *c*, Subarcuate fossa. *d*, Aquæductus vestibuli. *e*, Aquæductus cochleæ. *f*, Internal acoustic meatus. *g*, Upper end of carotid canal.

is ossified. Incomplete above, it displays two free extremities. Of these, the anterior is somewhat enlarged, and unites in front with the mandibular portion of the squamo-zygomatic, being separated from it by the petro-tympanic fissure and the downgrowth from the tegmen tympani; the posterior joins the post-auditory process of the squamo-zygomatic. Below, it blends medially with the portion of the petro-mastoid which forms the floor of the tympanum and ensheathes the tympanohyal behind. From the medial surface of the ring below there is an extension medially and forwards which forms the floor of the osseous part of the auditory tube, as well as the lateral wall and half of the floor of the carotid canal. From the lateral side of the lower part of this ring two tubercles arise, which grow laterally, and so form the floor of the bony external acoustic meatus. The interval between them remains unossified till about the age of five or six, after which closure takes place. The deficiency may, however, persist even in adult life.

At **birth** the temporal bone can usually be separated into its component parts. The lateral surface of the petrous part not only forms the medial wall of the tympanum, but is hollowed out behind and above to form the medial wall of the tympanic antrum, the lateral wall of which is completed by the post-auditory process of the squamo-zygomatic. As yet the mastoid process is undeveloped. It assumes its nipple-like form about the second year. Towards puberty its spongy substance becomes permeated with air spaces, which are extensions from the tympanic antrum. Occasionally this pneumatic condition is met with in early childhood. The external acoustic meatus is unossified in front and below, the outgrowth from the tympanic ring occurring subsequent to birth. The mandibular fossa is shallow and everted; the jugular fossa is ill-marked; whilst the subarcuate fossa is represented by a deep pit, the so-called *floccular fossa* of comparative anatomy. The hiatus of the facial canal is an open groove, displaying at either end the openings of the medial and lateral portions of the facial canal.

Structure and Variations.—The temporal bone is remarkable for the hardness and density of its petrous part, which contains the osseous labyrinth, wherein are lodged the delicate organs associated with the senses of hearing and equilibration. Owing to the disposition of the internal and external acoustic meatus the weakest part of the bone corresponds to a line connecting those two channels, the only parts intervening being the cochlea and tympanum. It is usually in this position that fracture of the bone occurs.

The line of the petro-squamosal suture is occasionally grooved for the lodgment of a sinus (petro-squamosal); sometimes the posterior end of the groove is continuous with a canal which traverses the upper border of the bone and opens into the transverse sulcus. Anteriorly the groove may pass into a canal which traverses the root of the zygoma and appears externally above the lateral end of the petro-tympanic fissure. They are the remains of channels through which the blood passed in the fœtal condition. Kazzander has recorded a case in which the squamous part of the temporal was pneumatic, the sinus reaching as high as the parietal and the squamoso-sphenoidal suture. Symington has described a case in which the squamous part was distinct and separate from the rest of the temporal bone in an adult; whilst Hyrtl has observed the division of the squamous part of the temporal into two by a transverse suture. The zygomatic process has been observed separated from the rest of the bone by a suture close to its root (Adacni). P. P. Laidlaw (*Journ. Anat. and Physiol.* vol. xxxvii.) describes a temporal bone in which there was absence of the internal acoustic meatus and of the stylo-mastoid foramen. The jugular fossa also was absent, and there was partial absence of the groove for the transverse sinus, associated with the presence of a large mastoid foramen. An instance of a rudimentary condition of the carotid canal is referred to in the same volume by G. H. K. Macalister. G. Caribbe (*Anat. Anz.* vol. xx.) notes the occurrence in idiots and imbeciles of a more pronounced form of post-glenoid tubercle, and associates it with regressive changes in the development of the temporal bone.

Occasionally the temporal articulates with the frontal, as happens normally in the anthropoid apes; although the region of the pterion is characterised by an X-like form in the lower races of man, there is no evidence that the occurrence of a fronto-squamosal suture is more frequent in the lower than the higher races, its occurrence being due to the manner of fusion of the so-called epipteric ossicles with the surrounding bones.

Os Sphenoidale.

The **sphenoid bone** lies in front of the basilar part of the occipital bone and the two temporal bones. It enters into the formation of the cranial, orbital, and nasal cavities, as well as the temporal, infra-temporal, and pterygo-palatine fossæ. It consists of a body and three pairs of processes, called the great wings, the small wings, and the pterygoid processes.

Corpus.—The **body** is more or less cubical in form, and is hollow, for it contains within it the two large **sphenoidal air sinuses**. The sinuses are separated by a median partition, which, however, is usually deflected to one or other side of the median plane. Each sinus may extend for a short distance into the root of the great wing and the base of the pterygoid process. They communicate by apertures with the upper and posterior part of the nasal cavities. In the adult the **posterior aspect** of the body displays a sawn surface due to its separation from the basi-occipital, with which, in the adult, it is firmly ankylosed. The **superior surface** displays an appearance comparable to that of an oriental saddle (**sella turcica**). Over its middle there is a deep depression, called the **fossa hypophyseos**, in which the hypophysis is lodged. The fossa is overhung posteriorly by a sloping ridge called the **dorsum sellæ**, the posterior surface of which is inclined upwards, and is in continuation with the basilar groove of the occipital bone. The upper angles of the dorsum sellæ are prominent tubercles called the **posterior clinoid processes.** In front of the fossa hypophyseos there is a transverse elevation called the **tuberculum sellæ**, behind the lateral ends of which there are sometimes little spurs of bone called the **middle clinoid processes.** In front of the tuberculum sellæ there is a groove called **sulcus chiasmatis** or **optic groove**, which passes laterally to become continuous with the optic foramina. In front of the optic groove the superior surface continues forwards on the same plane as the upper surfaces of the small wings, and terminates anteriorly in a ragged edge which articulates with the laminæ cribrosæ of the ethmoid, and has often projecting from it, in the median plane, a pointed process called the **sphenoidal spine.**

The lower parts of the **lateral aspects** of the body are fused with the great wings, and in part also with the roots of the pterygoid processes. Curving along the side of the body, above its attachment to the great wing, is an ſ-shaped groove, called the **carotid groove**, in which the internal carotid artery lies. Posteriorly, the hinder margin of that groove, formed by the salient lateral edge of the posterior surface of the body, articulates with the apex of the petrous portion of the temporal bone, and is hence called the **petrosal process**; just above it, on the lateral border of the dorsum sellæ, there is often a groove for the abducent nerve.

The **anterior surface** of the body displays a vertical, median ridge, called the **sphenoidal crest**, which is continuous above with the sphenoidal spine, and below with the pointed projection called the **sphenoidal rostrum.** The crest articulates in front with the perpendicular plate of the ethmoid. On each side of the median plane there is a triangular area which forms part of the roof of the nose; in that area there is an opening leading into the sphenoidal sinus. The lateral part of the anterior surface, on each side, articulates with the labyrinth of the ethmoid and the orbital process of the palatine bone. The **sphenoidal rostrum** is continued backwards for some

distance along the **inferior surface** of the body, where it forms a prominent keel which fits into the recess between the alæ of the vomer. Posteriorly, the inferior surface of the body of the sphenoid is rougher, and is covered with the mucous membrane of the roof of the pharynx.

Alæ Parvæ.—The **small wings** are two flattened triangular plates of bone which project laterally from the anterior and upper part of the body of the bone; each wing is united to the body by two roots, an anterior and a posterior, which enclose the **optic foramen.** The posterior

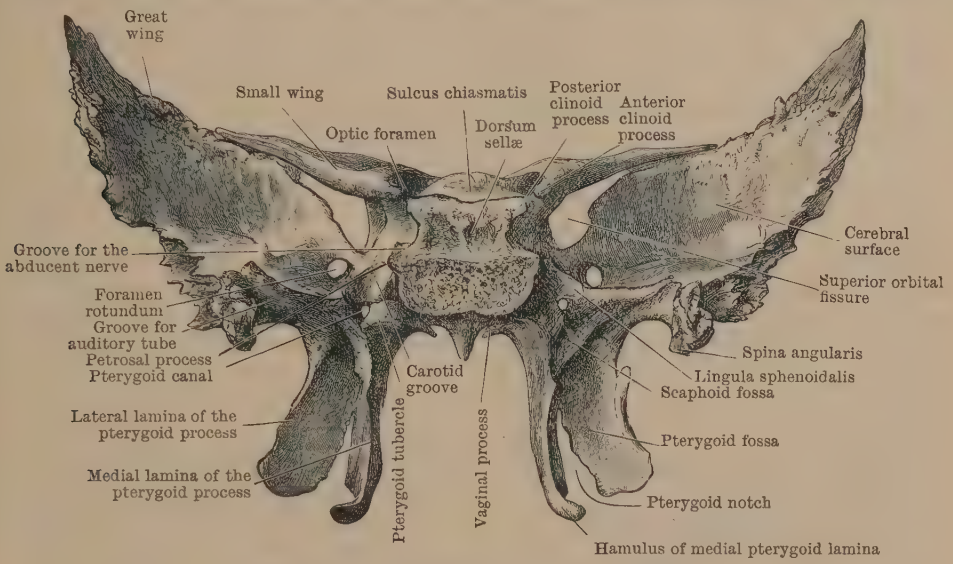


FIG. 169.—THE SPHENOID SEEN FROM BEHIND.

root springs from the body just wide of the tuberculum sellæ, separating the carotid groove behind from the optic foramen in front; laterally this root is confluent with the recurved posterior angle of the small wing which projects backwards and is known as the **anterior clinoid process.** The anterior root, broad and compressed, joins the anterior part of the upper surface of the body. Laterally, the small wing terminates in a pointed process which reaches the region of the pterion

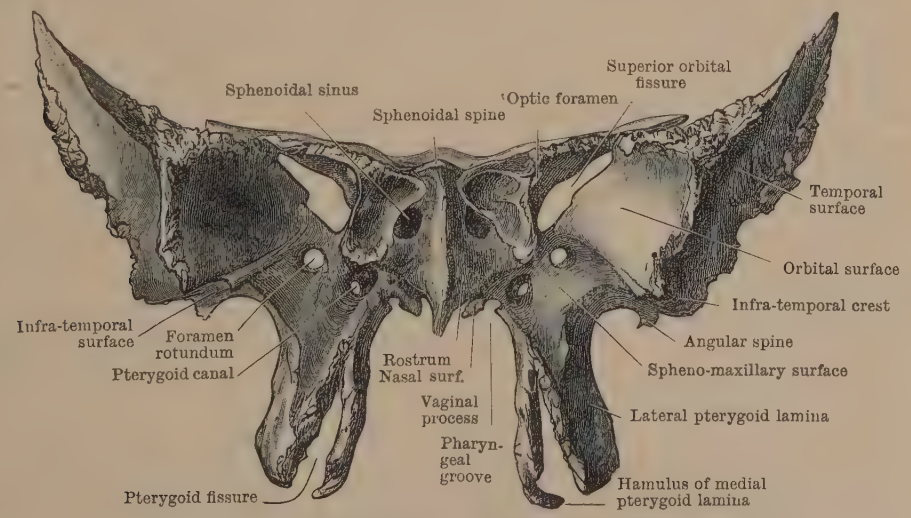

FIG. 170.—THE SPHENOID SEEN FROM THE FRONT.

and articulates there with the frontal, and may come in contact with the great wing. The superior aspect is smooth, and forms part of the floor of the anterior cranial fossa. The inferior surface constitutes part of the posterior portion of the roof of the orbit, and is also the upper boundary of the **superior orbital fissure,** which separates the small wing from the great wing. The anterior edge is ragged and irregular, and articulates with the orbital plate of the frontal bone. The posterior margin, sharp and sickle-shaped, separates the anterior from the middle cranial fossa, and ends medially in the anterior clinoid process.

Alæ Magnæ.—The **great wings,** as seen from above, are of a somewhat crescentic shape, and

form a considerable portion of the floor of the middle cranial fossa. Each great wing spreads out from the side of the body of the sphenoid in the floor of the middle cranial fossa, and turns upward into the side wall of the skull. It has three surfaces—an internal or *cerebral*, an *orbital*, and an external, which is divided into a *temporal surface* and an *infra-temporal*.

The **cerebral surface** is concave and is marked by digital impressions for gyri of the temporal lobe, and by grooves for meningeal vessels. Three, and sometimes four, foramina are seen in it. The **foramen rotundum** is a short horizontal canal that passes forwards below the medial part of the superior orbital fissure. The **foramen ovale** is situated about 10 or 12 mm. behind and lateral to the foramen rotundum. The **foramen spinosum** is the smaller aperture immediately behind and lateral to the foramen ovale. The fourth foramen, which is not always present, is a small hole, called the **foramen of Vesalius**, situated medial to the foramen ovale. In rare cases there is a fifth aperture, very small, called the **canaliculus innominatus**, situated behind the foramen ovale. The *borders* of the cerebral surface are upper or anterior, medial, and posterior. The *medial border* is fused with the side of the body of the sphenoid. The *posterior border* is divided into two distinct parts that meet together posteriorly in a sharp projecting **angle**. The medial part of the posterior border is a short distance behind the foramen ovale and spinosum and is oblique in direction; laterally it articulates with the petrous temporal, medially it forms the anterior boundary of the foramen lacerum, and there projects backwards from it a spur of bone of variable size called the **lingula**, which forms the anterior or lateral margin of the commencement of the carotid groove, and, when long enough, the lateral margin of the foramen lacerum. The lateral part of the posterior border is a long, concave, serrated edge that articulates with the squamous temporal. The *upper border* also is divided into parts. The medial part, thin and sharp, forms the lower boundary of the superior orbital fissure; the next part articulates with the frontal bone; and the third part is the extreme upper part of the wing and articulates with the antero-inferior angle of the parietal bone.

The **orbital surface** is smooth, nearly flat, more or less quadrilateral, and forms a great part of the lateral wall of the orbit. The *posterior border* is the medial part of the upper border of the cerebral surface and forms the lower margin of the superior orbital fissure; towards its lower or medial part there is sometimes a small projection, called the **spina recti lateralis**, for the attachment of the inferior common ligament of origin of the ocular muscles. The *lower border* is smooth and forms the upper or lateral boundary of a cleft called the inferior orbital fissure; immediately below that border there is an oblique, horizontal groove that forms part of the posterior wall of the pterygo-palatine fossa. The *anterior border* articulates with the zygomatic bone; and the *upper border* articulates with the frontal bone.

The **temporal surface** forms part of the floor of the temporal fossa; it slopes from above downwards and medially, and is concave from before backwards. *Posteriorly* it is separated from the cerebral surface by the part of the posterior border which articulates with the squamous temporal. *Anteriorly* it is separated from the orbital surface by the sharp border or crest that articulates with the zygomatic bone and sometimes also with the zygomatic process of the maxilla. *Superiorly* the uppermost part of the surface is separated from the cerebral surface by the short border that articulates with the parietal bone; in front of that it articulates with the frontal bone. The articulation of the great wing with the frontal bone is by a rough triangular area bounded by the upper margins of the three surfaces of the wing. *Inferiorly* the temporal surface is limited by a rough horizontal ridge called the **infra-temporal line** or **crest**.

The **infra-temporal surface** is situated almost at right angles to the temporal surface, and forms the greater part of the roof of the infra-temporal fossa. The **foramen ovale** and **foramen spinosum** are seen in it near its posterior border, and occasionally the **foramen of Vesalius**, medial to the foramen ovale. The *posterior border* articulates with the petrous temporal and is grooved lengthwise for the cartilage of the auditory tube, which lies along the junction of the two bones. *Medially* the surface is fused with the pterygoid process. *Anteriorly* it is bounded by a sharp margin behind the inferior orbital fissure. *Laterally* it is bounded by the infra-temporal crest, and behind that it is separated from the cerebral surface by the part of the posterior border that articulates with the lower part of the squamous temporal. That boundary and the posterior border which articulates with the petrous temporal meet at the **angle** of the great wing, which fits into the angular interval between the squamous and petrous temporal. From the angle a projection called the **angular spine** of the sphenoid juts downwards; it is situated behind and lateral to the foramen spinosum.

Processus Pterygoidei.—The **pterygoid processes** spring from the inferior surface of each lateral aspect of the body as well as from the under side of the roots of the great wings, and pass vertically downwards. Each consists of a *lateral* and a *medial lamina*, which enclose the **pterygoid fossa** between them; the upper parts of their anterior borders are fused together.

The **lateral pterygoid plate**, thin and expanded, is directed obliquely backwards and laterally, its lower part being often somewhat everted. Its posterior edge is sharp, and often has projecting from it one or two spines, to one of which (**processus pterygospinosus**) the pterygo-spinous ligament, which stretches towards the angular spine, is attached.

The **medial pterygoid plate** is narrower and rather thicker. It is placed between the pterygoid fossa and the posterior part of the nasal cavity. Its posterior edge ends below as a slender curved process, called the **hamulus pterygoideus**, which, reaching a lower level than the lateral plate, curves backwards and laterally, furnishing a groove on its lower surface in which the tendon of the tensor veli palatini muscle glides; superiorly, the sharp posterior margin of the medial plate bifurcates, so as to enclose a small, shallow, oval concavity called the **scaphoid fossa**; below the scaphoid fossa there juts backwards from the posterior

margin of the plate a small projection which supports the cartilage of the auditory tube. Above and medial to the scaphoid fossa, at the extreme upper end of the posterior border of the plate, there is a small, blunt projection called the **pterygoid tubercle**. A thin lamina, called the **vaginal process**, passes medially from the upper end of the plate. Near the plate it is fused with the lower surface of the body of the sphenoid. More medially it is free and is separated from the rostum by a groove in which the edge of the ala of the vomer fits in the articulated skull, and it articulates with the ala. On the lower surface of the vaginal process, near the medial pterygoid plate, there is a groove called the sulcus pterygo-palatinus or **pharyngeal groove**; in an articulated skull it leads forwards into the pharyngeal canal.

Above the pterygoid tubercle, and below the lingula, there is a small aperture leading into the **pterygoid canal**, which passes forwards through the root of the pterygoid process. In front, at its root, the pterygoid process displays a broad smooth surface (**facies sphenomaxillaris**), which is confluent above with the root of the great wing around the foramen rotundum, and forms the posterior wall of the **pterygo-palatine fossa**. To the medial side of the foramen rotundum, and below it, the anterior opening of the **pterygoid canal** is seen. Below, the pterygoid laminæ are separated by an angular cleft called the **pterygoid fissure**, in which is lodged the pyramidal process of the palate bone, the margins of which articulate with the serrated edges of the fissure.

Ossification.—The sphenoid of Man is formed by the fusion of two parts, the **pre-sphenoid** and the **post-sphenoid**, each associated with certain processes. In most mammals the **orbito-sphenoids** or small wings fuse with the pre-sphenoid, whilst the **ali-sphenoids** or great wings, together with the **medial pterygoid lamina**, ankylose with the post-sphenoid.

In the eighth week a centre appears in the root of the great wing between the foramen ovale and foramen rotundum; from that centre the ossification spreads laterally and backwards, and also downwards into the lateral pterygoid lamina. Two centres appear about the same time in the basi-sphenoid in relation to the floor of the fossa hypophyseos and on each side of the cranio-pharyngeal canal, around which they ossify, ultimately leading to the obliteration of that channel. Somewhat later a **sphenotic** centre appears on each side, from which the lateral aspect of the body and the **lingula** are ossified. Fusion between those four centres is usually complete by the sixth month.

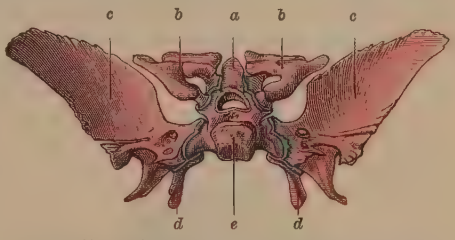

FIG. 171.—OSSIFICATION OF THE SPHENOID.

a, Pre-sphenoid; *b*, Orbito-sphenoids; *c*, Ali-sphenoids; *d*, Medial pterygoid laminæ; *e*, Basi-sphenoid.

In the **pre-sphenoid** a pair of lateral nuclei appear about the tenth week, just lateral to the optic foramina; from each of those the **orbito-sphenoids** (small wings) and their roots are ossified. About the same time another pair of centres, placed medial to the optic foramina, appear for the body of the pre-sphenoid. At first the superior surface of the body of the pre-sphenoid is exposed in the interval between the orbito-sphenoids, but by the ultimate coalescence of the medial borders of the orbito-sphenoids to form the **jugum sphenoidale**—*i.e.* the smooth surface in front of the optic groove—the body of the pre-sphenoid is almost completely covered over superiorly. By their coalescence in front, and their ultimate union with the basi-sphenoid behind, a cartilaginous interval is enclosed, of triangular shape, which, however, becomes gradually reduced in size by the ingrowth of its margins so as to form two medially placed foramina, as may be frequently observed in young bones—one opening on the surface of the tuberculum sellæ, the other being placed further forward (Lawrence, *Jour. Anat. and Phys.* vol. xxviii.).

The **medial pterygoid laminæ** are developed in membrane and are the first parts of the sphenoid to ossify. (Fawcett, *Anat. Anz.*, 1905.) Each is derived from a single nucleus which appears about the ninth or tenth week, and fuses with the inferior surface of the great wing, there forming a groove which is converted into the pterygoid canal when the ali-sphenoid and medial pterygoid laminæ fuse later with the body of the post-sphenoid. The hamulus, however, chondrifies before it ossifies during the third month.

At **birth** the sphenoid consists of **three parts**: one comprising the orbito-sphenoids together with the body of the pre-sphenoid and the basi-sphenoid, the others consisting of the ali-sphenoids, one on each side. Fusion of the latter with the former occurs near the end of the first year. The dorsum sellæ at birth consists of a cartilaginous plate which separates the body of the post-sphenoid from the basi-occipital. The plate slowly ossifies, but the cartilage does not entirely disappear till the age of twenty-five, by which time bony ankylosis of the basi-cranial axis is complete. For a considerable time the lower surface of the body of the pre-sphenoid displays a bullate appearance, with the sides of which the sphenoidal conchæ articulate. After the seventh or eighth year the spongy tissue within this part of the bone becomes absorbed to form the sphenoidal sinuses.

The **sphenoidal conchæ**, or bones of Bertin, best studied in children, are formed by the fusion of four distinct ossicles (Cleland), the centres for which appear during the later months of utero-gestation. Each bone is a hollow, three-sided pyramid, the apex of which is in contact with the anterior part of the vaginal process of the medial pterygoid lamina, whilst the base fits on to the posterior surface of the labyrinth of the ethmoid. The *inferior surface* of each forms part of the roof of the corresponding nasal cavity, and completes the formation of the spheno-palatine foramen, whilst the lateral aspect is united with the palatine bone and forms the medial

wall of the pterygo-palatine fossa, and occasionally constitutes a part of the orbital wall behind the ethmoid. The *superior surface* of each sphenoidal concha is applied to the anterior and inferior surface of the body of the pre-sphenoid on the corresponding side of the rostrum. It is by the absorption of that surface that the contained sphenoidal sinus is ultimately extended. In the bases of the pyramids are formed the apertures through which the sinuses open in to the nasal cavity in the adult. Up to the age of five those ossicles remain independent, but subsequently, owing to their firm ankylosis with the surrounding bones, they are represented in the adult disarticulated skull merely by the irregular fragments adherent to the separated borders of the ethmoid, palatine, and sphenoid bones.

Variations.—The foramen spinosum and the foramen ovale are sometimes incomplete posteriorly. Le Double records a case in which the foramen rotundum and the superior orbital fissure formed one cleft. The fissure, in rare cases, communicates with the optic foramen. The optic foramen has been found double, the nerve passing through one canal and the artery through the other. Ossification of fibrous bands leads to the formation of anomalous foramina, *e.g.* the *carotico-clinoid foramen*, between the anterior and middle clinoid processes; the *pterygo-spinous foramen*, enclosed by ossification of the band between the angular spine and the lateral pterygoid lamina; the *porus crotaphitico-buccinatorius*, enclosed by ossification of a ligament below and lateral to the foramen ovale. The sphenoidal sinus varies in extent, and is occasionally multilocular; sometimes it is absent.

Os Ethmoidale.

The **ethmoid bone** lies in front of the sphenoid, and occupies the interval between the orbital plates of the frontal bone; it enters into the formation of the anterior cranial fossa, the medial walls of both of the orbits and the roof and medial and lateral walls of the nasal cavities. The bone, which is extremely light, consists of two cellular parts called the **ethmoidal labyrinths**, united superiorly to a median **perpendicular plate** by two thin horizontal laminæ which, from their perforated condition, are called the **laminæ cribrosæ** or **cribriform plates.**

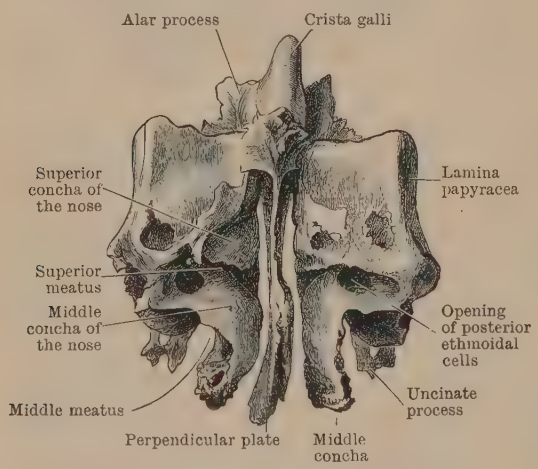

FIG. 172.—THE ETHMOID SEEN FROM BEHIND.

The study of the ethmoid bone will be much facilitated if the cribriform plate is cut through on one side of the perpendicular plate.

Lamina Perpendicularis.—The **perpendicular plate**, of irregular pentagonal shape, forms the superior part of the nasal septum. Its superior border projects above the level of the cribriform plates to form a crest, called the **crista galli.** The crest is thick and contains either spongy bone or an air cell. It is highest anteriorly, where its lower part divides into two **alar processes** which project forwards and articulate with the frontal bone, and enclose the **foramen cæcum.** The **posterior border** of the perpendicular plate is thin, and articulates with the crest of the sphenoid. The **posterior inferior border** in the adult is ankylosed with the vomer; and the **anterior inferior border**, which is usually thicker than the others, unites with the cartilaginous nasal septum. The **anterior superior border** articulates with the frontal spine and with the median crest formed by the union of the two nasal bones. The perpendicular plate, which is usually deflected to one or other side, has generally smooth *surfaces*, except above, where they are channelled by short and shallow grooves leading to the foramina in the cribriform plate.

Labyrinthus Ethmoidalis.—The **ethmoidal labyrinth** is composed of exceedingly thin bone, enclosing a large number of air cells; the cells are arranged in three groups—an anterior, a middle, and a posterior, the walls of which have been broken in front, above, behind, and below, in the process of disarticulation. *Laterally* they are closed in by a thin oblong lamina, called the **lamina papyracea**, which forms a part of the medial wall of the orbit. The lamina articulates *above* with the orbital part of the frontal bone; *in front* with the lacrimal bone; *below* with the orbital surface of the maxilla; *posteriorly* with the sphenoid; and, at its posterior inferior angle for a variable distance, with the orbital process of the palatine bone. The *medial aspect* of the ethmoidal labyrinth displays the convoluted **ethmoidal conchæ**, usually two in number, though occasionally there may be three—rarely more. In cases where there are two conchæ or **ethmo-turbinals**[1] they are separated posteriorly by a deep groove, called the **superior meatus**, which is roofed in by the **superior concha**, whilst its floor is formed by the superior surface of the **middle concha.** The posterior ethmoidal cells open into this meatus. In front of the superior meatus, which grooves only the posterior half of this aspect of the bone, the surface forms the medial wall of the anterior and middle ethmoidal cells. Running obliquely from above downwards and

[1] So called to distinguish them from the maxillo-turbinals and naso-turbinals of comparative anatomy.

backwards over the medial surface of the superior concha there is a number of fine grooves continuous above with the foramina in the cribriform plate; they are fewer and more scattered in front, do not pass on to the middle concha, and are for the lodgment of olfactory nerves.

The **middle concha** is nearly twice the length of the superior. It projects medially and then downwards from the labyrinth. Its anterior extremity articulates with the ethmoidal crest of the maxilla; its posterior extremity articulates with the ethmoidal crest of the palatine bone. The space that lies lateral to the concha is the upper part of the **middle meatus** of the nose. It receives the openings of the middle ethmoidal cells, which project into the meatus, forming a rounded elevation called the **ethmoidal bulla**. In front of and below the bulla there is a groove, called the **hiatus semilunaris**, which is continuous above with a canal, called the **infundibulum**, which runs upwards and forwards, and opens into the frontal sinus. A long process, called the **uncinate process**, curves downwards, backwards, and a little laterally from the roof of the anterior part of this meatus, in front of the hiatus. It bridges across the opening on the medial wall of the maxillary sinus, and articulates below with the ethmoidal process of the inferior concha.

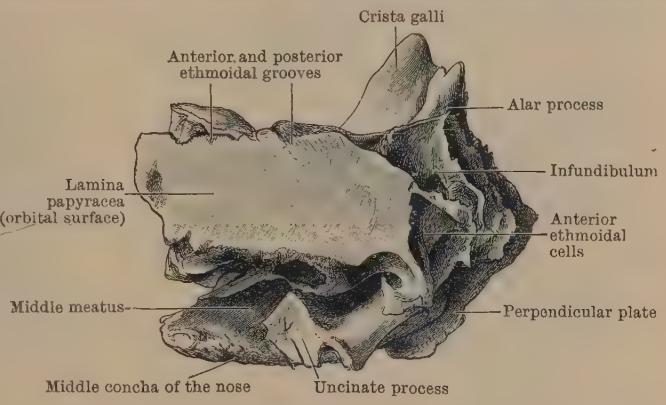

FIG. 173.—THE ETHMOID SEEN FROM THE RIGHT SIDE.

The *posterior aspect* of the labyrinth articulates with the front of the body of the sphenoid and the orbital process of the palatine bone, which close in the posterior ethmoidal cells. The *anterior aspect* is oblique and is covered by the lacrimal bone and the upper part of the frontal process of the maxilla, which close the anterior ethmoidal cells. The *upper surface* is covered by the orbital plate of the frontal bone, which completes the cells superiorly; and it is crossed by two grooves which are converted into the **anterior** and **posterior ethmoidal canals** when the orbital plate is in position.

Lamina Cribrosa.—Each **cribriform plate** is the horizontal lamina which connects the ethmoidal labyrinth with the perpendicular plate. It occupies the interval between the orbital plate of the frontal bone and the crista galli; it lies in the roof of the nose and in the floor of the anterior cranial fossa. There are numerous foramina in it for the transmission of olfactory nerves; and between its anterior part and the crista galli there is a narrow **nasal slit** which leads down to the nasal cavity. Posteriorly the lamina articulates with the sphenoid.

Ossification takes place in the cartilage of the nasal capsule. Each labyrinth has one centre, which appears about the fourth or fifth month in the neighbourhood of the lamina papyracea. According to Fawcett ossification first commences in a process which passes outside the naso-lacrimal duct to reach the frontal process of the maxilla. From that centre the laminæ around the ethmoidal air cells are formed, which are complete at birth, the air sinuses in this instance not being formed by the absorption of spongy bone. From that centre the conchæ also are developed, and they too are ossified at the ninth month.

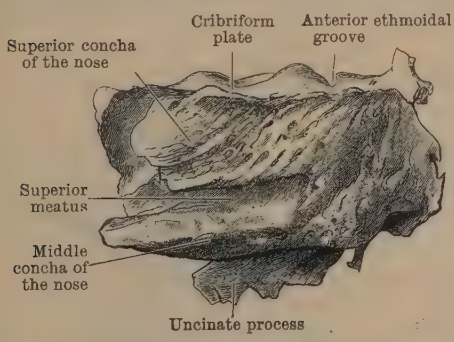

FIG. 174.—SECTION SHOWING THE NASAL ASPECT OF THE LEFT LABYRINTH OF THE ETHMOID.

At birth the ossified labyrinths are united to the cartilaginous septum by a fibrous layer. Two centres make their appearance in the septal cartilage on each side of the root of the crista galli about the end of the first year; from them the crista galli and the perpendicular plate are ossified, as well as the medial part of the cribriform plate, the lateral portions of which are ossified by a medial extension from the labyrinths.

Ossification is usually complete about the fifth or sixth year. About the twenty-fifth year bony union has taken place between the cribriform plate and the sphenoid, but ankylosis between the perpendicular plate and the vomer is not usual till the fortieth or forty-fifth year.

Variations.—The size of the lamina papyracea is liable to considerable variations. In the lower races it tends to be narrower from above downwards than in the higher, in this respect resembling the condition met with in the anthropoids. The lamina papyracea may fail to articulate with the lacrimal, owing to the union of the frontal with the orbital surface of the maxilla in front of it (Orbito-maxillary-frontal suture. A. Thomson, *Jour. Anat. and Physiol.* vol. xxiv. p. 349). Division of the lamina papyracea by a vertical suture into an anterior and

posterior part has been frequently recorded. The number of the conchæ may be increased from two to four, or may be reduced to one.

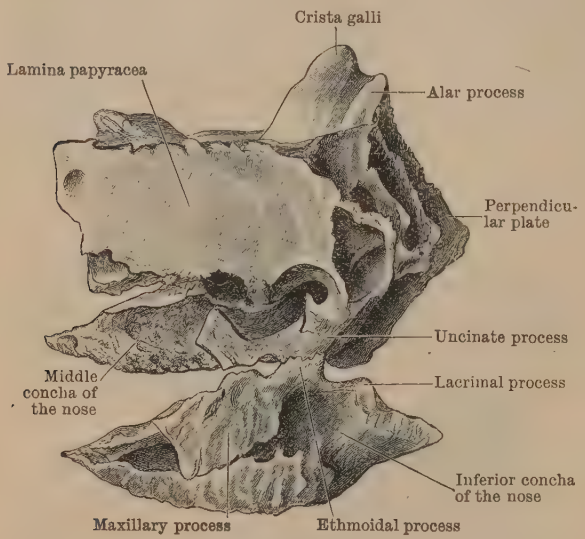

Fig. 175.—Showing the Articulation of the Inferior Concha with the Ethmoid.

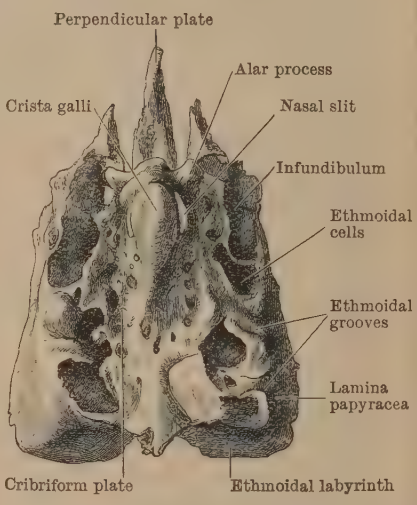

Fig. 176.—The Ethmoid seen from above.

Conchæ Nasales Inferiores.

Each **inferior concha** (O.T. **inferior turbinated bones**) is a shell-like lamina of bone lying along the lower part of the lateral wall of the nasal cavity. Of elongated form, the bone displays two curved borders bounding a medial and a lateral surface.

The **superior** or **attached border** is thin and sharp in front and behind, where it articulates with the conchal crests of the maxilla and the palatine bone, respectively. Between those two articulations the central part of the superior border rises in the form of a sharp crest; the anterior part of the crest forms the upstanding **lacrimal process**, which articulates above with the descending process of the lacrimal bone, as well as with the edges of the naso-lacrimal groove of the maxilla, thus completing the wall of the naso-lacrimal canal. The posterior end of the crest is elevated in the form of an irregular projection, called the **ethmoidal process**, which unites with the uncinate process of the ethmoid bone (see Fig. 175). Spreading downwards from the middle of the superior

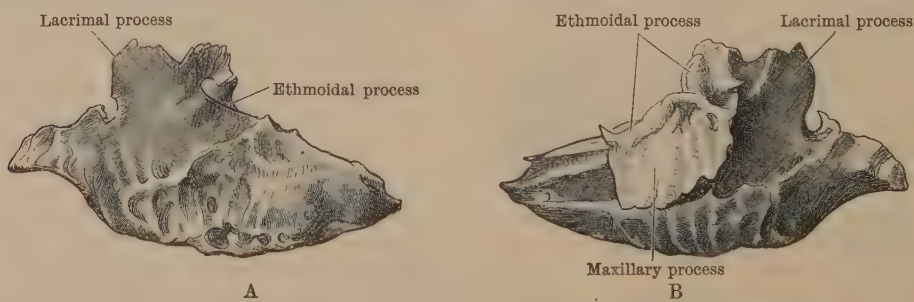

Fig. 177.—The Right Inferior Concha. A, Medial Surface; B, Lateral Surface.

border, on its lateral side, is a thin irregular plate of bone, called the **maxillary process**, which partially conceals the lateral, concave surface of the bone, and, by its union with the medial wall of the maxillary sinus, assists in the completion of the partition which separates that cavity from the inferior nasal meatus. The **inferior** or **free border**, gently curved from before backwards and turned slightly laterally, is rounded and full, and formed of bone which is deeply pitted and of a somewhat cellular character. The anterior and posterior extremities of the bone, formed by the convergence of the superior and inferior borders, are thin and sharp; as a rule the posterior end is the more pointed of the two.

The **medial surface** is uneven and convex and bulges into the nasal cavity; it is rough and pitted, and displays some scattered and longitudinally directed vascular grooves. The **lateral surface** is concave and forms the medial boundary of the inferior meatus of the nose. It is smooth in front, where it corresponds to the opening of the naso-lacrimal canal; posteriorly and towards its inferior border it is irregular and pitted. In the disarticulated bone this surface is in part

concealed by the downward projecting maxillary process. Hyrtl records a case in which the inferior conchæ were absent.

Ossification.—The inferior concha (the maxillo-turbinal of comparative anatomy) is derived from the cartilage forming the lateral wall of the nasal capsule. It ossifies, however, from a separate centre, which appears about the fifth month of fœtal life.

Ossa Lacrimalia.

The **lacrimal bone**, a thin scale of bone about the size of a finger-nail, forms part of the medial orbital wall behind the frontal process of the maxilla. Irregularly quadrangular, it has two surfaces—a medial and a lateral—and four borders.

Its **lateral** or **orbital surface** has a vertical ridge, called the **posterior lacrimal crest**, running downwards upon it. In front of this is the **lacrimal groove** for the lodgment of the lacrimal sac. The medial wall of this groove descends below the level of the main part of the bone, and forms the **descending process**, which helps to complete the naso-lacrimal canal, and articulates inferiorly with the inferior concha. The inferior end of the lacrimal crest terminates in a hook-like projection, called the **hamulus lacrimalis**, which curves round the posterior and lateral edge of the naso-lacrimal notch of the maxilla, and thus defines the upper aperture of the naso-lacrimal canal. The part of the bone behind the lacrimal crest is smooth and continuous with the surface of the lamina papyracea of the ethmoid. The **medial surface** is irregular and cellular above; it closes in some of the anterior ethmoidal cells and helps to complete the infundibulum. Where it is smoother it forms a part of the lateral wall of the middle meatus of the nose immediately behind the frontal process of the maxilla, and above the inferior concha. The **superior border** articulates with the medial angular process of the frontal bone; the **anterior edge** articulates with the posterior border of the frontal process of the maxilla, with which it completes the lacrimal groove for the lodgment of the lacrimal sac. The **inferior margin** articulates with the orbital surface of the maxilla, and in front, by its **descending process**, with the inferior concha. *Posteriorly* the bone articulates with the anterior border of the lamina papyracea of the ethmoid.

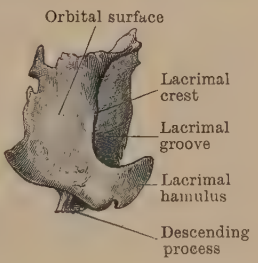

Fig. 178.—Right Lacrimal Bone (Orbital Surface).

Ossification.—The lacrimal is ossified from a single centre, which appears about the end of the second month of intra-uterine life in the membrane around the cartilaginous nasal capsule.

Variations.—The lacrimal bone is occasionally absent. In some cases it is divided into two parts; in others it is replaced by a number of smaller ossicles. In rare instances the hamulus may extend forwards to reach the orbital margin, and so bear a share in the formation of the face, as in lemurs (Gegenbauer). In other instances the hamulus is much reduced in size. Occasionally the lacrimal is separated from the lamina papyracea of the ethmoid by a down-growth from the frontal, which articulates with the orbital surface of the maxilla, as is the normal disposition in the gorilla and chimpanzee (Turner, *Challenger Reports*, "Zoology," vol. x. Part IV. Plate I.; and A. Thomson, *Jour. Anat. and Physiol.*, London, vol. xxiv. p. 349).

Vomer.

The **vomer** is placed in the posterior part of the nasal septum. It has four borders and two surfaces. The **superior border**, which can readily be distinguished by the presence on each side of an everted lip or **ala**, slopes from behind upwards and forwards, and articulates with the inferior surface of the body of the sphenoid, the rostrum of which is received into the groove between the alæ. The **alæ** are wedged in between the sphenoidal processes of the palate bones in front, and the vaginal processes of the medial pterygoid laminæ behind. The **posterior border**, which slopes from behind downwards and forwards, is a free, sharp, slightly curved edge, and forms the posterior margin of the nasal septum. The **inferior border**, more or less horizontal in direction, articulates with the nasal crest formed by the maxillæ and palatine bones. The **anterior edge** is the longest; it slopes obliquely from above downwards and forwards. In its upper half it is ankylosed to the perpendicular plate of the ethmoid; in its lower half it is grooved for

Fig. 179.—The Vomer as seen from the Right Side.

Fig. 180.

Vomer at Birth, displaying its formation by two Osseous Laminæ united inferiorly. The figure to the right exhibits the appearance of the bone, in vertical section, at the point marked ※ in the left figure.

the reception of the septal cartilage of the nose. The **anterior extremity** of the bone forms a truncated angle which articulates with the posterior border of the incisor crest of the maxillæ, and sends downwards a pointed process which passes between the incisor foramina. The *surfaces* of the bone are smooth; but a few vascular grooves may be noticed; and one groove, usually more distinct than the others, runs obliquely downwards and forwards, and lodges the naso-palatine nerve.

Ossification.—The vomer commences to ossify in membrane at the end of the second month. A nucleus appears on each side of the middle line, below the nasal septum, medial to the plane of the anterior paraseptal cartilages and posterior to them. During the third month the nuclei, which have increased in height and length, fuse at their lower edges, and by forward growth invade the posterior end of each anterior paraseptal cartilage, thus forming a deep groove in which the septal cartilage is lodged (Fawcett). As growth goes on, the groove becomes reduced by the further fusion of the lateral plates and the absorption of the cartilage, until the age of puberty, by which time the lateral laminæ have united to form a median plate, the primitively divided condition of which is now represented only by the eversion of the alæ and the grooving along the anterior border. According to Fawcett, the ossification of the Jacobsonian cartilage produces a hitherto undescribed element in the formation of the osseous nasal septum.

Structure and Variations.—The bone is composed of two compact layers fused below, but separated above by the groove for the lodgment of the rostrum of the sphenoid behind, and the septal cartilage in front. The lamellæ are also separated from each other by a canal which runs horizontally from behind forwards in the substance of the bone, and transmits the nutrient vessel of the bone.

Owing to imperfect ossification there may be a deficiency in the bone, filled up during life with cartilage. The separation of the two lamellæ along the anterior border varies considerably, and instances are recorded where they were separated by a considerable cavity within the substance of the bone. Instances of an extension forwards of the sphenoidal air sinus into and separating the laminæ of the bone have also been described. The *spheno-vomerine canal* is a minute opening behind the rostrum of the sphenoid, and between it and the alæ of the vomer, by which the nutrient artery enters the bone.

Ossa Nasalia.

The **nasal bones**, a right and a left, lie in the interval between the frontal processes of the maxillæ, and form the bridge of the nose. Each bone is of elongated quadrangular form, having two surfaces—an inner and an outer—and four borders. The **outer surface**, somewhat constricted about its middle, is convex from side to side, and slightly concavo-convex from above downwards. Near its centre there is usually the opening of a nutrient canal. The **inner surface** is concave, and is not so extensive as the outer, as the superior and anterior articular borders encroach upon it above. Running downwards along the surface there is a narrow groove (**sulcus ethmoidalis**) for the anterior ethmoidal nerve. The **anterior** or **medial border**, thin below, is thick above, and in conjunction with its fellow of the opposite side, with which it articulates, forms a median *nasal crest* posteriorly, which is united to the spine of the frontal, the perpendicular plate of the ethmoid, and the septal cartilage of the nose, in that order from above downwards. The **posterior** or **lateral border**, usually the longest, is serrated and bevelled to fit on to the anterior edge of the frontal process of the maxilla. The **superior border** forms a wide toothed surface, which articulates with the medial part of the nasal notch of the frontal bone anteriorly; whilst, posteriorly, it rests in contact with the root of the frontal spine. The **inferior border** is thin and sharp; it is connected with the lateral cartilage of the nose, and is usually deeply notched near its medial extremity.

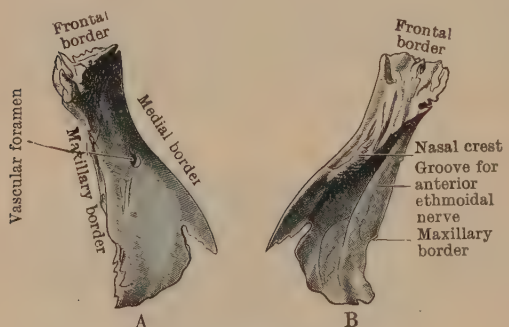

Fig. 181.—The Right Nasal Bone.
A, Lateral side; B, Medial side.

Ossification.—The nasal bones are each developed from a single centre, which appears about the end of the second month, in the membrane covering the cartilaginous nasal capsule.

Structure and Variations.—The nasal bone is made of dense compact tissue, and is strengthened by the formation of the nasal crest.

The size and configuration of the nasal bones vary greatly in different races, being, as a rule, large and prominent in the white races, and flat and reduced in size, as well as depressed, in the Mongolian and Negro stock. Complete absence of the nasal bones has been recorded, and their division into two or more parts has also been noted. Obliteration of the internasal suture is unusual; it is stated to occur more frequently in negroes, and is the recognised condition in adult apes. Duckworth has recorded a case (*Jour. Anat. and Physiol.* vol. xxxvi. p. 257) of undue extension downwards of the nasal bone, which may be perhaps accounted for on the supposition that the lower part is a persistent portion of the premaxilla.

Ossa Suturarum.

Along the line of the cranial sutures and in the region of the fontanelles, isolated bones of irregular form and variable size are occasionally met with. These are the once so-called Wormian bones, named after the Danish anatomist Wormius. They are now called **sutural bones.** They are developed either from distinct ossific nuclei, or, it may be, from division of the primary ossific deposits. Their occurrence may also be associated with certain pathological conditions which modify the development of the bone. They usually include the whole thickness of the cranial wall, but they may involve only the outer or the inner table. They are most frequent in the region of the lambda and the lambdoid suture. They occur commonly about the pterion, and in this situation are called *epipteric bones* (Flower). By their fusion with one or other of the adjacent bones they here lead to the occurrence of a fronto-squamosal suture. Their presence has been noted also along the line of the sagittal suture, and sometimes in metopic skulls in the inter-frontal suture. They are occasionally met with at the asterion and more rarely at the obelion. They appear less frequently in the face, but their presence has been noted around the lacrimal bone, and also at the extremity of the inferior orbital fissure, where they may form an independent nodule wedged in between the great wing of the sphenoid, the zygomatic bone, and the maxilla.

OSSA FACIEI.

Maxillæ.

The two **maxillæ** unite to form the upper jaw. Each consists of a **body** and four projections, named the **zygomatic, frontal, alveolar,** and **palatine processes.**

Corpus.—The **body** is of pyramidal form, and contains within it a cavity called the **maxillary sinus.** It has four surfaces—a facial or antero-lateral, an infra-temporal or posterior, an orbital or superior, and a nasal or medial.

The **antero-lateral surface** is confluent below with the alveolar process. Above, it is separated from the orbital aspect by the **infra-orbital margin,** whilst medially it is limited by the free margin of the **nasal notch,** which ends below in the pointed **anterior nasal spine.** Posteriorly it is separated from the infra-temporal surface by the **zygomatic process.** The facial aspect of the bone is ridged by the sockets of the teeth **(juga alveolaria).** The ridge corresponding to the root of the canine tooth is usually the most pronounced; medial to this, and overlying the roots of the incisor teeth, is the shallow **incisive fossa,** whilst placed laterally, on a higher level, is the deeper **canine fossa,** the floor of which is formed in part by the projecting zygomatic process. Above this, and near the infra-orbital margin, is the **infra-orbital foramen.**

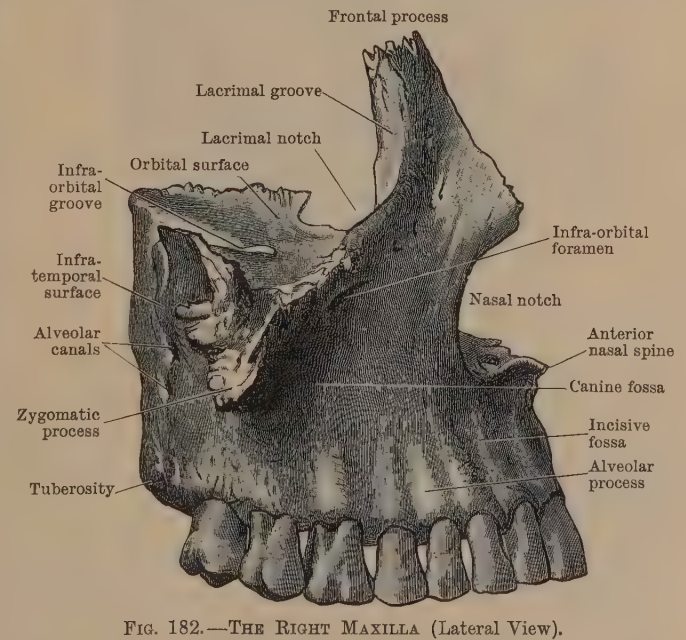

Fig. 182.—The Right Maxilla (Lateral View).

The **infra-temporal surface** is separated above from the orbital aspect by a rounded free edge, which forms the anterior margin of the **inferior orbital fissure** in the articulated skull. Anteriorly it is separated from the antero-lateral surface by the zygomatic process and its free lower border. Medially it is limited by a sharp, irregular margin with which the palatine bone articulates. The surface is more or less convex, and is directed towards the infra-temporal and pterygo-palatine fossæ. In its lower part there are the apertures of the **alveolar canals,** two or more in number, which transmit the nerves and vessels to the molar teeth. Its lower end is called the **maxillary tuberosity.**

The **orbital surface,** smooth and plain, is triangular in outline and forms part of the floor of the orbit. Its anterior edge corresponds to the infra-orbital margin; its posterior border coincides with the anterior boundary of the inferior orbital fissure. Its thin medial edge is notched in front to form the **lacrimal groove,** behind which it articulates with the lacrimal bone for a short

distance, then for a greater length with the lamina papyracea of the ethmoid, and terminates posteriorly in a surface for articulation with the orbital process of the palatine bone. Its lateral angle corresponds to the base of the zygomatic process. Traversing its substance is the **infra-orbital canal**, which ends anteriorly in the infra-orbital foramen; posteriorly, however, owing to deficiency of its roof, the canal forms a groove which begins at the margin of the inferior orbital fissure. If the canal is laid open, the orifices of the *middle* and *anterior alveolar canals* will be seen, which transmit the vessels and nerves to the premolar, canine, and incisor teeth.

The **nasal surface** is directed medially towards the nasal cavity. Below, it is confluent with the superior surface of the palatine process; anteriorly it is limited by the sharp edge of the nasal notch; above and anteriorly it is continuous with the medial surface of the frontal process; behind that it is deeply channelled by the **lacrimal groove**, which is converted into the naso-lacrimal canal by articulation with the lacrimal and inferior conchal bones. Behind the groove the upper edge of the nasal surface corresponds to the medial margin of the orbital surface, and articulates from before backwards with the lacrimal, lamina papyracea of the ethmoid, and the orbital process of the palatine bone. The posterior part of the surface, rough for articulation with the palatine bone, is traversed obliquely from above downwards, forwards and slightly medially by a groove, which, by articulation with the palatine bone, is converted into the **greater palatine canal** (canalis pterygo-palatinus). Towards its upper and posterior part the nasal surface displays the irregular, more or less triangular, opening of the **maxillary sinus**. The aperture, which, in the articulated skull, opens into the middle meatus of the nose, is much reduced in size by articulation with the lacrimal, ethmoid, palatine, and inferior conchal bones. In front of the lacrimal groove the nasal surface is ridged horizontally by the **conchal crest**, to which the inferior conchal bone is attached. Below that the bone forms the lateral wall of the inferior nasal meatus.

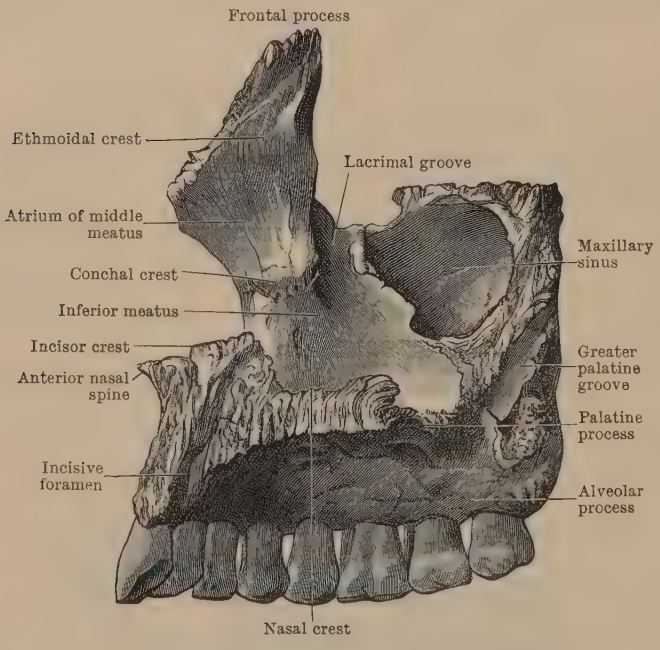

FIG. 183.—THE RIGHT MAXILLA (Medial Aspect).

Processus Zygomaticus.—The zygomatic process projects laterally from the region between the antero-lateral and infra-temporal surfaces, with which its surfaces are continuous; superiorly, it presents an oblique, rough surface which articulates with the zygomatic bone. Inferiorly, its anterior and posterior surfaces meet to form an arched border, which fuses with the alveolar process opposite the root of the first molar tooth.

Processus Frontalis.—The **frontal process** arises from the upper and anterior part of the body. It has two surfaces—a lateral, and a medial. The *lateral surface* is divided into two by a vertical ridge, called the **anterior lacrimal crest**, which is the upward extension of the infra-orbital margin. The narrow strip of bone behind this ridge is hollowed out, and leads into the lacrimal groove below, and by articulation posteriorly with the lacrimal, edge to edge, it completes the **fossa for the lacrimal sac.** In front of the vertical crest the lateral surface is confluent below with the facial surface of the body; one or two vascular foramina may be seen on it. Its anterior edge is rough, or grooved, for articulation with the nasal bone. Superiorly the summit of the process is serrated for articulation with the nasal notch of the frontal bone. The *medial surface* of the frontal process is directed towards the nasal cavity. It is crossed obliquely from below upwards and backwards by a ridge—the **agger nasi** or **ethmoidal crest**—which is considered to be a vestige of the naso-turbinal met with in some mammals. Below the ridge the bone is smooth and forms the side wall of the atrium of the middle meatus, whilst the ridge itself articulates posteriorly with the anterior part of the middle concha.

Processus Alveolaris.—The **alveolar process** projects downwards from the inferior part of the body. Together with its fellow of the opposite side it forms the alveolar arch, in which the roots of the teeth are imbedded in sockets or alveoli; ordinarily in the adult, when dentition is complete, each alveolar process supports eight teeth. Two small vascular foramina are usually visible on the lingual surface behind the incisor teeth. When any or all of the teeth are shed the alveoli become absorbed, and the process may under these circumstances be reduced to the level of the plane of the palatine process. Posteriorly the alveolar process ends in the **maxillary tuberosity**; anteriorly it shares in the formation of the **intermaxillary suture.**

Processus Palatinus.—The **palatine process** lies in the horizontal plane; it has two surfaces —superior and inferior—and three borders, a straight *medial*, a more or less straight *posterior*, and a curved *lateral*, by which it is attached to the medial side of the body and alveolar process as far back as the interval between the second and third molar teeth. Its *inferior surface*, together with that of its fellow, forms the anterior two-thirds of the hard palate; it is rough and pitted for the palatine glands, and is grooved, near the alveolar margin, by one or two channels which pass forward from the **greater palatine foramen**. Its *superior surface*, smooth and concave from side to side, lies in the floor of the nasal cavity. Its *medial border*, broad and serrated, rises in a ridge superiorly, so as to form, with its fellow of the opposite side, the **nasal crest**, which is grooved to receive the inferior border of the vomer. In front of its articulation with the vomer the ridge rises higher, for articulation with the septal cartilage, and is named the **incisor crest**; its anterior end projects beyond the free border of the nasal notch, and, together with its fellow, forms the projection called the **anterior nasal spine**. At the side of the incisor crest there is the opening of a canal, called the **incisive canal**, which leads downwards, forwards, and a little medially, to open into a broad groove on the medial border of the bone immediately behind the central incisor tooth. When the two maxillæ are articulated, the two grooves form the oval **foramen incisivum**, into which the canal of each side opens, their openings being called the **foramina of Stensen**. The canal represents the channel by which in lower animals the organ of Jacobson opens into the mouth. The *posterior border* of the palatine process, which is sharp and thin, falls in line with the interval between the second and third molar, and articulates with the horizontal part of the palate bone.

Ossification.—The maxillæ (proper) are developed in the connective tissue around the oral aperture of the embryo. Ossification commences from one centre, at the end of the sixth week, in membrane above the canine tooth germ. From that centre ossification extends rapidly upwards on the lateral side of the nasal capsule to form the posterior part of the frontal process, backwards to form the zygomatic process, downwards to form the lateral wall of the alveolar process, and medially to form the palatine process; from the palatine process it extends downwards to form the medial wall of the alveolar process. At first a large gap intervenes between the greater part of the palatine process and the zygomatic process, but bridges of bone ultimately connect the two, separating the various tooth germs, and so forming the tooth sockets. About the fourth month the maxilla invades a small lateral cartilaginous process of the nasal capsule (Mihalkovics), and incorporates it within itself. The infra-orbital nerve is at first placed considerably above the orbital surface of the maxilla, and comes in contact with it only in the second month, when a groove is formed on the bone, which is converted into the infra-orbital canal and foramen to enclose the nerve by the uprising and folding medialwards of its lateral boundary. In the early stages of the development of the bone the alveolar groove, in which the teeth are developed, lies close below the infra-orbital groove; later, they are separated by the maxillary sinus, which first makes its appearance as a shallow fossa to the medial side of the orbito-nasal element about the fourth month.

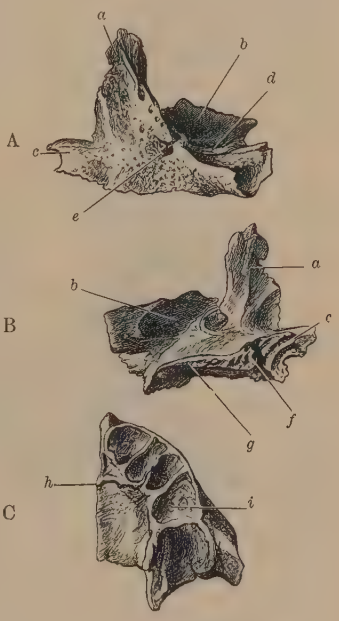

FIG. 184.—MAXILLA AT BIRTH.

A, Lateral side; B, Medial side; C, Under side. *a*, Frontal process; *b*, Orbital plate; *c*, Anterior nasal spine; *d*, Infra-orbital groove; *e*, Infra-orbital foramen; *f*, Anterior palatine groove; *g*, Palatine process; *h*, Premaxillary suture; *i*, Alveolar process.

The **premaxillæ**, which in most vertebrates are independent bones lying in front of the maxillæ, constitute in Man and Apes the portions of the maxillæ which lie in front of the incisive foramen, and carry the incisor teeth. Each premaxilla is ossified from two centres: a **facial**, for the part which ultimately contains the incisor teeth and forms the anterior part of the hard palate, as well as the anterior half of the frontal process of the complete maxilla (Fawcett); and a **palatine centre** (*infra-vomerine* of Rambaud and Renault) which forms the medial wall of the corresponding incisive canal. The facial centre appears early, either before or after that for the maxilla (Mall), and fuses almost at once with the maxilla along the alveolar margin; the palatine centre appears about the twelfth week, and soon fuses with the facial centre. The line of fusion of the premaxillæ with the maxillæ proper can be readily seen in young skulls, and occasionally also in the adult. It corresponds to a suture which passes obliquely laterally and forwards, from the incisive foramen to the interval between the lateral incisor and the canine tooth. In cases of alveolar cleft palate the bones fail to unite along the line of that suture. In some instances, however, the cleft passes between the central and lateral incisor teeth, and this condition suggests that the premaxillary element is derived from two centres—a lateral and a medial. The researches of Albrecht and Warinski support that view. Warinski further observes that the cleavage may lead to a division of the dental germ of the lateral incisor tooth, and so explain the occurrence of the supernumerary incisor which is occasionally met with. In this way the different varieties of cleft palate are readily explained. Median cleft palate

is due to failure of union between the two premaxillary bones. Lateral cleft palate may be of two types: the cleft in one case passing forwards between the central and lateral incisor, and being due to the non-union of the two elements from which the premaxilla is primarily developed; the other, in which the cleft passes between the lateral incisor and the canine, or between the lateral incisor and a supernumerary incisor, owing to the imperfect fusion of the premaxilla with the maxilla.

Variations.—Not infrequently there is a vertical suture in the bar of bone which separates the infra-orbital foramen from the infra-orbital margin. Through imperfections in ossification, the infra-orbital canal may be an open groove. Duckworth records four instances of a spinous process projecting into the apertura piriformis from the lower part of the nasal notch. A case has been described (Fischel) in which there was absence of the premaxillæ, together with the incisor teeth. A not uncommon anomaly is the occurrence of a rounded, elongated ridge extending along the interpalatal or intermaxillary sutures on the lower surface of the hard palate. It is called the *torus palatinus*, and is of interest because it has been regarded as pathological. The sulcus lacrimalis may be constricted towards its centre. A part of the maxillary sinus may be constricted off anteriorly and, owing to its relation to the naso-lacrimal canal, is called the *recessus lacrimalis*. Underwood (*Jour. Anat. and Physiol.* vol. xliv.) records the occurrence of almost complete septa in the maxillary sinus.

Ossa Palatina.

The **palatine bone**, of irregular shape, assists in the formation of the lateral wall of the posterior part of the nasal cavity, the posterior portion of the hard palate, the orbit, the pterygo-palatine, the infra-temporal, and the pterygoid fossæ. It consists of a **horizontal** and a **perpendicular part**, united to each other like the limbs of the letter L. At their point of union posteriorly there is an irregular projection called the **pyramidal process**; capping the summit

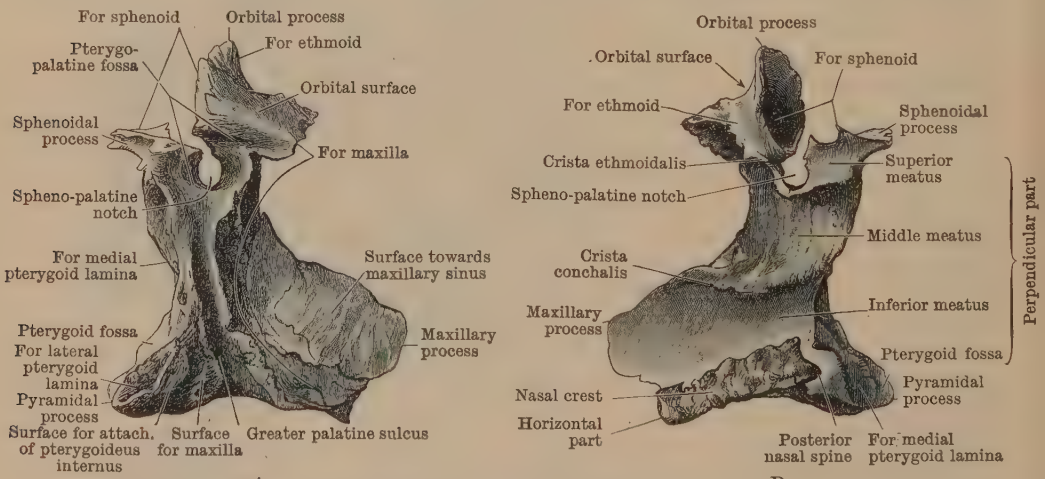

FIG. 185.—RIGHT PALATE BONE.

A, As seen from the Lateral Side; B, As viewed from the Medial Side.

of the perpendicular part there are two irregular projections, called the **sphenoidal** and **orbital processes**, which are separated by an interval called the **spheno-palatine notch.**

Pars Horizontalis.—The **horizontal part** forms the posterior third of the hard palate, and has two surfaces and four borders. Its *superior surface*, which is smooth, is slightly concave from side to side, and forms the floor of the posterior part of the nasal cavity. Its *inferior surface*, rougher, is directed towards the mouth, and, near its posterior edge, often displays a transverse ridge or crest. The *anterior border* is rough, and articulates with the posterior edge of the palatine process of the maxilla. The *posterior margin* is free and is concave from side to side. The *medial border* is upturned, and when it articulates with its fellow of the opposite side it forms superiorly a median crest, continuous in front with the nasal crest of the maxilla; the crest supports the posterior part of the inferior border of the vomer, and, projecting beyond the line of the posterior border, it forms the **posterior nasal spine.** The *lateral border* fuses with the perpendicular part, forming with it a right angle. The posterior extremity of this edge is grooved by the **greater palatine foramen.**

Pars Perpendicularis.—The **perpendicular part** is composed of thin bone, especially at its upper part, and it is very much broader below than above; it also has two surfaces and four borders. Its *medial surface* is crossed horizontally, about its middle, by the **conchal crest,** with which the posterior end of the inferior concha articulates; above and below the crest, the surface forms part of the lateral wall of the middle and inferior meatuses of the nose, respectively. Near

the upper end of the surface there is another horizontal ridge, called the **ethmoidal crest**, with which the posterior extremity of the middle concha articulates. The *lateral surface*, which forms the medial wall of the pterygo-palatine fossa, is channelled by an oblique groove which is converted into the **greater palatine canal** (canalis pterygo-palatinus) by articulation with the maxilla; the canal ends inferiorly as the **greater palatine foramen**. The perpendicular part projects forwards to a variable extent, forming a **maxillary process** which helps to close in the maxillary sinus. The *anterior border* is a thin edge, of irregular outline, which articulates above with the ethmoid, with the posterior edge of the maxillary process of the inferior conchal bone about its middle, and below with the maxilla. The *posterior border*, thin above, where it articulates with the anterior part of the medial pterygoid lamina, expands below into the **pyramidal process**. The *inferior border* is confluent with the lateral edge of the horizontal part; posteriorly, and immediately in front of the tuberosity, it is notched by the lower extremity of the greater palatine canal. The *superior border* supports the **orbital** and **sphenoidal processes**, the notch between which is converted into the **spheno-palatine foramen** by the articulation of the palatine bone with the inferior surface of the sphenoid.

Processus Pyramidalis.—The **pyramidal process** is directed backwards and laterally from the junction between the perpendicular and horizontal parts, and presents, on its *posterior surface*, a central smooth vertical groove, bounded on each side by rough articular furrows which unite above in a ∧-shaped manner. The furrows articulate with the anterior parts of the lower portions of the medial and lateral pterygoid laminæ, while the central groove fits into the wedge-like pterygoid fissure, thus entering into the formation of the pterygoid fossa. The *lateral surface* of the pyramidal process is rough above, and is confluent with the lateral surface of the perpendicular part where it articulates with the tuberosity of the maxilla; below, there is a small, smooth, triangular area which appears between the tuberosity of the maxilla and the lateral surface of the lateral pterygoid lamina, and so enters into the medial wall of the infra-temporal fossa. Passing through the pyramidal process in a vertical direction are the **lesser palatine canals**, which open on the inferior aspect of the process as the **lesser palatine foramina**.

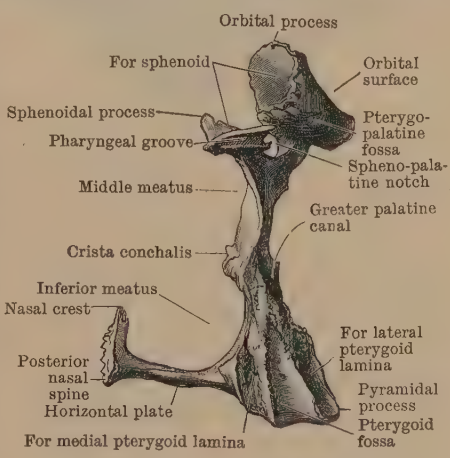

FIG. 186.—THE RIGHT PALATE BONE.
As seen from behind.

Processus Orbitalis.—The **orbital process**, shaped like a hollow cube, surmounts the anterior part of the perpendicular plate. The open mouth of the cube is usually directed backwards and medially towards the anterior part of the body of the sphenoid, with the cavity of which it commonly communicates; the anterior part of the cube articulates with the medial end of the angle formed by the orbital and infra-temporal surfaces of the maxilla. Of the remaining four surfaces, one, directed forwards and medially, articulates with the ethmoid. The others are non-articular: the *superior* forms the posterior part of the floor of the orbit; the *lateral* is directed towards the pterygo-palatine fossa; whilst the *inferior*, which is confluent with the medial surface of the vertical part, is of variable extent, and overhangs the superior meatus of the nose.

Processus Sphenoidalis.—The **sphenoidal process**, much smaller than the orbital, curves upwards, medially, and backwards from the posterior part of the summit of the perpendicular part. Its *superior surface*, which is grooved, articulates with the anterior part of the inferior surface of the body of the sphenoid and the root of the medial pterygoid lamina, thereby converting the groove into the **pharyngeal canal**. Its *lateral surface* forms part of the medial wall of the pterygo-palatine fossa. Its *medial surface* is directed towards the nasal cavity; its medial edge is in contact with the ala of the vomer.

Ossification.—The palatine bone ossifies from one centre which appears during the eighth week in the membrane in the side wall of the nasal cavity. Ossification spreads medially to form the palatine process, upwards to form the sphenoidal and orbital processes, and downwards and backwards to form the pyramidal process. The orbital process may be ossified from an independent centre. Until the third year the antero-posterior width is greater than the vertical height, which increases as the maxillary sinus enlarges.

Structure and Variations.—The greater part of the palatine bone is composed of two thin plates of compact substance, which may be separated, in the horizontal part, by an extension of the maxillary sinus. The lower part of the greater palatine canal may be completely bounded by the palatine bone. The orbital process varies greatly in size, and is not always pneumatic; occasionally it unites with the sphenoidal process and converts the spheno-palatine notch into a foramen, which may be divided into two by a bridge of bone.

Ossa Zygomatica.

The **zygomatic bone** (O.T. **malar**) lies in the most prominent part of the cheek, and is hence often called the *cheek-bone*. Placed below and lateral to the orbit, it forms the sharp lateral

border of that cavity, and serves to separate it from the temporal fossa and upper part of the infra-temporal fossa; below, it rests upon and is united to the maxilla; behind, it enters into the formation of the zygomatic arch. The zygomatic bone is described as having three *surfaces*, named the *malar*, the *orbital*, and the *temporal*, two processes, named the *fronto-sphenoidal* and the *temporal*, and two subordinate processes, named the *marginal* and the *orbital*.

The **malar surface** is the largest surface; it is slightly convex and rather uneven; its most elevated part is called the **malar tuberosity**, above which there is a small aperture called the **zygomatico-facial foramen**, which is often double. The lower margin of the surface is free and rough, and is continuous with the lower edge of the zygomatic process of the maxilla. The

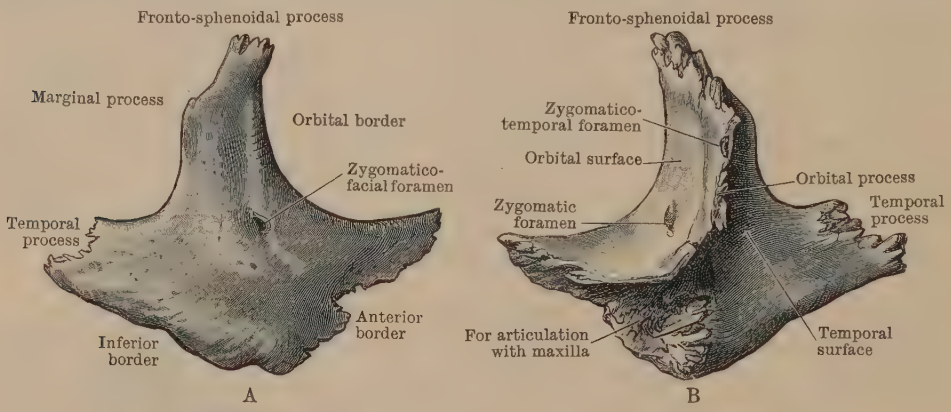

FIG. 187.—THE RIGHT ZYGOMATIC BONE. A, Lateral Side; B, Medial Side.

upper margin is smooth and forms a great part of the infra-orbital margin. The anterior margin is oblique and is united to the zygomatic process of the maxilla. The posterior margin is continuous with the two processes. The **temporal process** projects backwards and articulates by an oblique serrated extremity with the zygomatic process of the temporal bone. The **fronto-sphenoidal process** is a large process which projects upwards; its medial margin is smooth and forms the greater part of the lateral margin of the orbit; its lateral or posterior margin meets the upper border of the temporal process almost at a right angle. About half-way up that margin there is usually a prominence called the **marginal process.** The upper end of the fronto-sphenoidal process articulates with the zygomatic process of the frontal bone; and from its deep aspect a wide, thin, sharp crest projects backwards in the lateral wall of the orbit, between the orbit and the temporal fossa, and articulates by its sharp posterior edge with the great wing of the sphenoid. That crest is continuous inferiorly with a small shelf of bone which projects backwards from the infra-orbital margin, and the two together form a thin, curved lamina which is often called the **orbital process.** The posterior margin of the orbital process is sharp, rough, and uneven; its upper part articulates with the great wing of the sphenoid, as stated above; its lower part articulates with the maxilla; between those two articulations the margin may have a small, smooth notch that forms the anterior end of the inferior orbital fissure.

The **orbital surface** is the smooth, concave area between the posterior edge of the orbital process and the orbital margin, and it lies in the anterior part of the lateral wall and the floor of the orbit; at a varying point on the surface there is an aperture, called the **zygomatic foramen**, which may be double.

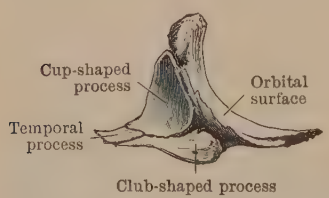

FIG. 188.—MEDIAL SURFACE OF THE ZYGOMATIC BONE AT BIRTH.

The **temporal surface** is a large concave surface which looks towards the temporal and infra-temporal fossæ, and includes the deep aspects of the temporal and fronto-sphenoidal processes. On that part which is formed by the fronto-sphenoidal process there is a small hole called the **zygomatico-temporal foramen.**

Besides those named surfaces there is a wide, rough, triangular area which articulates with the zygomatic process of the maxilla.

Ossification.—The zygomatic bone ossifies in membrane from one centre which appears between the eighth (Mall) and the tenth (Toldt) week. At birth there are narrow grooves or fissures on the temporal surface, produced by the overlapping edges of a cup-shaped and a club-shaped thickening of the bone; in some cases those grooves persist in the adult. Some authorities hold that there are more than one centre of ossification (Rambaud and Renault, Le Double), and that view is supported by the fact that the bone is sometimes divided in the adult.

Structure and Variations.—In structure the zygomatic bone is compact, with little spongy tissue. Together with the zygomatic process of the temporal bone it forms the buttress which supports the maxilla and the lateral wall of the orbit. Additional strength is imparted to the bone by the angular mode of union of its orbital and facial parts.

Cases of division of the zygomatic bone by a horizontal or a vertical suture have been recorded. Owing to the supposed more frequent occurrence of that divided condition in Asiatics the bone

has been named the *os Japonicum*. Barclay Smith (*Jour. Anat. and Physiol.*, 1898) describes a case in which the zygomatic bone was divided into an upper and a lower part by a backward extension of the maxilla, which articulated with the zygomatic process of the temporal, thus forming a temporo-maxillary arch. Varieties of a like kind have been described also by Gruber and others. Cases have been noted where, owing to deficiency in the zygomatic bone, the zygomatic arch has been incomplete.

The **mandible** and the **hyoid bone** are described on pp. 177, 182.

BONES OF THE UPPER LIMB.

The **upper limb** or **superior extremity** includes the shoulder, the upper arm, the forearm, and the hand (see Fig. 109, p. 92).

The **shoulder** is not a sharply defined region; it includes not only the familiar prominence at the proximal end of the arm, but also (1) the *scapular region*, that is the parts around the shoulder-blade; (2) the *pectoral region*, that is the parts overlying the upper part of the front of the chest; and (3) the *axilla* or armpit. The bones of the shoulder are the **scapula** or shoulder-blade and the **clavicle** or collar-bone. Those two bones constitute what is called the *shoulder girdle*; they articulate with one another, forming a joint called the *acromio-clavicular joint*. The clavicle articulates with the upper end of the sternum or breastbone, forming with it the *sterno-clavicular joint*; the scapula does not articulate with any part of the axial skeleton, being connected with it only by muscles.

The **upper arm** (brachium) is referred to in anatomical descriptions as the **arm**. The bone of the arm is called the **humerus**. The humerus articulates with the scapula to form the *shoulder joint*.

The **forearm** (anti-brachium) is continuous with the arm at the *elbow* (cubitus); there the humerus articulates with the two bones of the forearm to form the *elbow joint*. The bones of the forearm are called the **radius** and the **ulna**; they articulate with one another at their proximal and distal ends, forming *rădio-ulnar joints*.

The **hand** (manus) consists of three parts: (1) the wrist; (2) the hand proper, one surface of which is the palm, and the other surface is the "back of the hand"; (3) the five digits.

The bones of the **wrist** (carpus) are eight small bones, named collectively the **carpal bones**, and each has its own name besides. They are arranged in two rows —a proximal and a distal—four bones in each row. Three of the bones of the proximal row articulate with the radius and with a structure called the *triangular articular disc* to form the *radio-carpal* or *wrist joint*, where the hand joins the forearm. Each carpal bone articulates with the adjoining carpal bones, forming *inter-carpal joints*.

The bones of the **hand proper** (metacarpus) are called **metacarpal bones**. They are five in number, one corresponding to each digit. They are named, **first** metacarpal, **second** metacarpal, etc., beginning with the one which corresponds to the thumb. The metacarpal bones articulate with the distal row of carpal bones, forming *carpo-metacarpal joints*; and they articulate with one another at their proximal ends, forming *inter-metacarpal joints*; their distal ends are the rounded prominences known as the first row of *knuckles*.

Each of the **digits** is named: the thumb or *pollex*; the forefinger or *index*; the middle finger or *digitus medius*; the ring finger or *digitus annularis*; the little finger or *digitus minimus* vel *quintus*. The bones of the digits are called **phalanges**. The thumb has two phalanges, named the **first** or proximal phalanx and the **second** or distal phalanx. Each finger has three phalanges: **first**, **second**, and **third**, or proximal, middle, and distal. The distal phalanx is sometimes called the *ungual phalanx*, because the *nail* (unguis) is associated with it. The first phalanx of each digit articulates with the distal end of the corresponding metacarpal bone to form a *metacarpo-phalangeal joint*. The ends of the second phalanx articulate with the first and the third phalanx, forming *inter-phalangeal joints*.

Scapula.

The **scapula** is a thin, wide, triangular bone [σκαπάνη (scapanē) = a digging tool] which lies obliquely in the upper part of the back and in the posterior wall of the axilla, opposite the second to the seventh ribs. It is classed as a "flat" bone and possesses a main part or **body** and three processes,[1] named the **spine**,

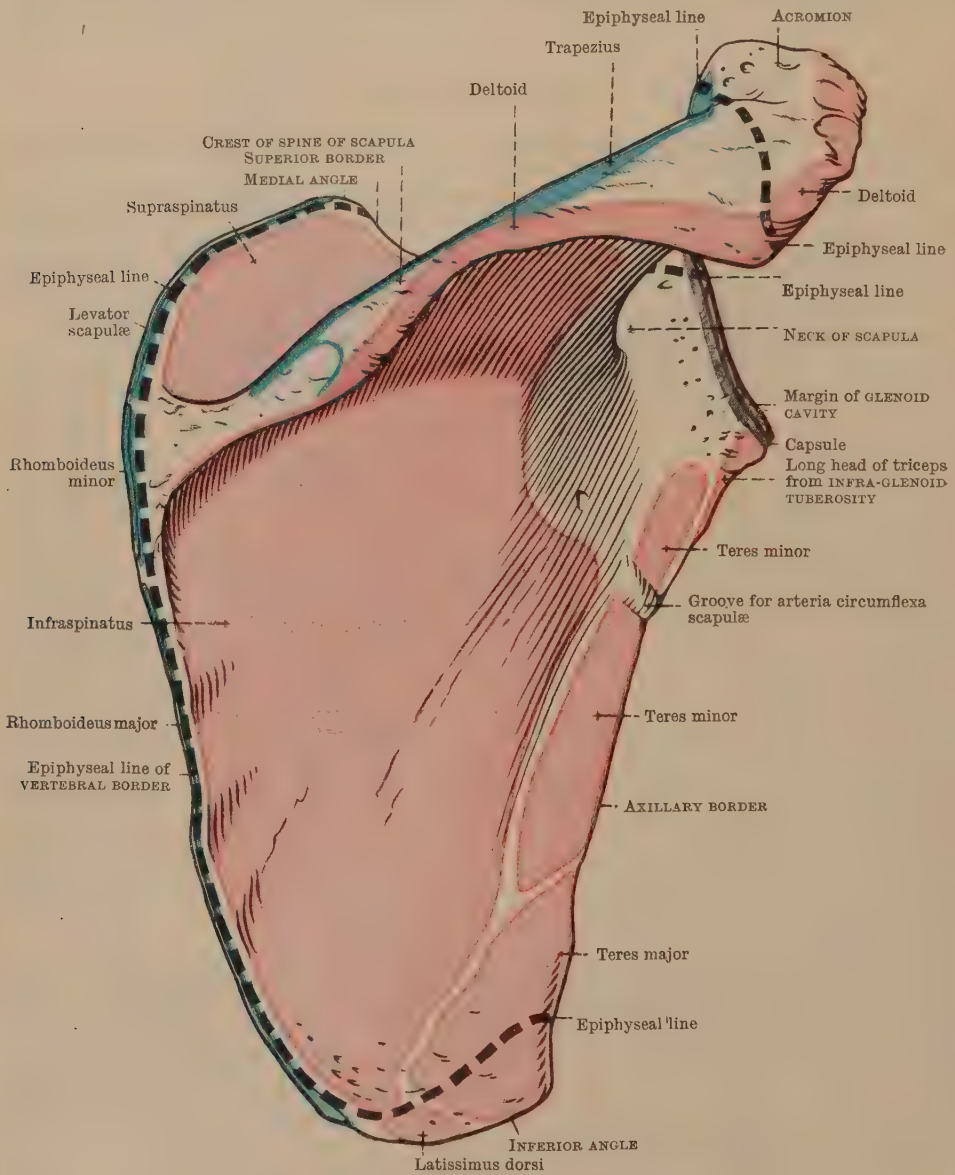

Fig. 189.—Dorsal Surface of Right Scapula.

the **acromion**, and the **coracoid process**. At one of its angles the body is greatly thickened and is coated with articular cartilage. The thickened angle is called the **head**, and the part contiguous to the head is called the **neck**. The spine is the large triangular plate attached to the posterior surface of the body; the acromion is the flattened piece of bone which is continuous with the spine at the angle between its two unattached borders; and the coracoid process is the thick, bent piece of bone that projects from the upper part of the head and neck.

[1] Definitions of terms are given on pp. 4 and 87.

The **body** is the blade proper; it is thin and even translucent in places, and is triangular in outline, possessing two surfaces, three borders, and three angles.

The **borders** of the scapula are named *superior*, *vertebral*, and *axillary*.

The **superior border** is the shortest of the three. At its lateral end, close to the root of the coracoid process, there is a notch called the *scapular notch*; it may be wide and shallow, or narrow and deep; it is bridged across by a fibrous band called the *superior transverse ligament*; in some scapulæ the ligament is ossified, so that the notch is converted into a foramen.

The **vertebral border** is the longest of the three, and looks medially and backwards towards the spines of the vertebræ—hence its name. When the shoulder is at rest the border lies two or three finger-breadths from those spines and can be both felt and seen in a thin person. It is divided into three parts: a small part opposite the spine of the scapula, a part above that and a part below, the lowest part being by far the longest.

The **axillary border** looks in a lateral direction and forwards, and lies in the posterior wall of the axilla, where it may be indistinctly felt. It is thick and rough, and extends downwards from the head. Its thickest and roughest part is immediately below the head and is called the *infra-glenoid tuberosity*.

The **angles** of the scapula are named *medial*, *inferior*, and *lateral*.

The **medial angle** is that between the superior border and the vertebral border; it is so thickly covered with muscles that it can scarcely be felt.

The **inferior angle** is that between the vertebral and axillary borders, and is the lowest part of the scapula. It is covered thinly with muscle and is easily felt; it is used as a landmark to locate spines of vertebræ, for, when the arm is hanging at rest, it is on a level with the spine of the *seventh* thoracic vertebra.

The **lateral angle** is that between the axillary and superior borders. It is only nominally an angle, for it is truncated and thickened to form the **head**. The lateral surface of the head is called the **glenoid cavity**; it is concave, smooth, articular, and pear-shaped in outline; it is directed forwards as well as laterally, and it articulates with the head of the humerus to form the shoulder joint [γλήνη (glēnē) = a socket]. The small rough area at the upper end or margin of the glenoid cavity is called the *supra-glenoid tuberosity*.

The **surfaces** of the scapula are named *costal* and *dorsal*.

The **costal surface** looks towards the ribs and is concave; the concavity is often referred to as the **subscapular fossa**, and is deepest opposite the spine. At the medial and lower angles there are usually flat triangular areas marked off by ridges from the rest of the surface, and those two areas are connected by a very narrow raised strip that lies alongside the vertebral border. The areas and the strip are for the insertion of a large muscle called the *serratus anterior*. Nearly all the rest of the costal surface, including the strong smooth ridge which runs downwards from the neck and the groove between that ridge and the axillary margin, gives origin to a muscle called the *subscapularis*. The low ridges that run from the vertebral margin towards the neck give attachment to tendinous fibres in the substance of the subscapularis.

The **dorsal surface** or posterior surface is divided into two unequal parts by the spine; the two parts are not in the same plane, for the scapula is bent at the attachment of the spine. The smaller, supraspinous part and the upper surface of the spine form the boundaries of a space called the **supraspinous fossa**. On the larger, infraspinous part there is a raised oval area, alongside the lower part of the axillary margin, from which a muscle called the *teres major* arises. Above that area there is a raised narrow strip which reaches up to the head of the bone; the *teres minor* muscle arises from the strip, and crossing it there is a narrow, shallow groove produced by an artery called the circumflex scapular artery; occasionally there are two grooves corresponding to branches of the artery. The remainder of the lower part of the dorsal surface forms one wall of a space called the **infraspinous fossa**, while the lower surface of the spine forms the other wall.

The **spine of the scapula** is a triangular plate of bone attached by one of its borders to the dorsum of the scapula. Another border of the spine looks in a lateral direction towards the shoulder joint; it is smooth and rounded, and the

wide notch between it and the neck of the scapula is called the **great scapular notch**. A weak fibrous band called the *inferior transverse ligament* bridges across the notch. The third border is called the **crest of the spine**. It is subcutaneous, and can be felt easily in all its length in the living person; it has fairly sharp *upper* and *lower lips* or edges; the prominence or enlargement on the lower lip near the vertebral border is called the **tubercle of the crest**. At the vertebral

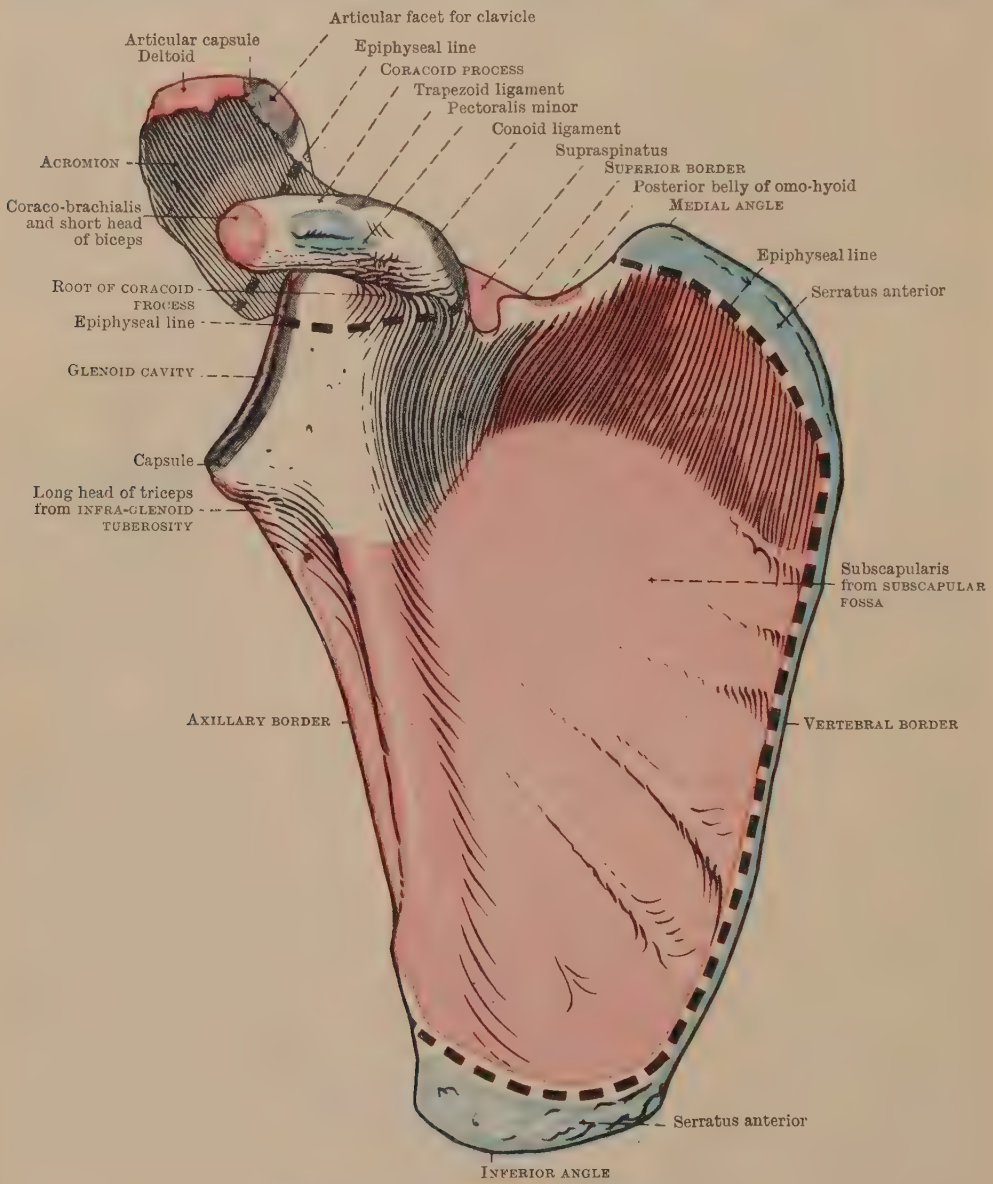

FIG. 190.—COSTAL SURFACE OF RIGHT SCAPULA.

margin the lips of the crest spread apart to enclose a small smooth triangular area which one can easily feel in the living person by pressing the finger along the crest; it is on a level with the spine of the *third* thoracic vertebra, and is used as a landmark for locating the spines of the vertebræ.

The **acromion** is broad and flattened; it is continuous with the spine at the angle where the crest and the lateral border of the spine meet; it extends in a lateral direction and forwards, and overhangs the shoulder joint above and behind. It lies at the top of the shoulder and is easily felt there, its upper surface being

subcutaneous and continuous with the crest of the spine [ἄκρον (acron) = highest point; ὦμος (ōmos) = shoulder (with upper arm)]. Its lateral border is long and is sharply bent to become continuous with the lower lip of the crest. The bend is called the **angle of the acromion**; it is easily located in the living person, and is used as a point from which measurements may be taken and as a guide to the back of the shoulder joint, which lies directly below and in front of it. The medial border of the acromion is short and is continuous with the upper lip of the crest;

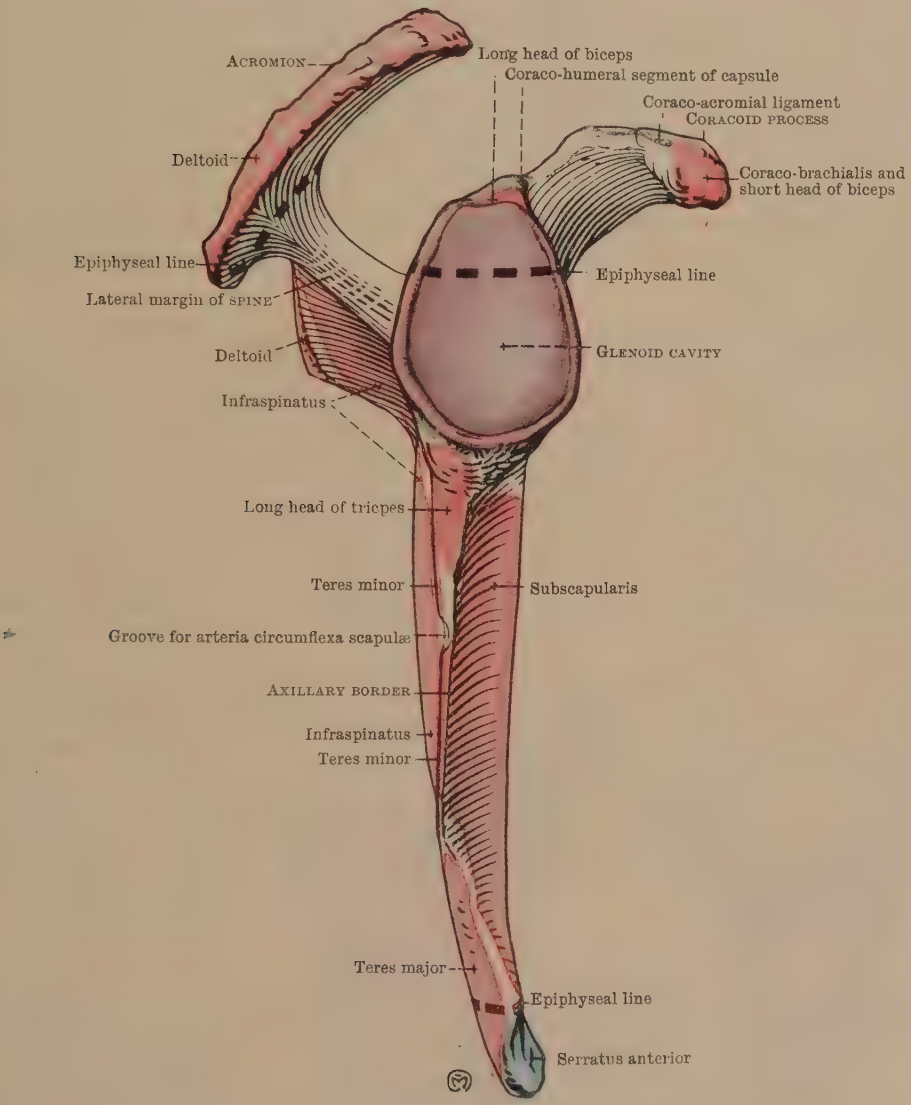

Fig. 191.—Lateral View of Right Scapula.

the anterior and larger part of the medial border is occupied by an oval facet for articulation with the lateral end of the clavicle to form the *acromio-clavicular joint.*

The **coracoid process** is the stout, blunt process that projects from the upper margin of the neck and head of the scapula. In shape it has some resemblance to the bill of a bird [κόραξ (corax) = a raven or crow], and it is divisible into a root and a coracoid process proper.

The **root** projects upwards and forwards from the neck and head and is flattened from before backwards, its anterior and posterior surfaces being continuous with the front and the back of the neck; its medial border is the

lateral margin of the small scapular notch on the upper border of the scapula; and its lateral border is immediately above the glenoid cavity.

The **coracoid process proper** extends from the top of the root almost horizontally, in a lateral direction and forwards, overhanging the shoulder joint above and in front. Its **borders** are called *lateral* and *medial*, though they look, respectively, backwards and forwards as much as in the directions indicated by their names. The lateral border is connected with the tip of the acromion by a strong, flat triangular band called the *coraco-acromial ligament*; the two processes and the intervening ligament form a wide arch called the **coraco-acromial arch**, which overhangs the shoulder joint and protects it. The **surfaces** of the coracoid process are *upper* and *lower*. The posterior part of the upper surface is roughened for the attachment of a strong *coraco-clavicular ligament* which binds it to the clavicle. The **tip of the coracoid process** is a landmark in the root of the upper limb. It is felt, rather indistinctly, as a hard resisting object in the hollow on the front of the shoulder about an inch below the clavicle.

Nutrient foramina, for the entrance of arteries into the bone and the exit of veins from it, are scattered here and there, and are largest near the attached margin of the spine.

Attachments.—The **upper margin** of the scapula gives attachment to only one small muscle, namely, the posterior belly of the omo-hyoid, which arises from the superior transverse ligament and the adjoining part of the upper margin. The **vertebral border** gives insertion to three muscles: (1) the levator scapulæ, opposite the supraspinous fossa; (2) the rhomboideus minor, opposite the spine; and (3) the rhomboideus major, opposite the infraspinous fossa.

The **costal surface** gives attachment to (1) the serratus anterior, which is inserted into the small areas at the medial and inferior angles and into the narrow strip along the vertebral border between those areas, and (2) the subscapularis, which arises from the whole costal surface except the parts for the insertion of the serratus anterior and a part near the neck; a *bursa* protrudes from the capsule of the shoulder joint and separates the subscapularis from the neck and from the root of the coracoid process, and those parts of the bone are smooth.

The **glenoid cavity** gives attachment by its circumference to the labrum glenoidale (glenoid ligament). The capsule of the shoulder joint is attached to the rim of the cavity outside the labrum glenoidale and to the labrum itself. The tendon of the long head of the biceps arises from the **supra-glenoid tuberosity**, and some of the fibres of the tendon are incorporated in the labrum glenoidale. The tendon of the long head of the triceps arises from the rough area on the **axillary margin** immediately below the glenoid cavity, and that is the only muscle attached to the axillary border.

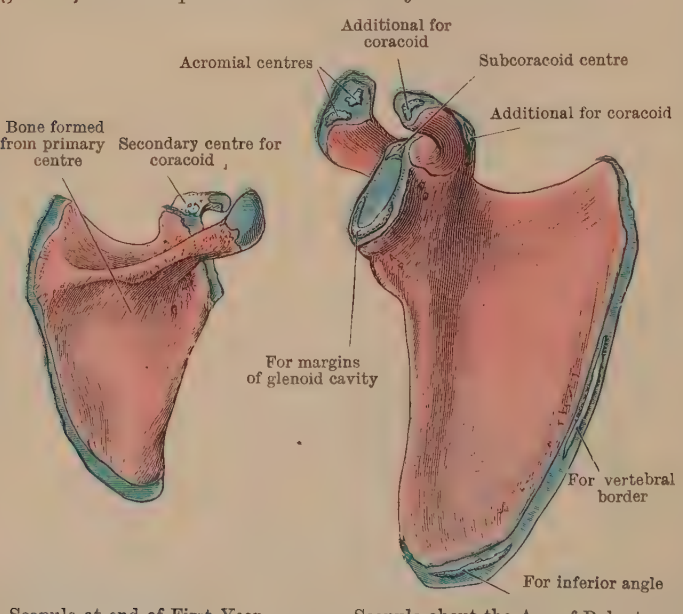

FIG. 192.—OSSIFICATION OF THE SCAPULA.

On the **dorsal surface** the teres major muscle arises from the oval or *triangular elevated area* near the inferior angle, and the latissimus dorsi muscle receives a small slip of origin from the lowest part of that area; the teres minor arises from the *elongated elevated area* that extends upwards to the head; the infraspinatus muscle arises from the **infraspinous fossa**, except a portion near the neck. The supraspinatus arises from the **supraspinous fossa**, except a part near the neck; as it passes over the shoulder joint towards its insertion into the humerus it is separated from the smooth lower surface of the acromion by a *bursa* called the subacromial bursa.

The *upper* and *lower surfaces* of the **spine** help to bound the supra- and infraspinous fossæ and give origin to some fibres of the supraspinatus and infraspinatus respectively. The inferior

transverse ligament stretches from the *lateral margin* of the spine to the back of the **neck** of the scapula. The whole of the *lower lip* of the **crest** and the *lateral margin* of the **acromion** give origin to fibres of the deltoid muscle. The circumference of the *facet* on the medial margin of the acromion gives attachment to the capsule of the acromio-clavicular joint. The coraco-acromial ligament is attached to the *tip* of the acromion in front of the facet. Fibres of the trapezius muscle are inserted into the small part of the *medial margin* behind the facet, and into nearly the whole length of the *upper lip* of the **crest** and the **tubercle** on the *lower lip* of the crest; and a tendinous part of the trapezius, before reaching its insertion, plays over the smooth area where the spine joins the vertebral border, and is separated from that area by a small *bursa*.

The **coracoid process** gives attachment to numerous structures. The coraco-humeral ligament is attached to the *lateral margin* of its **root**, and the superior transverse ligament to the *medial margin*. The coraco-brachialis muscle and the tendon of the short head of the biceps muscle arise conjointly from the *tip* of the **process proper**; the coraco-acromial ligament is attached to its *lateral margin*; the costo-coracoid membrane to the posterior part of the *medial margin*, while the pectoralis minor muscle is inserted into the anterior part of the *medial margin* and the adjoining part of the *upper surface*. The coraco-clavicular ligament is attached to the posterior part of the *upper surface*. The *lower surface* does not give attachment to any structure; it is smooth and is in relation with the subscapular *bursa* and muscle.

Ossification.—The **primary** centre appears at the eighth week of fœtal life. At birth the acromion, the coracoid process, the glenoid cavity, the inferior angle, and the vertebral border are still cartilaginous.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal line to Capsule of Neighbouring Joint.
For coracoid process (proper)	1st year	Puberty	None.
Subcoracoid, for lateral part of root of coracoid and upper third of glenoid cavity	10th year	Puberty	Partly outside, partly inside.
For margins of glenoid cavity	Puberty	20-25	Inside.
For inferior angle	Puberty	20-25	None.
For vertebral border	Puberty	20-25	None.
Two for acromion	Puberty	20-25	Outside.

Occasionally the epiphysis formed from the two acromial centres fails to fuse with the rest of the bone, and the greater part of *the acromion is* **throughout life a separable bone** united to the rest of the bone by periosteum and a strip of cartilage or by a diarthrodial joint, which appears like a line of fracture in an X-ray photograph; the condition is usually alike on the two sides. Sometimes one or two additional centres appear after puberty on the surface of the coracoid process and form small scaly epiphyses which join about the twentieth year.

Structure and Variations.—Two plates of compact bone separated by spongy tissue in the thicker parts and fused together in the thinner parts. In old people the bone may be absorbed in parts, but the periosteum remains. The coracoid process may be separate, but much more seldom than the acromion. In an infant the scapula is relatively wide.

Clavicula.

The **clavicle** is an elongated, slender curved bone which lies nearly horizontally in front of the upper part of the thorax at the root of the neck, stretching from the upper end of the sternum or breastbone to the acromion of the scapula; it can be felt through the skin from end to end [*clavicula*, diminutive of *clavis* = a key, or of *clavus* = nail or bolt]. It is a long bone and has a shaft or **body** and **two ends**. The **lateral third** of the bone is flattened from above downwards, and therefore the *lateral end* can be distinguished from the *medial end* at once; the lower surface of the lateral third is rougher than the upper surface, and therefore one can determine at a glance which is the *upper surface* and which is the *lower*. The bone as a whole has a double curve like the *italic* letter *f*: the **medial half or two-thirds** of the bone is convex forwards, as may be felt and seen in the living person, and the lateral half or third is concave forwards; the *anterior* and *posterior aspects* of the bone are therefore easily identified.

The **lateral** or **acromial extremity** of the clavicle articulates with the medial margin of the acromion and is occupied by an oval *articular facet*. The margins of the facet are often raised or "lipped," and the ridge at the upper margin may

assist one in locating the acromio-clavicular joint in the living person. Its articulation with the acromion is not direct, for an *articular disc* of fibro-cartilage intervenes between the two bones. The articular surface slopes downwards and medially, so that when the bones are dislocated the clavicle overrides the acromion, and is difficult to keep in place once dislocated.

The **medial** or **sternal extremity** is thick. It articulates with the clavicular notch on the upper end of the sternum and with the cartilage of the first rib at the side of the sternum, and the joint is called the *sterno-clavicular joint.* The end of the clavicle is larger than the clavicular notch on the sternum and its upper part can be felt above the level of the sternum; the *articular facet* occupies the lower three-fourths of the end of the clavicle, but it curves also on to the inferior aspect for articulation with the first costal cartilage. In some clavicles the facet has been destroyed during maceration. The articulation with the sternum is not direct, for an *articular disc* separates the clavicle from actual contact with the sternum, though not from the first costal cartilage.

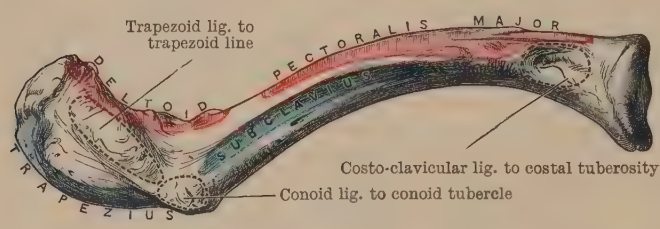

FIG. 193.—LOWER SURFACE OF RIGHT CLAVICLE.

The *anterior* aspect is that on which deltoid and pectoralis major are marked; the medial extremity is the end directed towards the right-hand side of the page.

The **body** of the clavicle is divided, for descriptive purposes, into a lateral third and a medial two-thirds.

The **lateral third** has two surfaces—upper and lower, and two borders—anterior and posterior. The **anterior border** is rough and concave; the **posterior border** is smooth and convex. The **superior surface** is subcutaneous and is usually smooth, but may be rough near the borders, because the muscles attached to the borders sometimes extend their attachments on to the surface. The **inferior surface** is rough. At the posterior border there is a blunt rounded prominence called the **conoid tubercle**; a broad rough ridge, called the **trapezoid ridge**, extends from the tubercle towards the lateral extremity of the clavicle; the tubercle and the ridge, together, form what is called the **coracoid tuberosity.** The lateral third of the clavicle lies above the coracoid process of the scapula, and is attached to it by a strong, important band called the coraco-clavicular ligament, which consists of two parts named from their shape, *conoid* and *trapezoid*, and they give the names to the tubercle and the ridge to which they are attached.

The **medial two-thirds** of the clavicle has four surfaces—anterior, posterior, superior, and inferior; they are separated by borders to which it is not necessary to give names.

FIG. 194.—UPPER SURFACE OF RIGHT CLAVICLE

The **anterior surface** is the convex surface; laterally it narrows down to become continuous with the anterior border of the lateral third. Nearly all of it is occupied by an impression for the origin of part of a large muscle called the *pectoralis major.* The **posterior surface** is the concave surface; it is smooth and is continuous with the posterior border of the lateral third. The **upper surface** is continuous with the upper surface of the lateral third, and is usually smooth and flat. It may be so narrow that it is a mere ridge, or it may be blended with the anterior surface.

Close to the medial end of the **lower surface** there is a rough mark of variable size and character; it may be an elevation or it may be a depression; it is called the **costal tuberosity** because it gives attachment to a strong fibrous band, called

the *costo-clavicular ligament*, which binds the clavicle to the first rib. The lateral part of the lower surface of the medial two-thirds is occupied by a shallow furrow, called the **subclavian groove**, which extends as far as the trapezoid ridge. The rest of the surface may be of appreciable width, but in many clavicles it is narrowed down to a mere border.

The **nutrient foramen** is situated on the posterior aspect near the junction of the lateral third with the medial two-thirds, and it is directed towards the lateral end.

The clavicle varies a great deal in different people, and the beginner may have difficulty in identifying the surfaces of the medial two-thirds if he is using a poorly developed bone as a specimen for study.

Attachments.—The capsule of the acromio-clavicular joint is attached to the margins of the *facet* on the **lateral extremity**. Part of the trapezius is inserted into the *posterior border* of the **lateral third**; part of the deltoid arises from the *anterior border*, and the small rough tubercle occasionally present on that border is called the **deltoid tubercle**; the conoid and trapezoid ligaments (*i.e.* the two parts of the coraco-clavicular ligament) are attached to the **conoid tubercle** and the **trapezoid line.**

The capsule of the sterno-clavicular joint is attached to the margins of the *facet* at the **medial extremity**; the capsule, the articular disc and the interclavicular ligament are attached to the rough *area above the facet*. The costo-clavicular ligament is attached to the **costal tuberosity**. The subclavius muscle is inserted into the **subclavian groove,** and the costo-coracoid membrane, which splits to enclose the subclavius, is attached to the *margins of the groove*. Part of the pectoralis major muscle arises from the *anterior surface* of the **medial two-thirds**. Part of the sterno-mastoid muscle arises from the *upper surface* of the medial third. Fibres of the sterno-thyreoid and sterno-hyoid muscles arise from the *posterior surface* near the medial extremity.

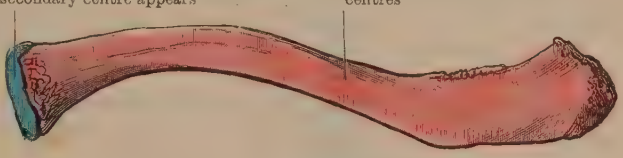

FIG. 195.—OSSIFICATION OF THE CLAVICLE.

Ossification.—The clavicle is the first bone in the body to begin to ossify. Two **primary** centres appear in the fifth week of fœtal life; they soon coalesce, and from them almost the whole bone is ossified.

Secondary Centre.	Appears at	Epiphysis fuses at	Epiphyseal Line is inside
For medial end	20th year	25	Capsule of sterno-clavicular joint.

Structure and Variations.—The clavicle, though a long bone, has no medullary cavity. It consists of spongy tissue surrounded by a shell of compact bone which is thickest in the middle.

The clavicle in women is shorter and more slender than in men, and the curvatures are less marked; its acromial end is at a lower level than the sternal end, while in men the ends are at the same level or the acromial end is the higher. Occasionally the clavicle is perforated by one of the supraclavicular nerves. In rare cases the clavicle is incompletely developed or is absent. Cases have been recorded recently in which (*a*) the medial end of the clavicle was freely movable (*Anat. Record*, Vol. xvi.), and (*b*) there was bifurcation of the lateral part of the clavicle (*Jour. Anat.*, July 1921).

Humerus.

The **humerus** is the bone of the upper arm; its length is about one-fifth of the height of the person; though nearly all thickly covered with muscles it can be felt by deep palpation in all its length. It is a long bone, possessing a shaft or **body** and **two ends.**

It is necessary first to distinguish the ends and ascertain the general direction of its surfaces. The **proximal** or upper end is the thick, rounded end, while the distal end is compressed from before backwards; there is a wide, deep hollow on the **posterior** aspect of the distal end; the smooth hemispherical part of the proximal end looks in a **medial** direction.

The **proximal end** includes the head, the anatomical neck, the greater tubercle, the lesser tubercle, and part of the inter-tubercular sulcus.

The **head** is the large, convex, smooth articular part which is directed not only medially but also upwards, and, when the arm is hanging naturally by the side, it looks backwards as well. It articulates with the glenoid cavity of the scapula; and it may be indistinctly felt by the fingers pushed well up into the axilla.

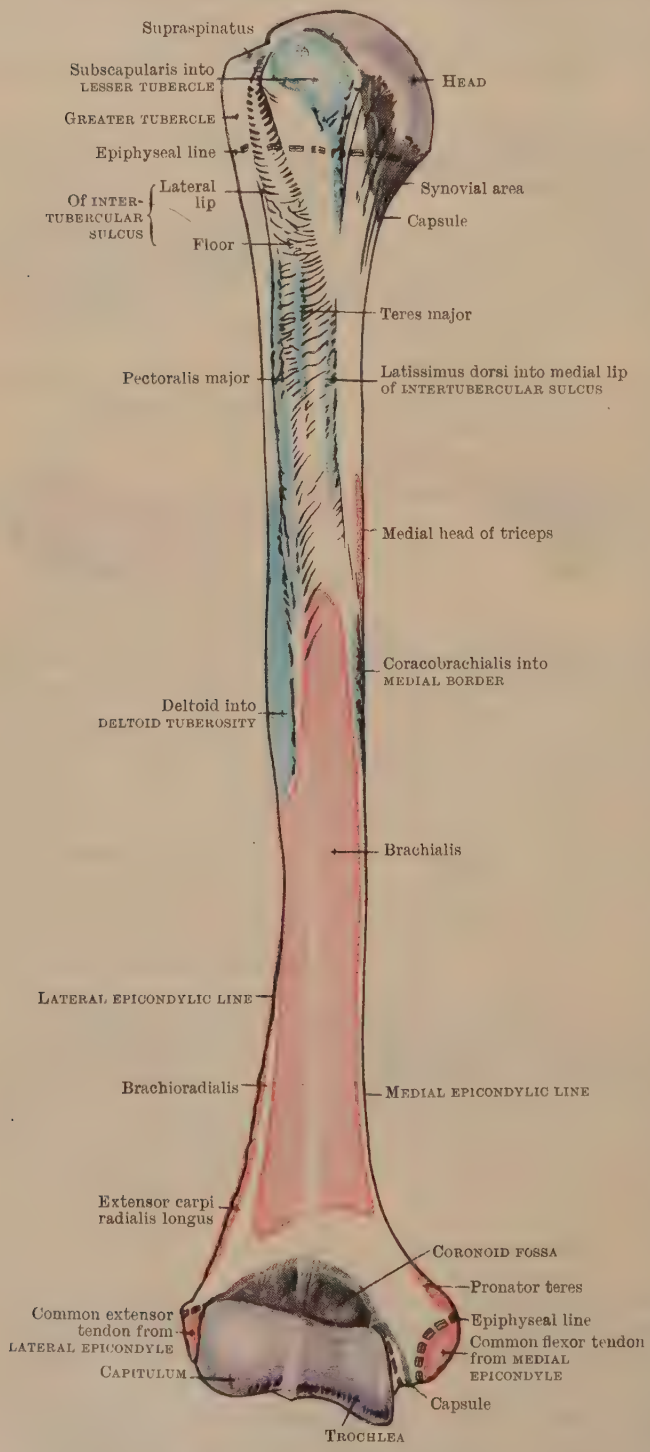

FIG. 196.—FRONT OF RIGHT HUMERUS.

The **lesser tubercle** is the well-marked prominence on the anterior surface of the proximal end; the part of it nearest the head has an impression, usually smooth, for the insertion of the tendon of the subscapularis. The lesser tubercle can be felt in the front of the shoulder just lateral to the coracoid process (and may be mistaken for it) when the arm is hanging comfortably by the side, but at a little distance from that process when the limb is rotated so that the palm of the hand looks forwards.

The **greater tubercle** is the prominence on the lateral aspect of the proximal end. Though larger than the lesser tubercle it is not so clearly defined, for its lateral surface shades off into the lateral aspect of the body of the bone. Its upper surface or border and its posterior surface have smooth impressions for the insertion of certain muscles. The greater tubercle forms the "point of the shoulder," *i.e.*, its most projecting lateral part, and may be felt there a little below the lateral margin of the acromion.

The **intertubercular sulcus** is the clean-cut groove between the two tubercles, and it is prolonged for two inches or more on to the body, where it is not so sharply defined. The tendon of

the long head of the biceps, after it emerges from the shoulder joint, lies in the groove.

The **anatomical neck** is the narrow strip that encircles the margins of the head; its upper part is the narrow and shallow depression between the head and the tubercles.

Collum Chirurgicum.—The **surgical neck** is the region immediately distal to the head and tubercles where the proximal end and the body join. It does not have sharp limits, and may be reckoned as about a finger's breadth in extent all round the bone. The name is given because the bone is often fractured there.

The **distal end** includes the capitulum, the trochlea, the radial, coronoid and olecranon fossæ, and the lateral and medial epicondyles.

The **capitulum** is the smooth, rounded knob placed near the lateral part of the distal end. It is situated partly on the front and partly on the distal aspect, but not at all on the back. It articulates with the head of the radius.

The **radial fossa** is the shallow depression immediately above the capitulum; the margin of the head of the radius comes into close relation with it when the forearm is fully bent.

The **trochlea** is the wide, smooth, pulley-shaped surface at the medial side of the capitulum [τροχιλία (trochilia) = the sheave of a pulley]. It is situated both on the front and back and distal aspect, and its medial lip stands out as a prominent rim. It articulates with the wide semilunar notch, on the front of the proximal end of the ulna.

The **coronoid fossa** is the depression on the anterior aspect just above the trochlea. It is related to the coronoid process of the ulna when the forearm is fully flexed.

The **olecranon fossa** is the large depression in a corresponding position on the back; the olecranon of the ulna fits into it when the forearm is straightened out. The bony substance between the coronoid and olecranon fossæ is very thin.

The **medial epicondyle** is the prominent projection on the medial side of the distal end. It is easily felt at the medial side of the elbow and can be gripped between finger and thumb. Its anterior surface has impressions on it for the origin of muscles; its posterior surface is smooth and has a shallow groove which lodges the *ulnar nerve* as it passes from the arm to the forearm; the nerve can be felt and rolled between the finger and the bone.

The line or ridge (often poorly marked) which extends from the epicondyle on to the body of the bone for two or three inches is called the **medial epicondylic line.**

The **lateral epicondyle** is the projection on the lateral side of the distal end; it is not nearly so prominent as the medial epicondyle. Its anterior surface is small and is occupied by an impression for the origin of muscles. Its posterior surface is broad and smooth and subcutaneous; it can be felt on the back of the arm just above the lateral part of the elbow joint, that part of the joint being recognisable as a transverse depression.

The strong ridge which extends on to the shaft from the lateral epicondyle is called the **lateral epicondylic line**; it is easily felt when the elbow joint is in the bent position and the muscles are relaxed.

When the upper limb hangs comfortably by the side with the palm looking towards the thigh, the arm is then rotated so that the lateral epicondyle is felt on the antero-lateral aspect of the limb, and the medial epicondyle on the postero-medial aspect.

Corpus Humeri.—The **body** or **shaft** of the humerus is more or less cylindrical in its proximal half, but is rather compressed from before backwards in its distal part; it is described as having three borders and three surfaces. The **borders** are anterior, medial, and lateral; the **surfaces** are posterior, antero-lateral, and antero-medial.

The **anterior border** begins at the anterior margin of the greater tubercle, runs along the front of the bone, and ends near the radial and coronoid fossæ; its proximal third is the lateral margin or lip of the intertubercular groove.

The **medial border** begins at the lesser tubercle and ends at the medial

epicondyle. It is not nearly so well marked as the anterior border. Its proximal third is the medial lip of the intertubercular sulcus; its distal third is the medial epicondylic line; in bones in which muscular markings are well seen its middle part is roughened for the insertion of a muscle called coraco-brachialis.

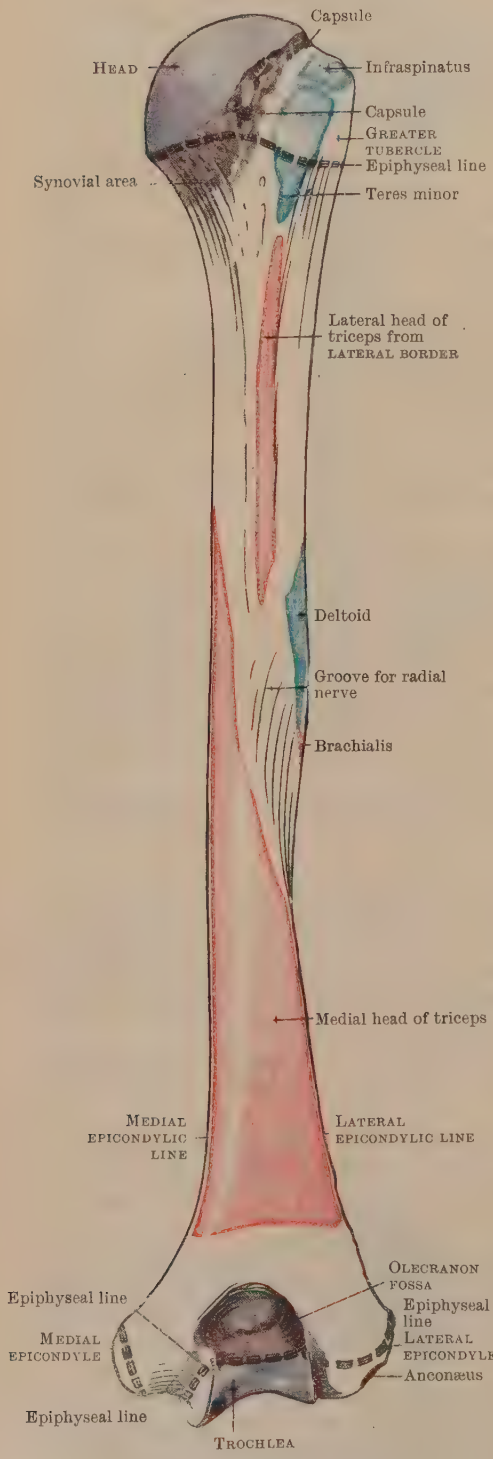

Fig. 197.—Back of Right Humerus.

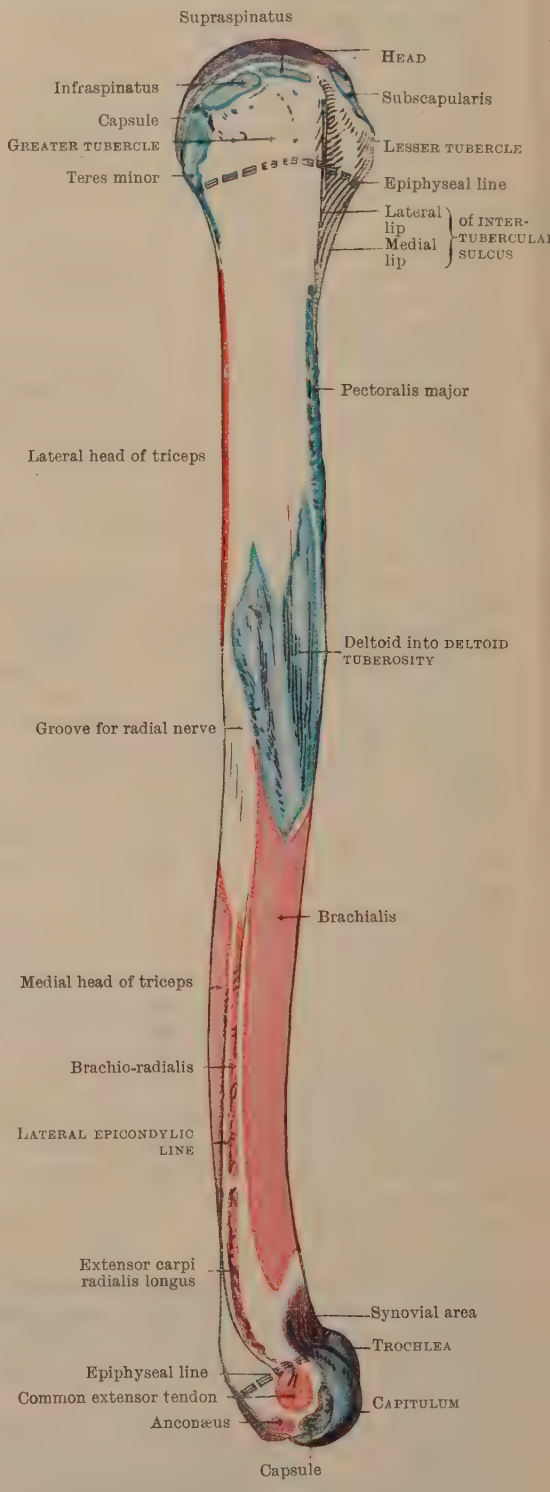

Fig. 198.—Lateral Aspect of Right Humerus.

The **lateral border** begins at the posterior surface of the greater tubercle and ends at the lateral epicondyle. Its distal third is the lateral epicondylic line; its proximal third is an indistinct ridge which descends from the back of the greater tubercle; it is interrupted in its middle third by a broad shallow groove which extends obliquely across it. The groove begins on the back of the bone and is directed downwards and forwards on to the front; the radial nerve, winding round the humerus, lies in it along its posterior or distal margin, and it is named accordingly the **groove for the radial nerve.**

The **posterior surface** is the area between the lateral and medial borders.

The **antero-lateral surface** is the area between the anterior and lateral borders. Its proximal part is continuous with the lateral surface of the greater tubercle. About its middle it is occupied by a rough, V-shaped mark called the **deltoid tuberosity**, so named because the deltoid muscle is inserted into it. The anterior margin of the V is part of the anterior border of the humerus, and its posterior margin is one of the boundaries of the groove for the radial nerve, for that groove is just behind and distal to the tuberosity. The tuberosity can usually be made out in the living person by deep pressure on the middle of the lateral aspect of the arm.

The **antero-medial surface** is the area between the anterior and medial borders. Its proximal part is narrow, for it is merely the floor of that part of the intertubercular groove which extends on to the shaft.

The distal halves of the antero-lateral and antero-medial surfaces are often spoken of together as the distal half of the anterior aspect of the humerus, in order to simplify the description of the brachialis muscle, which arises from the whole of that region.

The principal **nutrient foramen** is almost always situated just in front of the medial border, not far from its middle, and is directed towards the distal end. Sometimes it is in the proximal part of the groove for the radial nerve; and there may be a foramen in both places.

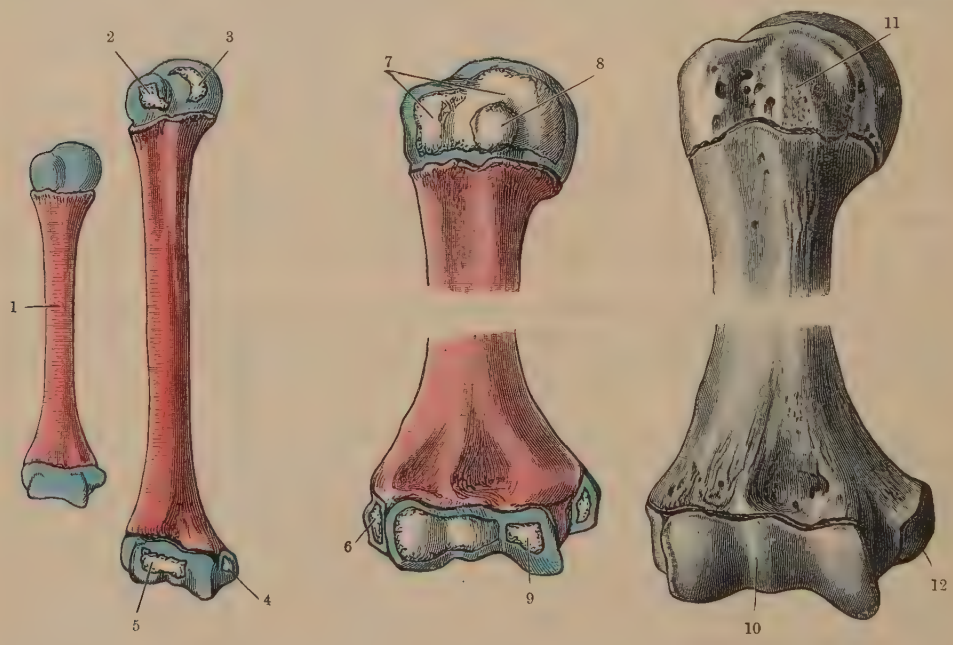
Attachments.—The capsule of the shoulder joint is attached to the **anatomical neck** above and in front and behind, but is attached to the bone nearly a finger's breadth below the head on the medial side, so that the medial part of the bone, just below the head, is covered with synovial membrane; the coraco-humeral ligament is attached to the anatomical neck at the anterior and upper part of the greater tubercle. The supraspinatus is inserted into the anterior impression on the top of the **greater tubercle**, the infraspinatus into the impression behind that, the teres minor into the impression on the back and into a strip below that for half an inch; the subscapularis into the **lesser tubercle** and into the surface below for half an inch. The transverse ligament of the humerus is attached to *both tubercles* and bridges across the proximal end of the **intertubercular groove**, holding the tendon of the long head of the biceps in place; further down, on the shaft, the pectoralis major is inserted into the *lateral lip* of the groove, the teres major into the *medial lip*, and the latissimus dorsi into *its floor*; the tendon of the long head of the biceps lies in the groove, enclosed in a sheath of synovial membrane, which is prolonged from the synovial lining of the capsule of the shoulder joint and envelops the tendon and lines the groove; deep to that sheath a little artery, a branch of the anterior circumflex, runs upwards in the groove to the shoulder joint.

The common extensor tendon (the combined tendons of origin of the extensores carpi radialis brevis, digitorum communis, digiti quinti and carpi ulnaris) arises from the *front* of the **lateral epicondyle**; the radial collateral ligament is attached to its *distal margin*, while the tendon of the anconeus arises immediately behind the attachment of the ligament, leaving the large posterior surface smooth. The common flexor tendon (the combined tendons of origin of the flexores carpi radialis, palmaris longus, digitorum sublimis and carpi ulnaris) arises from the impressions on the lower part of the *front* of the **medial epicondyle**, the pronator teres from the flatter, upper part and adjoining lower end of the epicondylic line; the ulnar collateral ligament is attached to the *distal margin* of the epicondyle. The anterior ligament of the elbow joint is attached to the *proximal margins* of the **radial** and **coronoid fossæ** and to the front of the epicondyles near the capitulum and trochlea. The posterior ligament is attached to the *floor* of the **olecranon fossa**, to its margins on each side, and to the backs of the epicondyles close to the margins of the trochlea.

The deltoid is inserted into the **deltoid tuberosity**; the coraco-brachialis into the middle of the **medial border.** The medial intermuscular septum is attached to the *edge* of the **medial epicondylic line**; the lateral intermuscular septum to the *edge* of the **lateral epicondylic line**; the brachio-radialis arises from the proximal two-thirds of the *anterior aspect* of the lateral line, and the extensor carpi radialis longus from its distal third. The lateral head of the triceps arises from the *proximal third* of the **lateral border**; the medial head from the *whole width* of the **posterior surface** below the groove for the radial nerve; the brachialis from the distal half or two-thirds of the **anterior aspect** of the body of the humerus.

Ossification.—The **primary** centre appears at the eighth week of fœtal life. At birth only the ends are cartilaginous.

Secondary Centre	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For head	1st year	20-25	Medial part inside, remainder outside.
For greater tubercle	3rd ,,		
For lesser tubercle	5th ,,		
For capitulum and lateral half of trochlea	3rd ,,	17	Lateral extremity outside, remainder inside.
For medial half of trochlea	12th ,,		
For lateral epicondyle	12th ,,		
For medial epicondyle	5th ,,	18	Outside.



At birth. About 5 years. About 12 years. About 16 years.

FIG. 199.—OSSIFICATION OF THE HUMERUS.

1. Body, from primary centre.
2. Centre for greater tubercle.
3. Centre for head.
4. Centre for medial epicondyle.
5. Centre for capitulum and lateral half of trochlea.
6. Centre for lateral epicondyle.
7. 8. Centres for head and tubercles coalesced.
9. Centre for medial half of trochlea.
10. =5, 6, and 9 coalesced.
11. Proximal epiphysis.
12. Epiphysis of medial epicondyle.

The centres for the head and the two tubercles coalesce in the seventh year to form **one** epiphysis. The centres for the capitulum, trochlea, and lateral epicondyle coalesce to form **one** epiphysis.

Structure and Variations.—The structure is that of a typical long bone; the walls of the medullary cavity are thickest just below the middle of the bone. In some cases, more often in lower races, the thin bone of the floor of the olecranon fossa is perforated. In rare cases a small projection is found about two inches above the medial epicondyle, with which it is connected by a fibrous band; the median nerve and brachial vessels, taking an unusual course, pass under cover of the band. The humerus normally appears twisted, so that while the articular surface at the proximal end looks mainly in a medial direction, the articular surfaces at the distal end look backwards and forwards; the twist is more marked in adults than in children and fœtuses, and in modern Europeans than in more primitive races or in prehistoric Europeans.

Ulna.

The **ulna** is the medial and longer bone of the forearm [from ὠλένη (ōlenē) = forearm or elbow]. It is easily felt on the back of the forearm in its whole length.

It is a long bone, about one-sixth of the body length, and has a **body** or shaft and **two extremities.**

The **proximal** end is the larger end, and has two large projections which give it a resemblance to a spanner and enable the beginner to pick the ulna out from among other bones. The wide, deep concavity between those two projections is directed **forwards.** The lateral aspect can be distinguished from the medial because the **lateral** border of the body is the sharpest and most outstanding of the three borders.

The **proximal end** includes the olecranon, the coronoid process, the semilunar notch, the radial notch, and the tuberosity of the ulna.

The **olecranon** is the larger of the two projections and is the most proximal part of the ulna [ὠλένη—see p. 230; κρανίον (cranion) = head]; it is the prominence felt at the back of the elbow, and is the part which rests on the table when one leans on the elbow. It is in line with the body of the bone, and though stout and strong it is sometimes broken off. It has proximal, anterior, and posterior surfaces, and lateral and medial borders or surfaces. The **posterior** surface is smooth and subcutaneous, and nearly triangular in outline with the apex pointing downwards. The **anterior** surface is smooth and coated with articular cartilage. The **proximal** surface is the very end of the bone, and the tendon of the triceps muscle is inserted into its posterior part. The **lateral** and **medial** borders are thick, and are rough for the attachment of ligaments and muscles.

The **coronoid process** is the projection that juts forward from the proximal part of the shaft and has a fancied resemblance to the beak of a bird [κορώνη (corōnē) = a sea crow]. Its *proximal* surface is smooth and coated with articular cartilage; its volar or *anterior* surface is rough for the insertion of a muscle called brachialis; on its *medial* side there is a rounded tubercle for the attachment of part of the ulnar collateral ligament of the elbow joint; the tubercle can be felt about a thumb's breadth below the medial epicondyle of the humerus, and the ulnar nerve, as it passes into the forearm, can be felt and rolled over the tubercle by the finger.

The **radial notch** is the shallow, smooth hollow on the lateral surface of the coronoid process; it is coated with articular cartilage and articulates with the side of the head of the radius. Immediately distal to the notch, on the body of the bone, there is a rough, shallow hollow, triangular in outline with its base at the notch; it is named the *supinator fossa,* and its posterior margin, which is often a strong ridge, is named the *supinator crest,* for the supinator muscle arises from both.

The **semilunar notch** is the wide concavity between the coronoid process and the olecranon. The trochlea of the humerus fits into it; therefore both olecranon and coronoid process articulate with the trochlea, and their articular surfaces are the reverse of a pulley, being elevated in the middle and sloping to the sides. If the humerus and the ulna are placed together properly, the olecranon fits into the olecranon fossa when the bones are in line, *i.e.,* when the forearm is extended; and the coronoid process comes into relation with the coronoid fossa when the two bones make an acute angle, *i.e.,* when the forearm is fully flexed. Where the olecranon and the coronoid process join each other the semilunar notch has little rough patches at its sides; those patches may meet, forming a rough narrow strip across the notch, separating the front of the olecranon from the proximal surface of the coronoid process.

The **tuberosity** of the ulna is a rough mark at the distal end of the volar or anterior surface of the coronoid process, and is continuous with that surface; but it is on the body rather than on the proximal end of the ulna.

The **distal end** of the ulna is small, and includes the head and the styloid process.

The **head** is the larger, rounded part. It should be noted that in the ulna the part called the *head* is at the *distal* end. When the hand is held with the palm looking downwards, the head of the ulna can be seen as a knob on the back of the forearm just above the wrist on the ulnar side (that is, the side in line with the

little finger). The *lateral* and *volar aspects* of the head are smooth and convex, and articulate with the distal end of the radius, the radius articulating with the lateral aspect when the limb is in the position in which the thumb is directed away from the body, and with the volar aspect when the thumb is directed medially. The *distal surface* of the head also is smooth; it articulates not with a bone but with a triangular plate of fibro-cartilage, called the *triangular articular disc*, which separates the head from the bones of the wrist.

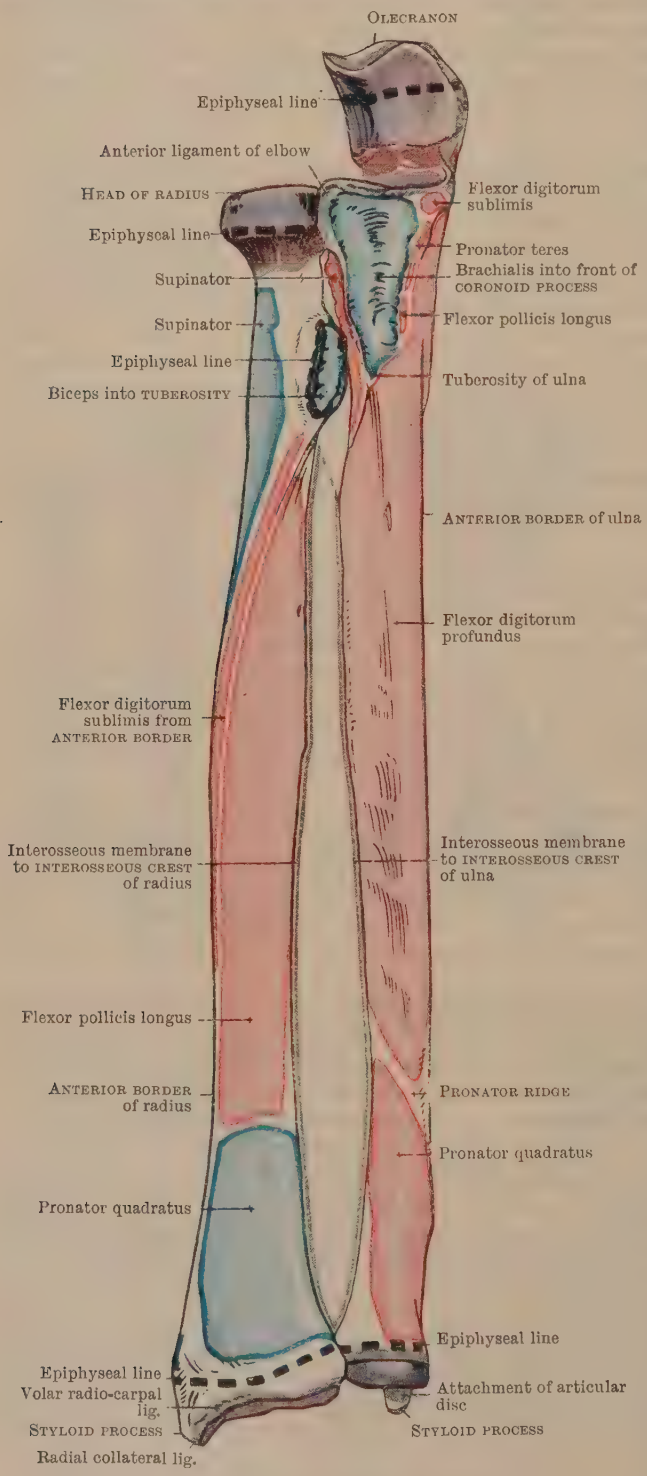


Fig. 200.—Volar Surface of Right Radius and Ulna.

The **styloid process** is the small, conical projection that juts downwards towards the wrist from the postero-medial aspect of the distal end. Between the base of the styloid process and the distal surface of the head there is a small rough patch to which the apex of the articular disc is attached. On the *back of the bone*, between the styloid process and the head, there is a well-marked **groove** which lodges the tendon of a muscle called the *extensor carpi ulnaris*.

When the hand is in the position in which the palm looks towards the shoulder (the elbow being bent) the styloid process, along with the tendon of the extensor carpi ulnaris, can be felt as a ridge on the ulnar border of the back of the forearm, but the head of the ulna is scarcely palpable. When the hand is held palm downwards the head of the ulna appears as a round knob at the ulnar border of the back of the forearm, and the styloid process is then felt on the ulnar surface of the limb. The apparent differences in position are not due to movements of the ulna, but to movements of the radius called *supination* and *pronation* (p. 237).

Corpus Ulnæ.—The **body** or shaft of the ulna diminishes in thickness from above downwards. It has three **borders**, named volar, dorsal, and lateral, and **three surfaces**, named dorsal, volar, and medial.

The *volar* **or anterior border** is smooth and rounded. It begins at the tuberosity of the ulna and ends at or near the base of the styloid process.

The **dorsal border** begins at the distal angle of the back of the olecranon, extends sinuously along the body, and fades away near the distal end. It is felt as a sharp subcutaneous ridge on the back of the forearm.

The **lateral border** is a sharp, salient ridge. It begins at the distal angle of the supinator fossa, becomes very prominent in the middle of the bone, and fades away near the distal end. It is called also the **interosseous crest**, because a strong, wide, fibrous sheet, called the *interosseous membrane*, stretches across from it to the radius.

The *volar surface* **or anterior surface** lies between the volar margin and the interosseous crest; and the tuberosity of the ulna is situated at its proximal end. It is usually hollowed out longitudinally in its proximal two-thirds or more, and the distal end of the hollow is limited by an oblique ridge, called the *pronator ridge* because part of the pronator quadratus muscle arises from it.

The **dorsal surface** lies between the dorsal margin and the interosseous crest. In a well-marked bone an oblique ridge runs from the back of the radial notch to a point on the dorsal border about an inch below the distal end of the back of the olecranon. A muscle called the anconæus is inserted into the area above the ridge. Below the ridge a vertical line maps off a long, flat strip between itself and the dorsal border. The strip does not give attachment to any muscle, but the extensor carpi ulnaris lies upon it; nearly all the rest of the dorsal surface is mapped out by faint oblique ridges into areas for the origin of muscles.

The **medial surface** is the smooth, slightly convex surface between the volar and dorsal borders. Its proximal part is covered with muscle, but its distal third is subcutaneous and therefore easily felt.

The **nutrient foramen** is situated on the volar surface about the junction of the proximal and middle thirds, and is directed towards the proximal end.

Attachments.—The tendon of the triceps is inserted into the posterior part of the *proximal surface* of the **olecranon**, and the posterior ligament of the elbow joint is attached to the anterior edge of the surface, while a small *bursa* lies between them on the intervening part; the posterior ligament is attached also to the rough *lateral surface* or border, and the anconæus is inserted into that surface behind the ligament; the posterior band of the ulnar collateral ligament of the elbow joint is attached to the *medial surface* or border, and fibres of the flexor carpi ulnaris and of the flexor digitorum profundus arise from it behind the ligament.

The anterior band of the ulnar collateral ligament is attached to the *tubercle* on the *medial border* of the **coronoid process**, some fibres of the flexor digitorum sublimis arise from it, while slips of the pronator teres and flexor pollicis longus arise from the ridge which descends from the tubercle, and fibres of the flexor profundus from the hollow behind that ridge; the anterior ligament of the elbow joint is attached to the sharp *volar margin* of the process, and the brachialis is inserted into the *volar surface* and also into the **tuberosity** immediately below. The annular ligament which surrounds the head of the radius is attached to the *volar* and *dorsal margins* of the **radial notch**, and the ligamentum quadratum to its *distal margin*.

The capsule of the distal radio-ulnar joint is attached to the *front* and *back* of **head**, and a septum of the dorsal carpal ligament to the radial border of the **groove** on the back; the ulnar collateral ligament of the wrist to the tip of the **styloid process**, and the apex of the triangular articular disc to the small rough mark between its base and the head.

On the **body** or shaft, the chorda obliqua, as well as part of the brachialis, is attached to the **tuberosity**. The supinator arises from the **supinator crest** and **fossa**. The interosseous membrane is attached to the **interosseous crest**. The flexor carpi ulnaris arises by a wide aponeurosis from the proximal three-fourths of the *dorsal border*, besides having a small origin from the lateral surface of the olecranon. By means of the same aponeurosis part of the extensor carpi ulnaris arises from the middle third of the dorsal border. The anconæus is inserted into the proximal part of the *dorsal surface*; parts of the abductor pollicis longus, extensor pollicis longus, and extensor indicis proprius arise from the lateral part of the dorsal surface, in that order from above downwards. The pronator quadratus arises from the **pronator ridge** and the distal fourth of the *volar surface*, and the flexor digitorum profundus from the two-thirds or three-fourths of the *volar* and *medial surfaces*, extending up to the medial surfaces of the coronoid process and olecranon.

Ossification.—The **primary centre** appears at the eighth week of fœtal life, and from it the body, the coronoid process, and nearly the whole of the olecranon are ossified, though at birth a great part of the olecranon, as well as the distal end, is cartilaginous.

Secondary Centre.	Appears at	Epiphysis joins at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For distal end	6th year	21	Outside.
For top of olecranon	10th ,,	Puberty	Outside; anterior part sometimes inside.

Structure and Variations.—The structure resembles that of the humerus and other long bones. The medullary canal extends from the root of the coronoid process to the distal fifth of the bone. The weakest parts are at the junction of the olecranon and the coronoid process, and the junction of the middle and distal thirds of the shaft.

In rare cases the ulna is incompletely developed or is absent. In one recorded case the olecranon was a separate bone.

Radius.

The **radius** is shaped like the spoke of a wheel—hence its name. It is the lateral and shorter bone of the forearm, and can be felt in all its length, though deep pressure is necessary at its middle. It is a long bone with a **body** or shaft and **two ends.**

The **proximal** end is the smaller end. The distal end is a block of bone; it is slightly bent forwards, and its **anterior** or volar surface is broad, concave, and fairly smooth; from the **lateral side** of the distal end a short, thick, pointed process projects downwards.

The **proximal end** includes the head, the neck, and the tuberosity.

The **head** is a circular disc, cupped on its proximal surface, and that surface is smooth and articulates with the capitulum of the humerus. The circumference of the head is smooth; it articulates with the radial notch of the ulna and with the inner surface of a fibrous band, called the *annular ligament* of the radius, which encircles five-sixths of the head of the radius and is attached by its ends to the volar and dorsal margins of the radial notch of the ulna; the ligament and the notch, together, constitute a complete ring within which the head of the radius rotates during the movements of supination and pronation (p. 237). The head of the radius can be felt, through the ligament, on the back of the limb towards the lateral side, immediately distal to the lateral epicondyle of the humerus.

The **neck** is the cylindrical, slightly constricted part of the bone that supports the head.

The **tuberosity** of the radius is the broad, low prominence on the medial side, just distal to the neck. The tendon of the biceps is inserted into it.

When the humerus and radius are fitted together properly the proximal surface of the head of the radius articulates with the distal part of the capitulum of the humerus when the bones are in line; it comes into full articulation with the capitulum when they are at right angles; and its edge comes into relation with the radial fossa of the humerus in extreme flexion. The radius only touches the capitulum, while the semilunar notch of the ulna grips the trochlea; the ulna is therefore much the more important constituent of the elbow joint, and the stability of the joint depends on it, the radius offering no bar to dislocation. The grip of the ulna is least secure when the forearm is extended, *i.e.* in line with the arm; the ulna can then slip backwards off the humerus. But the olecranon is a positive bar to forward dislocation until the forearm is becoming acutely flexed.

The **distal end** of the radius has five surfaces and a styloid process. The surfaces are volar, dorsal, medial, lateral, and distal or carpal.

The *volar surface* or **anterior surface** is broad and slightly concave; at its distal margin there is a broad, rough ridge that can be felt on the front of the forearm about an inch above the ball of the thumb; it indicates the position of the distal epiphyseal line, and is also a guide to the position of the wrist joint, which is immediately distal to it.

The **dorsal surface** is more uneven, being occupied by grooves and ridges. The most prominent ridge is about the middle of the surface; it is called the **dorsal tubercle**, and can usually be felt in the living limb. On the lateral side of the tubercle there is a shallow groove, more than half an inch wide, on which two thick tendons lie; they are the tendons of the extensor carpi radialis longus and brevis muscles, and when the closed fist is bent slightly backwards they can be seen as they pass off the radius on to the back of the wrist. On the medial side of the tubercle there is a narrow, oblique, clean-cut groove for the tendon of the extensor pollicis longus, which can be seen reaching almost to the thumb nail when the thumb is outstretched. The rest of the dorsal surface, *i.e.* the part medial to the narrow groove, is a broad shallow groove which lodges the tendons of the extensor digitorum communis and extensor indicis proprius.

The **lateral surface** is less than half an inch wide; it is occupied by a shallow groove for the tendons of the abductor pollicis longus and extensor pollicis brevis, and is separated from the volar surface by a sharp ridge which is easily felt in the living limb.

The lateral part of the distal end of the radius is prolonged downwards as the short, thick **styloid process.** When the thumb is outstretched a hollow is seen on the radial side of the wrist, called by the French

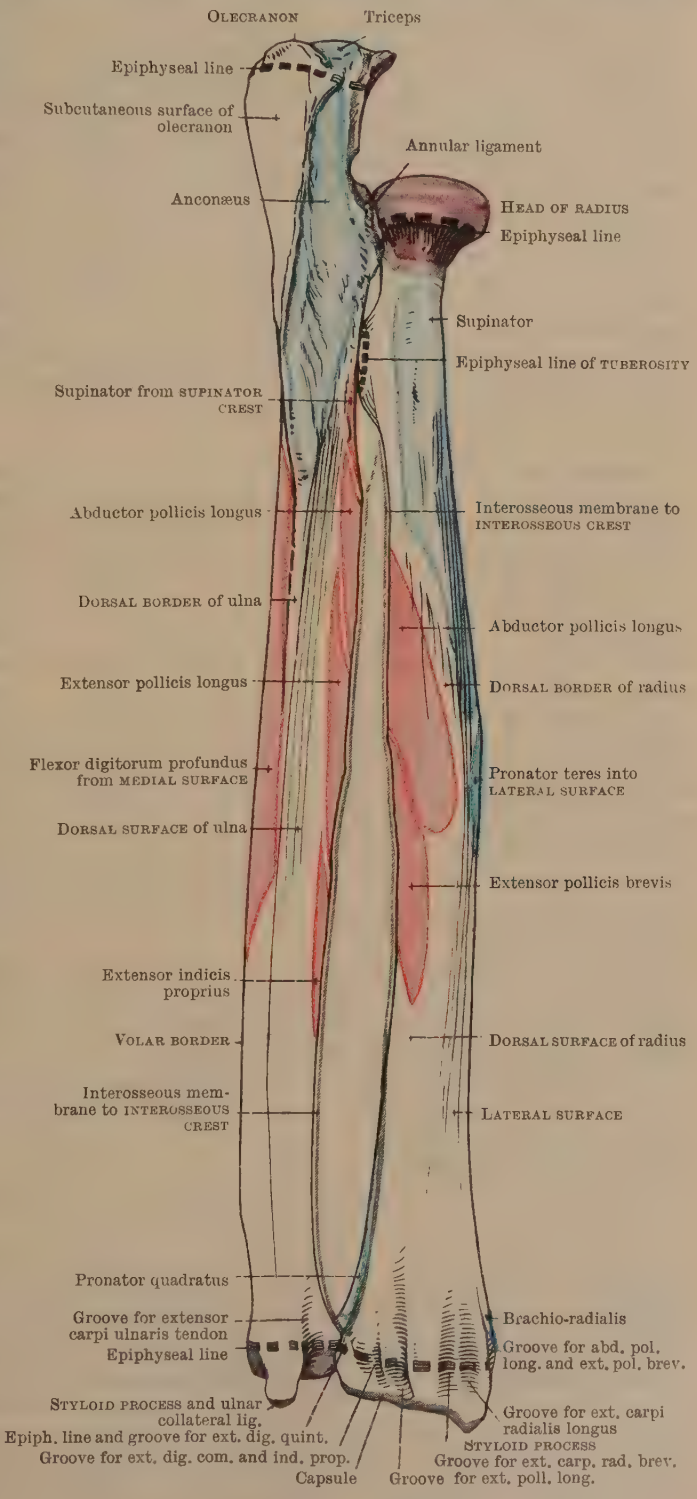

Fig. 201.—Dorsal Surface of Right Radius and Ulna.

the *anatomical snuff-box* (Tabatière anatomique); its dorsal boundary is the tendon of the extensor pollicis longus; its volar boundary is the tendons of the abductor pollicis longus and extensor pollicis brevis, which lie close together and make a ridge between the front of the wrist and its lateral surface; the styloid process is the bone felt in the proximal part of the floor of the hollow. Its position should be compared with that of the styloid process of the ulna; the radial styloid process is at a more distal level than that of the ulna; in the common variety of fracture of the distal end of the radius that relationship may be reversed.

The **medial surface** is small, concave, and smooth; it is sometimes called the **ulnar notch**, for it articulates with the head of the ulna and rotates round it during the rotatory movements of the forearm and hand (pronation and supination).

The *distal* or **carpal surface** is concave and smooth, and articulates with bones of the wrist or carpus. It is divided into two areas: a medial area nearly quadrilateral, and a lateral area nearly triangular, the apical part of which extends on to the styloid process. Between the carpal surface and the medial surface there is a sharp edge to which the base of the triangular articular disc is attached. The dorsal and lateral boundaries of the distal surface project downwards more than the others, and in a fall on the hand the dorsal and lateral part of the distal end is liable to be chipped off.

Corpus Radii.—The **body** or shaft of the radius increases in girth from above downwards, but is most often broken near the distal end; it has three borders and three surfaces. The **borders** are volar, dorsal, and medial; the **surfaces** are dorsal, volar, and lateral.

The **medial border** is the most definite and sharpest of the three, and it is called also the **interosseous crest**, because the interosseous membrane is attached to it. It begins near the tuberosity; towards its distal end it divides into two ridges which diverge slightly and become continuous with the margins of the ulnar notch.

The *volar* or **anterior border** begins at the tuberosity and ends at the ridge between the volar and lateral surfaces of the distal end of the bone. Its proximal part is well marked and oblique; its distal part is rounded and indistinct.

The **dorsal border** is most distinct in the middle third of the bone; the proximal part is an indistinct line stretching from the middle third obliquely towards the back of the tuberosity; the distal part is a smooth indistinct ridge which runs from the middle third to the dorsal tubercle on the distal end.

The **volar** and **dorsal surfaces** lie between the interosseous crest and the volar and dorsal margins.

The **lateral surface** lies between the volar and dorsal margins. It is roughened at its middle for the insertion of the pronator teres muscle. Its proximal part encroaches greatly on the volar and dorsal aspects of the bone owing to the obliquity of the proximal parts of the volar and dorsal margins; the distal part of the surface also encroaches on the dorsal aspect, and is continuous not only with the lateral surface of the distal end but also with the groove on the dorsal surface lateral to the dorsal tubercle.

The **nutrient foramen** is situated on the volar surface about the junction of its proximal and middle thirds, and it is directed towards the proximal end.

Attachments.—The distal margin of the annular ligament and the lateral margin of the lig. quadratum are attached round the **neck** *loosely*, so as not to interfere with the rotatory movements of the radius. The tendon of the biceps is inserted into the rough posterior part of the **tuberosity**, and is separated by a *bursa* from the smooth anterior part.

At the **distal end**, the volar ligament of the wrist joint (volar radio-carpal lig.) is attached to the distal margin of the *volar surface*; the radial collateral ligament to the **styloid process**; the dorsal ligament of the wrist joint to the distal edge of the *dorsal surface*; the capsule of the distal radio-ulnar joint to the volar and dorsal margins of the **ulnar notch**; the base of the triangular articular disc to the border between the notch and the *carpal surface*; the lateral end of the dorsal carpal ligament to the *sharp border* between the lateral and volar surfaces, and its septa to the ridges bounding the grooves on the *dorsal surface*; the tendon of the brachio-radialis is inserted into the proximal part of the *lateral surface*.

On the **body**, the chorda obliqua is attached to the bone just distal to the tuberosity; the interosseous membrane to the **interosseous crest** and to the more dorsal of the two ridges into which the distal end of the crest divides. Part of the flexor digitorum sublimis arises from the

proximal half of the *volar margin*, and the flexor pollicis longus from the proximal three-fourths of the *volar surface*; the pronator quadratus is inserted into the distal fourth of the volar margin and volar surface, into the volar surface of the distal end, and into the narrow triangular area above the ulnar notch. The pronator teres is inserted into the rough mark on the middle of the *lateral surface*; the supinator into the proximal third, including its encroachments on the volar and dorsal aspects. Parts of the abductor pollicis longus and extensor pollicis brevis arise from the *dorsal surface*, the abductor just above the middle of the bone, and the extensor just below.

The radius is slightly curved so that it is convex in a medial direction in its proximal quarter, and in a lateral direction in the distal three-quarters; the biceps and the pronator teres are inserted into the maximum points of the curves, so that their value as supinator and pronator, respectively, is increased.

Ossification.—The **primary centre** appears at the eighth week of fœtal life. At birth only the distal end, the head, and the tuberosity are cartilaginous.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For distal end	2nd year	21	Outside.
For head	6th ,,	Puberty–20	Inside.
For tuberosity	Puberty	Shortly after puberty	Outside.

Structure and Variations.—The medullary canal reaches the neck but does not reach the distal part of the body. The neck of the bone is the most slender part of the bone, but the commonest seat of fracture is near the distal end, for that part of the bone bears the impact of a fall on the hand. Absence of the radius has been recorded more than once, and in some of those cases the thumb also was absent.

Supination and Pronation.

The terms *supination* and *pronation* refer to position and movements of the forearm and hand, though in ordinary circumstances supination and pronation of the forearm are always supplemented by rotation of the upper arm.

The **supine position** is that in which the two bones of the forearm are parallel and the thumb is directed away from the side of the body (Fig. 109); in that position the palm of the hand looks forwards when the limb hangs by the side, upwards when the elbow is flexed to a right angle [*supinus* = lying on the back], and backwards when the elbow is acutely flexed.

The **prone position** is that in which the thumb is directed towards the side of the body, and the two bones of the forearm are crossed; the proximal end of the radius is still lateral to the ulna, but the radius is crossed in front of the ulna so that its distal end is on the medial side; the palm looks backwards or downwards or forwards according to the state of the elbow joint [*pronus* = inclined downwards, here referring to the palm when the elbow is flexed to a right angle].

When the upper limb hangs free and naturally by the side the palm of the hand looks towards the thigh as though the forearm were in a position midway between supination and pronation; but it is nearer the supine position than the prone; in the natural pendent position of the limb the whole limb is rotated in a medial direction at the shoulder joint, and that makes the forearm appear more prone than it really is; ready evidence of the rotation at the shoulder joint is afforded by the lateral epicondyle of the humerus; the epicondyle is felt, in that position, well round towards the front, instead of on the lateral aspect of the limb. When the forearm is brought into the position of complete supination, the medial rotation at the shoulder is at the same time undone, and the epicondyle is felt on the lateral aspect. The position of complete supination is, however, an unnatural one, and soon becomes uncomfortable; none the less, the structures are all described on the assumption that the limb is in the supine position, because, the radius and ulna being then parallel, the relations of all the other structures in the forearm can be more simply stated.

The **movement of supination** is the movement by which the forearm and hand are rotated from the position of pronation, or from the intermediate position, into

the position of supination; and the **movement of pronation** is the reverse. The movement of supination is the stronger; and screws and screwing instruments are made so as to be manipulated by supination of the right forearm.

When the upper arm is rotated the forearm rotates with it, but in the movements of simple supination and pronation the ulna remains practically stationary. It is the radius that is moved, and the hand is moved with the radius. The head of the radius rotates within the ring composed of the annular ligament and the radial notch of the ulna, while the distal end of the radius rotates round the head of the ulna and carries the hand with it. The actual movements in the living limb are not only greatly supplemented by rotation of the humerus at the shoulder joint, but are also slightly added to by movement at the wrist joint and intercarpal joints.

Carpus.

The skeleton of the **carpus** or **wrist** consists of *eight* small bones closely held together by ligaments, and arranged in two rows—a proximal and a distal. From lateral to medial side, the names of those in the **proximal row** are: os naviculare, os lunatum, os triquetrum, os pisiforme; and in the **distal row**: os multangulum majus, os multangulum minus, os capitatum, os hamatum.

The **pisiform bone** is the hard knob at the medial border of the front of the wrist. It is rather loosely attached and can be moved slightly from side to side if the hand is held slack; the sinew which can be seen and felt descending to it, along the medial border of the forearm, is the tendon of the flexor carpi ulnaris muscle.

The **other bones** of the wrist are so tightly bound together that, until the ligaments are cut, they form **one compact mass** with *six* surfaces—volar, dorsal, medial, lateral, proximal, and distal. (See Fig. 283, p. 333.)

The *proximal surface* is smooth, convex, and elongated from side to side; it articulates with the radius and the articular disc to form the radio-carpal or wrist joint. The *distal surface* is uneven and elongated from side to side; it articulates with the bases of the five metacarpal bones to form the carpo-metacarpal joints. The *medial surface* is small, and can be felt on the medial side of the wrist. The *lateral surface* also is small; it is partly palpable in the "anatomical snuff-box," and is partly hidden by the tendons in the volar boundary of that hollow; an artery, called the radial artery, crosses it obliquely, under cover of those tendons.

The *dorsal surface* is large and rough; it is convex from side to side, and is to a large extent concealed by tendons. The *volar surface* is large, and is concave from side to side; the concavity is greatly deepened by, and, indeed, is largely owing to, the shape and position of the bones at the sides. On the medial side there is the prominence due to the pisiform bone, and, distal to that, a hook-like process projects forwards from the os hamatum [*hamatus* = hooked]. On the lateral side a tubercle on the navicular bone and a ridge on the os multangulum majus project forward. The deep concavity is called the **carpal groove**; it is bridged across and converted into a **carpal canal** or tunnel by a very strong fibrous band, called the *transverse carpal ligament*, which holds the tendons proceeding to the thumb and fingers in their place in the groove.

Those projections can all be felt in the living hand. The **pisiform bone** has been referred to already. The **hook of the os hamatum** can be felt if deep pressure is made by the thumb of the other hand on the ball of the little finger, *i.e.* the fleshy eminence on the medial side of the palm; the pressure should be made at a point 15-25 mm. from the pisiform bone and on a line drawn from the pisiform towards the centre of the palm. A nerve can often be felt slipping from side to side on the hook; that is the ulnar nerve as it enters the palm.

The **tubercle of the navicular bone** can always be felt and often is a visible projection. The guide to its position is a tendon. In the distal half of the front of the forearm, about midway from side to side, the tendons of the palmaris longus and the flexor carpi radialis can be seen, close together, extending to the wrist; the tendon of the flexor carpi radialis is the more lateral of the two, and sometimes,

of the two, it alone is present. Where it passes out of sight at the wrist the tubercle of the navicular bone can be felt, partly under cover of the tendon and partly lateral to it, just proximal to the ball of the thumb.

The **ridge on the os multangulum majus** is not so easily felt. It is situated just distal to the tubercle of the navicular in the medial edge of the ball of the thumb, and pressure should be made there with the hand bent backwards; the bony resistance encountered there is the ridge; it may be felt as a prominence separate from the tubercle of the navicular, but the two often are felt as one continuous bony resistance.

If the student has a skeleton of the hand in which the carpal bones are strung or wired together he will be able to identify them from their position. If they are separate he may require the aid of a demonstrator, but should try himself to identify them by means of their chief characters, beginning with those that are more easily recognised.

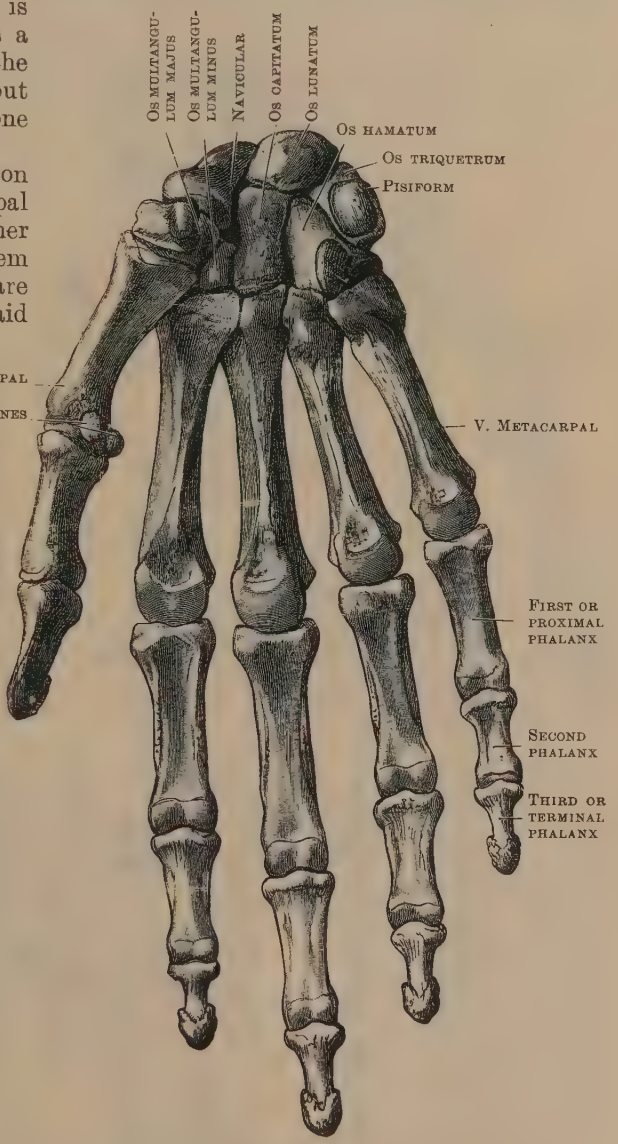

Fig. 202.—Volar Aspect of Bones of Right Hand.

The **pisiform bone** is the smallest of all. It resembles a large pea with a slice cut off [*pisum* = a pea].

The **os hamatum** has a large, compressed, curved process that juts forwards from its volar surface.

The **os capitatum** is usually the largest. Its proximal surface or end is smooth and rounded, resembling a head.

The **navicular** is one of the larger bones. It is somewhat comma-shaped, the tubercle being the bent, narrower end of the comma. Of its *articular* surfaces two are convex and one is concave in each direction, fitting the tip of a finger. The bone is called the "navicular" from a far-fetched resemblance to a boat given to it by that concave surface.

The **os lunatum** is one of the smaller bones. Its distal surface is markedly concave in one direction and fits the tip of a finger. On another surface (the lateral) it has an articular facet, shaped like a crescent moon, which gives the bone its name.

The **os multangulum majus** is medium in size. One of its articular surfaces is saddle-shaped; one of its non-articular surfaces has the prominent ridge mentioned before, with a groove alongside the ridge.

The os triquetrum and the os multangulum minus are the only two left. The **os triquetrum** is more or less pyramidal in shape [*triquetrus* = three-cornered], and

on one of its surfaces it has a circular, flat facet which occupies a great part of that surface but not the whole of it. The **os multangulum minus**, though very distinctive and very unlike the others, has no outstanding characters. It has four definite articular surfaces set almost at right angles to each other, and two non-articular surfaces, one of which is considerably larger than the other; when it is placed on that larger surface it has a fanciful resemblance to a Chinese boot.

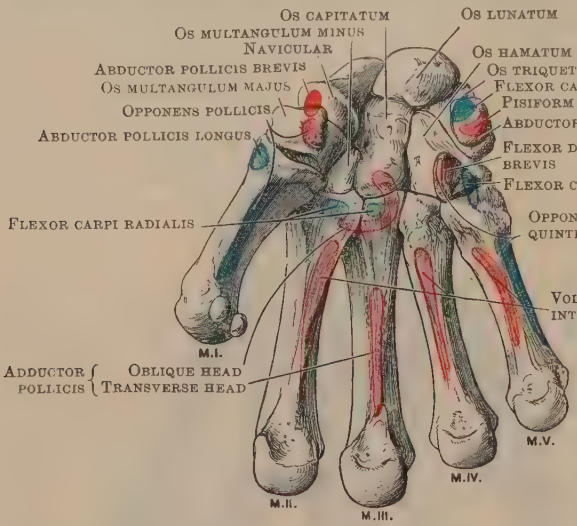

Fig. 203.—Volar Aspect of Bones of the Right Carpus and Metacarpus with Muscular Attachments mapped out.

Each of the carpal bones has six surfaces—proximal, distal, volar, dorsal, lateral, and medial.

Os Naviculare Manus.—The *proximal surface* is the larger of the two convex articular surfaces; it articulates with the distal end of the radius. The *distal surface* is the smaller of the two convex surfaces, and articulates with the proximal surfaces of the multangulum majus and minus. The *dorsal surface* is the narrow strip between the proximal and the distal surface, and is rough for the attachment of ligaments. The *medial surface* has a smooth area, concave in each direction, for articulation with the lateral surface of the head of the os capitatum, and above that there is a semilunar strip which articulates with the lateral surface of the os lunatum. The *lateral surface* is greatly reduced and is represented by the **tubercle.** The *volar surface* is concave in one direction and is the concave side of the comma; the concavity lodges the tendon of the flexor carpi radialis.

Os Lunatum.—The *distal surface* is the concave surface and articulates with the top of the head of the os capitatum. The *proximal surface*, directly opposite, is convex, and articulates with the distal end of the radius. The *lateral surface* is that which is shaped like a crescent moon, and it articulates with the navicular bone. The *medial surface*, directly opposite, is flat and nearly quadrilateral and articulates with the base or lateral surface of the os triquetrum. Between the medial and the distal surface there is usually a narrow strip which articulates with the upper edge of the os hamatum. The *volar* and *dorsal surfaces* give attachment to ligaments; the volar surface is convex and is larger and smoother than the dorsal surface.

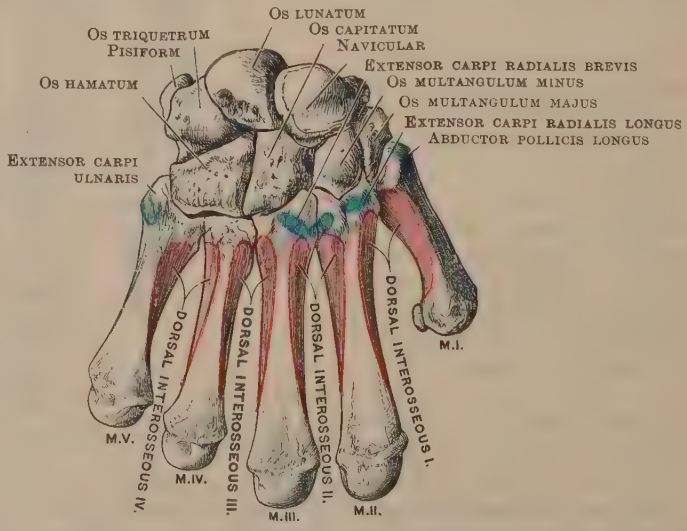

Fig. 204.—Dorsal Aspect of Bones of the Right Carpus and Metacarpus with Muscular Attachments mapped out.

Os Triquetrum.—The *volar surface* is nearly flat; its medial two-thirds is covered with a flat, circular facet which articulates with the pisiform bone. The *distal surface* is concavo-convex or undulating, and articulates with the medial surface of the os hamatum. The *lateral surface* is the base of the pyramid and articulates with the os lunatum. The *medial surface* is the blunted apex of the pyramid, and can be felt on the side of the wrist distal to the styloid process of the ulna and behind the pisiform bone. The *proximal* and *dorsal surfaces* are confluent, making one

uneven convex surface ; its lateral part has a facet which articulates with the triangular articular disc.

Os Pisiforme.—The *dorsal surface* articulates with the os triquetrum. The other surfaces are confluent, and give attachment to muscles and ligaments.

Os Multangulum Majus.—The *distal surface* is saddle-shaped and articulates with the base of the first metacarpal bone. The *proximal surface* is the small, smooth, concave surface opposite ; it articulates with the navicular bone. The *medial surface* has a large facet which is separated by a smooth ridge from the proximal surface, and articulates with the lateral surface of the os multangulum minus ; lower down there is a small facet for articulation with the base of the second metacarpal bone. The *volar*, *dorsal*, and *lateral surfaces* are non-articular ; the volar surface has an upstanding ridge at the lateral margin, and along the medial side of the ridge there is a well-defined narrow groove which lodges the tendon of the flexor carpi radialis. The lateral surface is continuous with the lateral aspect of the ridge, and the dorsal surface is directly opposite the volar.

Os Multangulum Minus.—Beginners find difficulty in identifying its surfaces. The *dorsal* and *volar surfaces* are both non-articular ; the volar surface is much the smaller. The other four surfaces are articular. The *distal surface* is the largest of those four ; it is concave from before backwards and convex from side to side ; it articulates with the base of the second metacarpal bone. From the volar surface a rough strip, which may be V-shaped, passes backwards between the distal and lateral surfaces, and so the *lateral surface* can be identified ; it articulates with the os multangulum majus. The *proximal surface*, opposite the distal, articulates with the navicular bone. The *medial surface* articulates with the lateral surface of the os capitatum.

Os Capitatum.—The *proximal surface* is the rounded top of the head, and articulates with the concave surface of the os lunatum. The *distal surface* is the base ; its greater part articulates with the base of the third metacarpal bone, but at the sides it articulates also with the second and the fourth. The *volar surface* is rough and protuberant. The *dorsal surface* also is non-articular, but is nearly flat. The *lateral surface* of the head is convex and articulates with the concave facet of the navicular bone ; lower down, on the lateral surface of the body, there is a facet for articulation with the medial surface of the os multangulum minus. The *medial surface* has a large facet, which includes the medial side of the head, for articulation with the lateral surface of the os hamatum.

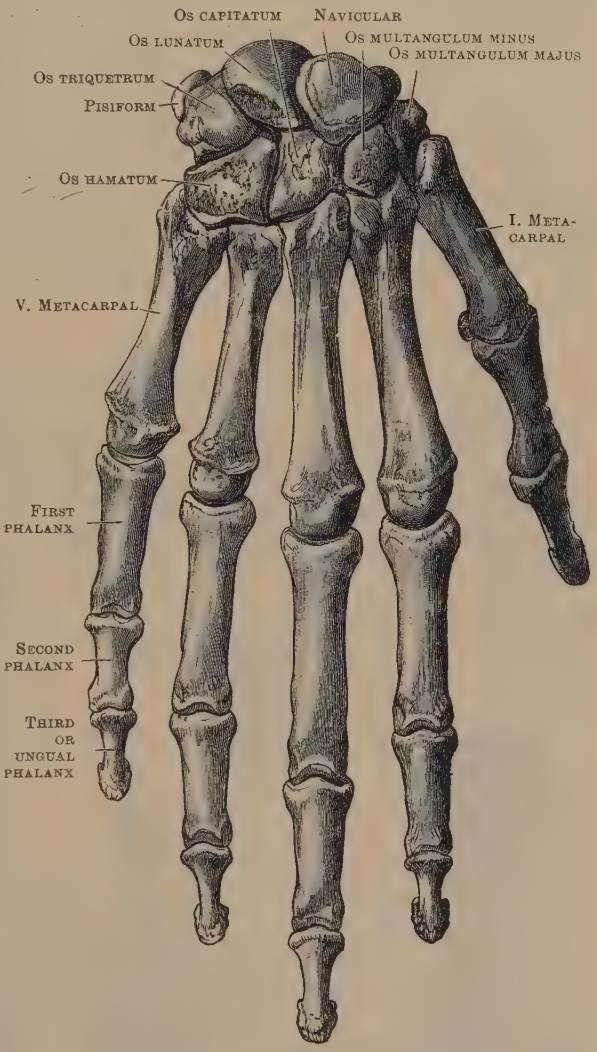

Fig. 205.—Dorsal Aspect of Bones of Right Hand.

Os Hamatum.—The hook juts forwards from the distal and medal part of the volar surface ; the concave side of the hook looks in a lateral direction. The body of the bone is shaped somewhat like a wedge. The base of the wedge is the *distal surface* ; it is concave from before backwards and convex from side to side ; it articulates with the bases of the fourth and fifth metacarpal bones, and usually an indication of subdivision into two corresponding parts can be made out. The *proximal surface* is reduced to a blunt border between the medial and lateral surfaces and is the edge of the wedge ; it articulates with the os lunatum. The distal and volar part of the *lateral surface* is rough ; the remainder is covered with a large facet for articulation with the os capitatum. The *medial surface* is wholly articular except at its distal margin, and is undulating ; it articulates with the distal surface of the os triquetrum, which is correspondingly concavo-convex. The *dorsal surface* is non-articular and fairly flat. The *volar surface*, also non-articular, bears the hook.

Attachments.—The pisiform is attached to the front of the os triquetrum by an articular capsule. The other seven bones are closely bound together by (1) volar intercarpal ligaments attached to their *volar* surfaces, (2) dorsal intercarpal ligaments attached to their *dorsal* surfaces, (3) interosseous intercarpal ligaments attached to the rough areas and edges of *contiguous surfaces*, and (4) ulnar and radial collateral intercarpal ligaments attached to the surfaces on the *ulnar and radial borders of the wrist.* The ulnar and radial collateral ligaments of the wrist joint also are attached to those surfaces, while the volar ligament of the wrist joint (volar radio-carpal) is attached to the volar surfaces of the *navicular bone* and *os lunatum*, and the dorsal ligament to the dorsal surfaces of the *navicular*, *lunatum*, and *triquetrum.* The *distal row* of bones is closely bound to the bases of the medial four metacarpal bones by dorsal and volar carpo-metacarpal ligaments, while the *os multangulum majus* is more loosely attached to the base of the first metacarpal bone by a separate articular capsule.

One end of the transverse carpal ligament is attached to the *pisiform* bone and the *hook* of the os hamatum, and the other end to the *tubercle of the navicular* bone and the volar surface of the *os multangulum majus*; an additional band called the volar carpal ligament connects the front of the transverse ligament with the *pisiform.* The dorsal carpal ligament stretches obliquely from the distal end of the radius to the *os triquetrum* and the *pisiform bone.*

The tendon of the flexor carpi ulnaris is inserted into the *pisiform bone*, but many of the tendinous fibres are continued onwards to the *hook* of the os hamatum and the base of the *fifth metacarpal* as two distinct strong bands called the piso-hamate and piso-metacarpal ligaments. The abductor digiti quinti muscle arises partly from the *pisiform bone.* The flexor digiti quinti brevis and the opponens digiti quinti arise partly from the *hook* of the os hamatum. The abductor pollicis brevis arises in great part from the *tubercle of the navicular* and the *ridge* on the *os multangulum majus*; and portions of the flexor pollicis brevis and opponens pollicis also arise from that ridge. A portion of the oblique head of the adductor pollicis arises from the volar surfaces of the *multangulum majus* and *minus* and *capitatum.*

Metacarpus.

The **metacarpus** is the skeleton of the hand proper [*μετά* (meta) = next after; *καρπός* (carpos) = wrist]. It consists of five separate bones, called **metacarpal bones,** one corresponding to each digit. They are named by number, *first, second,* etc., beginning with the one corresponding to the thumb. Each of them is a miniature long bone, possessing a **body** or shaft and **two extremities.** Each is slightly concave lengthwise on the volar or **palmar** surface; the **distal end** is the rounded end and is called the *head*; the

Fig. 206.—First Right Metacarpal Bone.

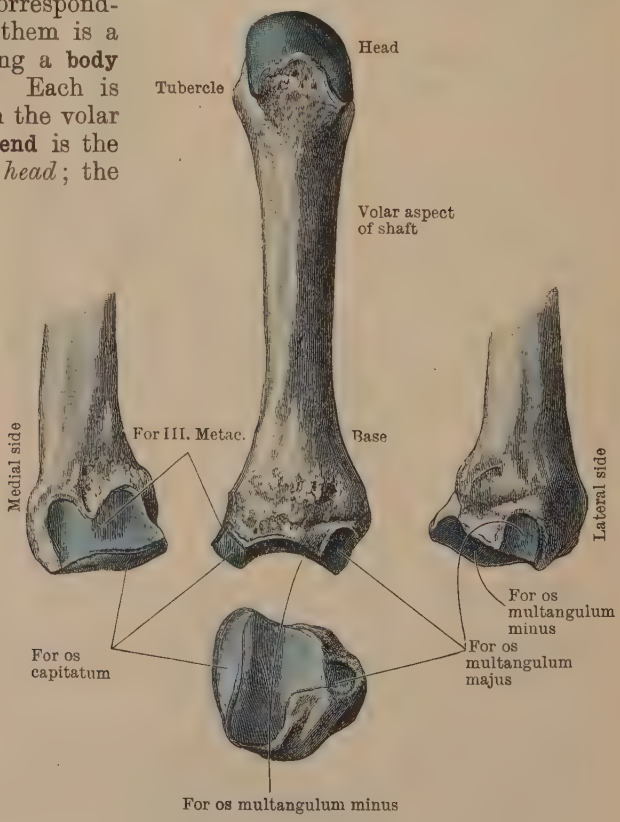

Fig. 207.—Second Right Metacarpal Bone.

proximal end is called the *base*. The lateral surface can be distinguished from the medial after the base is examined.

The corresponding bones of the **foot** are called *metatarsal bones*; they are not at all unlike the metacarpals, and a beginner may mistake the one for the other if they are loose and mixed. The metacarpals are between two and three inches long, and are rather shorter than the metatarsals, but are relatively thicker and less compressed; they have on the dorsal surface an elongated, nearly flat, triangular area with its base at the distal end of the bone; and the distal end is larger, conforming to the larger size of the finger. Those distinctions do not apply to the first metacarpal and metatarsal, but the first metacarpal is the shortest of all those bones, and the first metatarsal is the thickest. A beginner may also mistake the *proximal phalanx* of a finger for a metacarpal bone; but the phalanx is smaller, smoother, and more regular in contour, and its smaller end or head is distinctly pulley-shaped.

Capitulum.—The **distal ends** or **heads** of the metacarpal bones are familiar as the proximal row of knuckles. Each head has pits and tubercles at the *sides* for the attachment of ligaments; the *distal surface* is convex and smooth for articulation with the base of the proximal phalanx when the digit is straightened; the articular surface extends much further on to the palmar or volar surface than on to the dorsal, for when a digit is *flexed*, as when the hand is closed, the phalanx articulates with the palmar surface of the head. When a finger is *extended* it is in straight line with the hand, and the phalanx articulates with the distal surface of the head. The degree to which the finger can be *dorsiflexed*, *i.e.*, bent backwards beyond the straight line, varies considerably in different people, and the greater the degree of dorsiflexion possible the more does the articular surface extend on to the dorsal aspect of the head of the metacarpal bone.

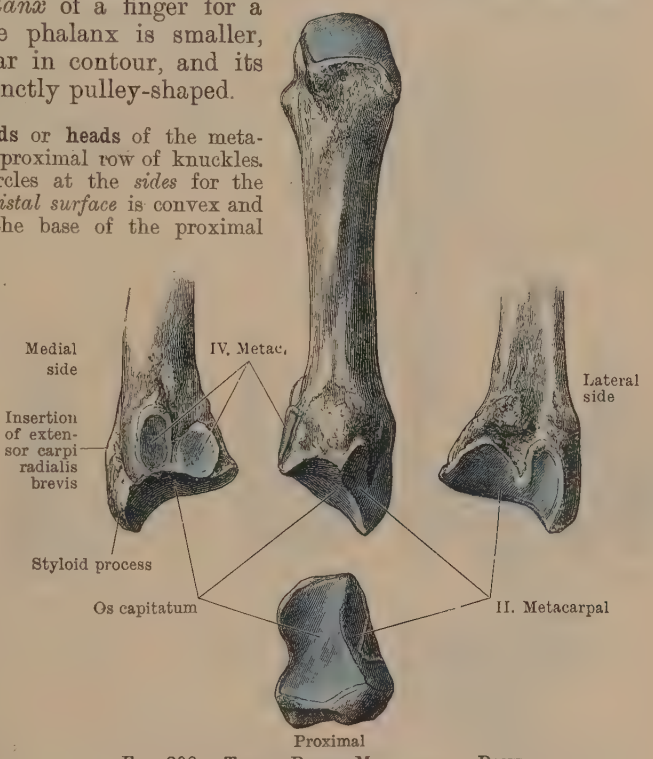

FIG. 208.—THIRD RIGHT METACARPAL BONE.

NOTE.—The whole bone shows its volar aspect.

Corpus.—The **body** or shaft is slightly curved so that it is concave towards the palm. It has a *dorsal surface* which can be felt on the back of the hand, and a *medial* and a *lateral surface*. The blunt *volar border*, which separates the lateral and medial surfaces, broadens out into a surface near each end.

Basis.—The **proximal end** or **base** of a metacarpal bone articulates with the carpus by its *proximal surface*, which is therefore smooth; the bases of the medial four articulate with each other by their *sides*, and therefore there are articular facets on the sides. The readiest means of identifying the individual metacarpal bones is found in the base, and in the medial four the base provides the means of distinguishing the lateral from the medial surface.

The **first** metacarpal bone is shorter than the others. It is slightly compressed from before backwards, so that the surfaces of the **body** are usually regarded as two—a *dorsal* and a *palmar*; but the palmar surface is divided by a blunt ridge into a radial and an ulnar half, of which the radial or *lateral* half is slightly the larger. The **base** has no facets on its *sides*; its *proximal surface* is saddle-shaped and articulates with the saddle-shaped distal surface of the os multangulum majus. The *volar surface* of the **head** has two shallow grooves which articulate with the sesamoid bones (p. 247).

The **second** metacarpal has a wide groove or *notch* on the *proximal surface* of its **base**. The notch articulates with the os multangulum minus. The ridge forming the medial boundary of the notch articulates with the os capitatum; the pointed tubercle on the *lateral side* articulates with the os multangulum majus. There is a facet on the *medial side* of the base for articulation with the lateral surface of the base of the third metacarpal.

The **third** metacarpal has a thick pointed projection, called its **styloid process**, which juts upwards from the junction of the *dorsal* and *lateral* surfaces of the **base**, and by that the **lateral**

side can be recognised. The *proximal surface* of the base articulates with the os capitatum, and on the sides there are facets for articulation with the second and fourth metacarpals.

The **fourth** metacarpal has a cubical **base**. Its *proximal surface* is nearly flat and articulates chiefly with the os hamatum and slightly with the os capitatum. There are two nearly circular facets on the *lateral surface* of the base for articulation with the third metacarpal, and a single facet on the *medial surface* for articulation with the fifth.

The **fifth** metacarpal, being the bone on the side of the hand, has a facet on only one side of the **base**, and that is on the *lateral surface* for articulation with the fourth; there is a tubercle on the *medial surface*, while the *proximal surface* is convex from before backwards and slightly concave from side to side, and articulates with the os hamatum.

Attachments.—The **base** of the *first metacarpal* is attached to the os multangulum majus by an articular capsule. The *other four* are bound to the carpus by volar and dorsal carpo-metacarpal ligaments attached to their volar and dorsal surfaces; they are bound to each other by volar and dorsal ligaments and by interosseous ligaments attached to the rough parts of their sides; the **base** of the *fifth* has two additional ligaments—the piso-metacarpal attached to the volar surface, and an ulnar collateral stretching from the side of the carpus to the tubercle on the medial side. The **head** of each metacarpal is attached to the proximal phalanx by an articular capsule; the fibrous layer of the capsule is thickened at the sides to form radial and ulnar collateral ligaments, which are attached to the *sides* of the head, and it is thickened in front to form what is called the volar accessory ligament, which is attached loosely to the *volar*

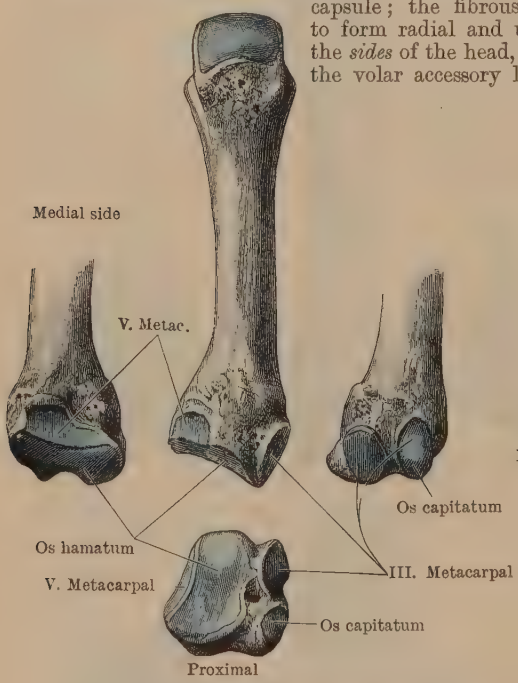

Fig. 209.—Fourth Right Metacarpal Bone.

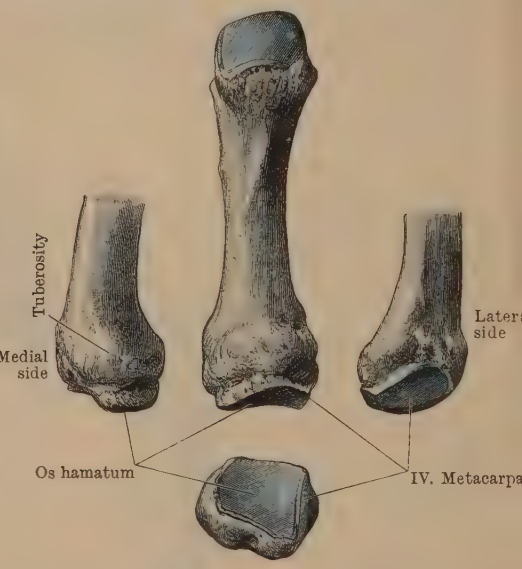

Fig. 210.—Fifth Right Metacarpal Bone.

Note.—The whole bone presents its volar surface.

surface just proximal to the smooth articular part, while, on the back, the fibrous layer is either fused with or is replaced by the extensor tendon overlying the joint.

The abductor pollicis longus tendon is inserted into the radial and volar surfaces of the **base** of the *first*; the flexor carpi radialis tendon into the volar surface of the base of the *second* and slightly into the base of the *third* also; the extensor carpi radialis longus tendon into the radial part of the back of the base of the *second*; the extensor carpi radialis brevis tendon into the radial part of the base of the *third* at the root of the *styloid process*, and slightly also into the base of the *second*; the extensor carpi ulnaris tendon into the back and ulnar side of the *fifth*. The interosseus primus volaris arises from the ulnar side of the base of the *first*; part of the oblique head of the adductor pollicis from the volar surfaces of the *second*, *third*, and *fourth*.

The opponens pollicis is inserted into the radial half of the volar surface of the **body** of the *first*; the opponens digiti quinti into the ulnar surface of the *fifth*. The four dorsal interosseous muscles lie between the metacarpal bones and are attached to *all* of them; each arises by two heads which spring from the adjacent sides of the two metacarpal bones between which the muscle lies. The three volar interosseous muscles lie in front of the dorsal interosseous; they arise by single heads from the *second*, *fourth*, and *fifth*. The transverse head of the adductor pollicis arises from the volar border of the *third*.

The structures attached to each individual metacarpal bone are as follows:—

First Metacarpal Bone.—**Base**: Articular capsule; abductor pollicis longus; interosseus primus volaris. **Body**: Opponens pollicis; first dorsal interosseous. **Head**: Volar accessory and collateral ligaments.

Second.—**Base**: Carpo-metacarpal and intermetacarpal ligaments; flexor carpi radialis,

extensor carpi radialis longus and brevis; oblique head of adductor pollicis. **Body**: First and second dorsal interosseous, first volar interosseous. **Head**: Volar accessory and collateral ligaments. (Volar interossei are differently numbered in chapter on Muscles, p. 397.)

Third.—**Base**: Carpo-metacarpal and intermetacarpal ligaments; flexor carpi radialis, extensor carpi radialis brevis; oblique head of adductor pollicis. **Body**: Second and third dorsal interosseous, transverse head of adductor pollicis. **Head**: Volar accessory and collateral ligaments.

Fourth.—**Base**: Carpo-metacarpal and intermetacarpal ligaments; oblique head of adductor pollicis. **Body**: Third and fourth dorsal interosseous, second volar interosseous. **Head**: Volar accessory and collateral ligaments.

Fifth.—**Base**: Carpo-metacarpal (including piso-metacarpal and ulnar collateral) and intermetacarpal ligaments; extensor carpi ulnaris. **Body**: Fourth dorsal interosseous, third volar interosseous; opponens digiti quinti. **Head**: Volar accessory and collateral ligaments.

Phalanges Digitorum Manus.

Each **phalanx** is a miniature long bone possessing a **body** or shaft and **two ends** [φάλαγξ (phalanx) = a round log or roller]. The **proximal** end is the larger end and is called the *base*; the **distal** end is called the *head*. The **body** is markedly *convex* from side to side on its *dorsal* surface and nearly flat on the *palmar* surface. There is little distinction between the lateral and medial sides of a phalanx.

The **first** phalanx of a digit is the largest; the proximal surface of its **base** is hollowed out as a single concavity, and its **head** is pulley-shaped. The **head** of the **second** also is pulley-shaped, but its **base**, since it articulates with the head of the first, is the reverse of a pulley, having two shallow concavities with a low intervening ridge; that distinguishes the second phalanx of a large hand from the first phalanx of a small hand. The **base** of the **third** phalanx also is the reverse of a pulley, but the third phalanx is the smallest and its **head** is non-articular.

The **thumb** has only *two* phalanges. They are shorter and broader than those of the fingers; the **first** resembles the first of a finger, but the **second** resembles the third phalanx of a finger.

The phalanges of the toes should not be mistaken for those of the fingers. The first phalanx of a toe is about the same length as the second phalanx of a finger, but its body is much thinner and its base is relatively large. Both of the phalanges of the big toe are so thick, and the second and third phalanges of the other toes are so short, that they cannot be mistaken.

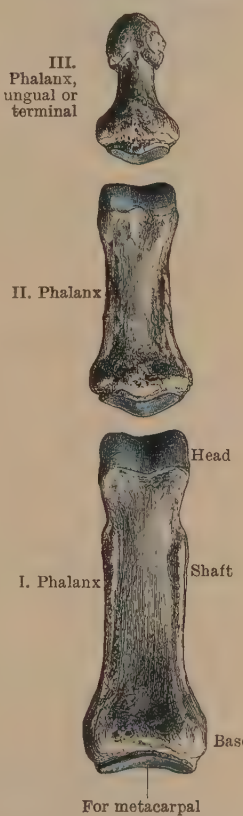

FIG. 211.—PHALANGES OF A FINGER (Volar Aspect).

The **first phalanx** of a finger measures 35-45 mm. in length, and is curved so that it is slightly concave lengthwise on its *volar* surface. The concave *proximal surface* of its **base** articulates with the convex head of the metacarpal; the *sides* of the base are slightly enlarged and give attachment to muscles and ligaments. The convex *dorsal surface* of the **body** is separated from the flat *palmar surface* by sharp margins. The pulley-shaped **head** articulates with the base of the second phalanx; the articular surface extends much further on to the volar aspect than on to the dorsal, just as on the head of a metacarpal bone and for the same reason. The *sides* of the head show shallow pits for the attachment of ligaments.

The **second phalanx** measures 25-30 mm. Its **body** and **head** resemble those of a first phalanx, but the **base** differs in the way already mentioned. The **third phalanx** is very small and is not curved. Its **base** is relatively large, and resembles that of a second phalanx. The **body** is short. The **head** is slightly expanded sideways, is non-articular, and is very rough on its volar surface.

Attachments.—The **base** of the *first* phalanx is attached to the metacarpal bone by a joint capsule, the characters of which are briefly indicated in the account of the metacarpals; the volar accessory ligament is attached firmly to the volar surface of the base, and the collateral ligaments to its sides. The *second* phalanx is attached to the first and the third by similar capsules. Each

of the four tendons of the extensor digitorum communis spreads out on the back of a first phalanx to form an *extensor expansion* which is inserted into the back of the base of the *second* and *third* phalanges of a finger; the tendon of the extensor indicis proprius joins the tendon of the communis for the forefinger, and the tendon of the extensor digiti quinti proprius joins that for the little finger; the tendons of the interossei and of the lumbricales are inserted partly into the sides of the base of the *first* phalanx, but chiefly into the extensor tendon of a finger; therefore each *extensor expansion* is made up of several tendons. Each of the four tendons of the flexor digitorum sublimis is inserted into the margins of the **body** of a *second* phalanx. Each of the four tendons of the flexor digitorum profundus is inserted into the volar surface of the **base** of a *terminal* phalanx. The abductor digiti quinti and the flexor digiti quinti brevis are inserted into the ulnar side of the **base** of the *first* phalanx of the *little finger*.

The tendons of the long flexors of a digit are held in place along its volar surface by a fibrous strap, called the fibrous flexor sheath, the edges of which are attached to the margins of the **body** of the *first* phalanx of the *thumb* and of the *first* and *second* phalanges of the *fingers*, while its distal extremity is attached to the volar surface of the *terminal* phalanx, just beyond the insertion of the flexor tendon.

The structures attached to the individual phalanges are as follows:—

First phalanx.—Of forefinger. Articular capsules; flexor sheath; first dorsal and first volar interosseous, first lumbrical.—**Of middle finger.** Capsules; sheath; second and third dorsal interosseous, second lumbrical.—**Of ring finger.** Capsules; sheath; second volar and fourth dorsal interosseous, third lumbrical.—**Of little finger.** Capsules; sheath; third volar interosseous, fourth lumbrical, abductor digiti quinti, and flexor digiti quinti brevis.

Second phalanx of each finger.—Articular capsules; flexor sheath; extensor expansion, flexor digitorum sublimis.

Third phalanx of each finger.—Articular capsule; flexor sheath; extensor expansion; flexor digitorum profundus.

Thumb.—The extensor pollicis brevis is inserted into the *dorsal* surface of the **base** of the **first phalanx**; the flexor brevis and abductor brevis together into the *radial* side of the base; the adductor and interosseus primus volaris into the *ulnar* side. The extensor longus into the *dorsum* of the **base** of the **second phalanx**; and the flexor longus into the *volar* surface. The fibrous flexor sheath is attached to the *margins* of the **body** of the **first phalanx** and the *volar surface* of the **second**. Articular capsules, like those of the fingers, connect the first phalanx with the metacarpal bone and the second phalanx.

Ossification of Bones of Hand.—The **carpus** is cartilaginous at birth. Each carpal bone has **one** centre; ossification is completed between 20 and 25.

	Capitatum.	Hamatum.	Triquetrum.	Lunatum.	Naviculare.	Multangulum majus.	Multangulum minus.	Pisiforme.
Centre appears	1st year	1st	3rd	5th	5th	5th	7th	10th

Metacarpus.—The *primary* centre, one for each metacarpal bone, appears in the ninth week of fœtal life. The metacarpal bones are well ossified at birth.

Secondary Centre.	Appears at	Epiphysis joins at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For base of first	3rd year	20	Outside.
For head of others	3rd ,,	20	Outside.

The **first** differs from the others in having the epiphysis at the base instead of at the head, possibly because movement is more free at the carpo-metacarpal joint of the thumb than at the metacarpo-phalangeal joint, while the reverse is the case at the joints of the other metacarpal bones. In rare cases an epiphysis appears in the head of the first at the seventh year; and the base of the second may have an epiphysis.

Phalanges.—The *primary* centre for each appears between the eighth and the twelfth week of fœtal life. At birth the phalanges are well formed.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For base	3rd year	Rather before 20	Outside.

The **ungual phalanges** are the first bones of the hand to ossify, and their primary centres appear near their distal ends instead of in the middle.

Structure and Variations of Bones of Hand.—**Carpal bones** have the typical structure of short bones. **Metacarpal bones** and **phalanges** have the structure of long bones.

Occasionally one of the carpal bones is divided, giving rise to an additional bone in the carpus. The **os centrale**, though normally a separate bone in the carpus of most mammals, and represented by a separate cartilage in the earlier months of fœtal life, is almost always fused with the navicular bone, but sometimes it is a separate ossicle on the back of the carpus between the navicular, the capitatum, and the multangulum minus. X-ray photographs sometimes reveal what appear to be small additional nodules in the carpus. Diminution of the number of carpal bones is usually due to fusion caused by disease. The *styloid process* of the third metacarpal bone may have an epiphyseal centre, and may be a separate bone, or may be fused with the os capitatum or the os multangulum majus, instead of with the metacarpal.

Sometimes an *ungual phalanx* is bifurcated. The thumb may have three phalanges. Occasionally a phalanx is absent or has been absorbed by another phalanx. A case has been recorded in which the first phalanx had an epiphysis at its head as well as at its base.

FIG. 212.—RADIOGRAPHS OF FŒTAL HANDS.

1. About 10 weeks. The centres for terminal phalanges and medial four metacarpal bones are seen.
2. A little later. The centres for the first metacarpal, for the proximal row of phalanges, and for the second phalanx of middle and ring fingers are seen.
3. During the 3rd month. All the primary centres for metacarpal bones and phalanges are seen.
4. About the fourth to fifth month. 5. About the sixth to seventh month.

FIG. 213.—AT BIRTH.

Carpus is still entirely cartilaginous.

Compare this with the tarsus at birth, in which the tarsus is shown in part already ossified.

Ossa Sesamoidea.

The **sesamoid bones** of the hand are two very small nodules that lie in the tendons of insertion of the flexor pollicis brevis and the adductor pollicis. They are blended with the volar accessory ligament of the metacarpo-phalangeal joint, and play against the volar surface of the head of the metacarpal bone. Occasionally little nodules are found also in the volar accessory ligament of the other metacarpo-phalangeal joints and in the interphalangeal joint of the thumb.

BONES OF THE LOWER LIMB.

The **lower limb** or **inferior extremity** includes the hip and buttock, the thigh, the leg, and the foot (Figs. 109, 110, pp. 92 and 93).

The **hip** (*coxa*), above and at the side, and the **buttock** (*natis*), below and behind, make up the **gluteal region**, which extends from the waist and the small of the back down to the level of the horizontal crease that limits the buttock below; the crease is called the *gluteal fold*; the interval between the buttocks is called the *natal cleft* [γλουτός (glūtos) = *natis* = buttock]. The lower end of the trunk, between the thighs and between the buttocks, is called the *perineum* [περίνεος (perineos) = the perineum: derivation uncertain].

The skeleton of the hip and buttock of each side is a single bone called the **hip bone** or os coxæ. It forms part of the framework of the trunk also, for the

right and left hip bones, together with the sacrum and the coccyx, form the bony walls of the pelvis; and the hip bone is sometimes referred to as the *pelvic girdle.* (The sacrum and coccyx are the lowest subdivisions of the backbone; the pelvis is the lower subdivision of the abdomen or belly, and the perineum is included in the pelvis.)

The **thigh** (*femur*) extends from the gluteal region to the knee. On the lateral[1] side it is continuous with the hip; posteriorly it joins the buttock at the gluteal fold; on the medial side it joins the perineum, which separates it from the other thigh; anteriorly it joins the anterior wall of the abdomen and reaches a higher level than it does behind; the depression between the front of the thigh and the front of the abdomen is the *groin* or *inguinal region* [*inguen* = groin, from *inquinare* = to stain].

The bone of the thigh is called the **femur.** At its proximal end the femur articulates with the hip bone to form the *hip joint.* At the knee joint the distal end of the femur articulates (1) with the tibia or shin bone, which is the larger of the two bones of the leg, and (2) with the patella or knee cap—the small bone that lies in the front of the knee joint. The hollow at the back of the knee is the ham or *popliteal fossa* [*poples* = the hough; the ham of the knee].

The term **leg** (*crus*) is often applied to the whole free part of the lower limb, but in Anatomical text-books it is limited strictly to the segment between the knee joint and the ankle joint. The two bones of the leg are called the **tibia** and the **fibula.** They articulate with each other at their proximal and distal ends, and the joints so formed are called the *tibio-fibular joints.* The tibia articulates with the femur at the *knee joint,* but the fibula does not do so; the tibia and fibula both articulate with one of the bones of the foot, called the talus, to form the *ankle joint.*

The **foot** (*pes*) is joined to the leg at the ankle joint. It consists of the foot proper and the toes. The **foot proper** includes all the region from the point of the heel to the roots of the toes. Its upper surface is called the *dorsal surface* or *dorsum* of the foot; the *sole* is often called the *plantar surface* [*planta* = the sole]. The foot proper consists of (1) the *tarsus,* which is the hinder half of the foot proper, and corresponds to the carpus or wrist, and (2) the *metatarsus,* which is the half next the toes, and corresponds to the metacarpus or hand proper.

The bones of the **tarsus** are seven in number; they are named collectively the **tarsal bones,** and each has its own name besides; they articulate with one another, forming *inter-tarsal joints.* They are arranged in two rows—two bones in the first row and four bones in the second row—and an intermediate bone between the rows. The bones of the second row are placed side by side; the bones of the first row are placed one above the other, and the upper one—the talus—articulates with the bones of the leg at the *ankle joint.*

The bones of the **metatarsus** are called **metatarsal bones.** There are five of them, placed side by side, one corresponding to each toe. They are named by number: **first** metatarsal, **second,** etc., beginning with the one that corresponds to the big toe. The proximal or posterior ends of the metatarsal bones articulate (1) with the second row of tarsal bones, forming *tarso-metatarsal joints,* and (2) with each other, side by side, forming *inter-metatarsal joints.*

Toes or **Digits.**—The great toe is called the **hallux** [probably from *allex* = thumb or great toe]. The other toes are usually designated by number—**second, third,** etc.

The bones of the toes are called **phalanges.** The great toe has two phalanges, named the proximal or **first** phalanx and the distal or **second** phalanx. Each of the other toes has three phalanges—proximal, middle, and distal, or **first, second,** and **third.** The distal phalanx is sometimes called the *ungual phalanx,* because the nail (*unguis*) is associated with it. The first phalanx of a digit articulates with the distal end of the corresponding metatarsal bone to form a *metatarso-phalangeal joint*; and the second phalanx articulates with the first and the third, forming *inter-phalangeal joints.*

[1] Definitions of terms are given on pp. 4, 5, 87.

Os Coxæ.

The **hip bone** is the broadest bone in the skeleton. It is large, expanded, and unevenly compressed. On one side of it there is a deep cup or cavity with a broken rim; the cavity is called the **acetabulum**, and near it there is a large aperture called the **obturator foramen.**

The hip bone lies in the side wall and the anterior wall of the pelvis. In the anterior wall it articulates with its fellow of the opposite side to form a joint called the *symphysis pubis*; posteriorly the hip bone articulates with the side of the sacrum, which lies in the back wall of the pelvis between the two hip bones, and the joint is called the *sacro-iliac joint.*

The hip bone consists of three originally distinct bones which in the adult are fused together at the acetabulum. The three bones or parts are named the os ilium, the os ischii, and the os pubis, but those names are usually shortened to *ilium*, *ischium*, and *pubis.*

The **ilium** is the largest and broadest of the three parts. It is the uppermost part of the hip bone; and the bone should be held in the hand so that this broad part is uppermost, and the deficient side of the acetabulum looks directly downwards. The **ischium** is the thick, three-sided part below and behind the acetabulum and behind the obturator foramen; from the lower end of the ischium a broad, fairly flat bar of bone, called the *ramus of the ischium*, projects forwards, forming the lower boundary of the obturator foramen, and joins the pubis. The **pubis** is the remaining part of the hip bone, and forms the other boundaries of the obturator foramen. The pubis has three main parts: (1) an expanded part in front, commonly called the *body* of the pubis; (2) a compressed bar of bone, called the *inferior ramus* of the pubis, which extends backwards from the body and fuses with the ramus of the ischium; (3) a thicker bar, called the *superior ramus*, which extends from the body to the acetabulum.

The position of parts is roughly as follows: the ilium is the upper part; the ischium is the lower and posterior part; the pubis is the lower, anterior, and medial part; the acetabulum is on the lateral surface; the obturator foramen is below and medial to the acetabulum.

Os Ilium.—The **ilium** is "the bone of the flank" [*ilia* (plural) = the flank]. It lies below the waist in the uppermost part of the hip. It is large, compressed, and fluted, and possesses two ends, three borders, and three surfaces.

The two **ends** are upper and lower. The **lower end** forms the upper part of the acetabulum, and is fused there with the ischium and the pubis.

The **upper end** is scarcely recognisable as an end, for the ilium in Man is so expanded that the upper end is drawn out like the wide end of an open fan and resembles a border; it is called the **iliac crest.** The crest is curved like the *italic* letter *f*; the curve of the anterior half is convex in the lateral direction, and the curve of the posterior half is convex in the medial direction. The anterior and posterior ends of the crest are named, respectively, the **anterior superior iliac spine** and the **posterior superior iliac spine.** The margins of the crest are called its *outer* and *inner lips*; the interval between the lips is called the *intermediate line.* Two or three inches behind the anterior superior spine the crest is thicker than it is elsewhere; the thickening affects the outer lip, producing a low prominence on it called the **tubercle of the crest.**

The iliac crest can be felt from end to end in the living body, along the lower boundary of the waist. By tracing the crest forwards one can locate the anterior superior spine, and can almost grip it between finger and thumb when the muscles attached to it are relaxed—as they are when one is sitting. The tubercle of the crest is easily felt, two or three inches behind the anterior spine. The posterior superior spine is not distinctly palpable in the living body like the anterior spine, but its position can always be recognised by a dimpling of the skin overlying it; the dimple is seen above the buttock about two finger-breadths from the median plane, and the spine is the bone felt in its floor; it is on a level with the second spine of the sacrum and the middle of the sacro-iliac joint. The highest point of

the crest is about its middle point, one or two inches behind the tubercle of the crest, and is on a level with the fourth lumbar vertebra; the tubercle of the crest is the highest point that can be seen when the body is examined from the front, and is on a level with the fifth lumbar vertebra.

The **borders** of the ilium are anterior, posterior, and medial.

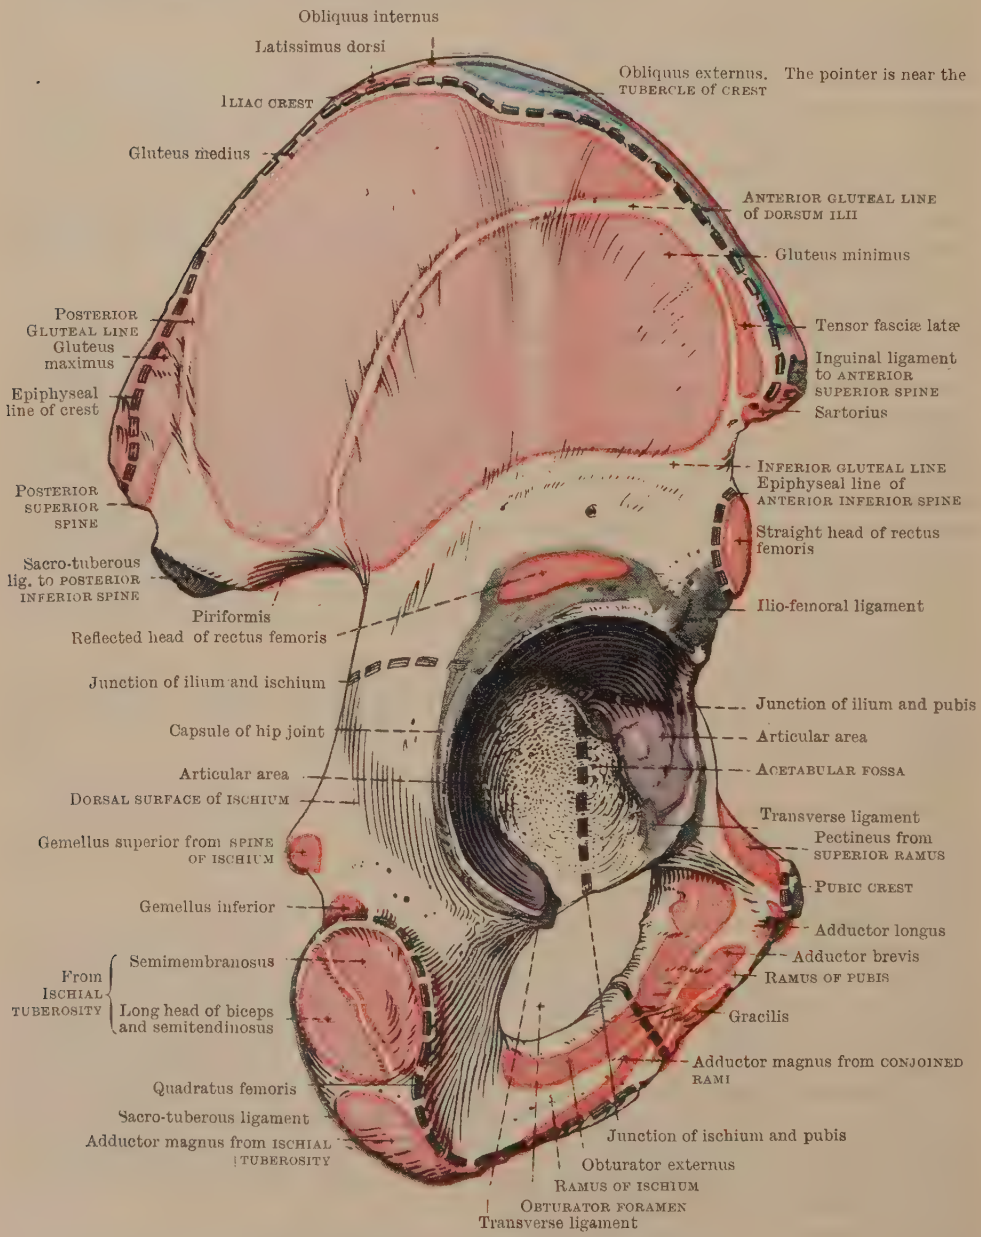

FIG. 214.—LATERAL ASPECT OF RIGHT HIP BONE.

The **anterior border** begins at the anterior superior spine and extends downwards and backwards to end at the anterior margin of the acetabulum. On the anterior border, a little above the acetabulum, there is a considerable prominence called the **anterior inferior iliac spine**. About an inch medial to the lower end of the anterior border, in front of the acetabulum, there is a low diffuse swelling called the *ilio-pectineal eminence*; it marks the region where ilium and pubis fuse.

The **posterior border** begins at the posterior superior spine and runs in an undulating manner downwards and forwards to end just above the level of the middle of the acetabulum, where it becomes continuous with the posterior border of the ischium. At a point about an inch below the posterior superior spine, the posterior border makes an abrupt bend forwards; that point is called the **posterior inferior iliac spine.** The wide notch which is bounded by the part of the posterior border below the inferior spine and by the adjoining part of the posterior border of the ischium is called the **greater sciatic notch.**

The **medial border** is a ridge on the medial aspect of the ilium. It begins at the crest at the point where the posterior half of the crest is most convex, and it ends at the ilio-pectineal eminence. Its *lower half* is smooth and blunt; its *upper half* separates a rough region behind from a smooth, concave region in front.

The three **surfaces** of the ilium are the dorsal or lateral, the sacro-pelvic, and a third surface moulded into a large concavity called the iliac fossa.

The **iliac fossa** is situated between the anterior and medial borders. It is smooth and concave and lodges a large muscle called the iliacus.

The **sacro-pelvic surface** is the region between the posterior and medial borders. Its uppermost and largest part is very rough for the attachment of muscles and ligaments, and is called the **iliac tuberosity.** The middle part usually has a sharply defined outline, and is called the **auricular surface,** because its shape resembles that of an ear (though turned the wrong way); it articulates with a corresponding "auricular" surface on the sacrum to form the *sacro-iliac joint,* but though it is an articular surface it is uneven and rather rough; the lobe of the "ear" is the posterior inferior iliac spine. The lowest part of the sacro-pelvic surface is smooth; it is the area between the lower smooth part of the medial border and the bottom of the greater sciatic notch; it forms part of the side wall of the pelvis minor, which is the basin-like, lower part of the pelvis.

The **dorsal** or **lateral surface** of the ilium, often called the **dorsum ilii,** is the wide, concavo-convex or undulating surface above the acetabulum, between the anterior and posterior borders. It is divided into areas by three curved ridges, called gluteal lines, which vary in distinctness with the muscularity of the subject. The *inferior gluteal line* begins at the anterior border above the anterior inferior spine and curves backwards, about an inch above the acetabulum, towards the greater sciatic notch. The *anterior gluteal* line begins at the crest about an inch behind the anterior superior spine and arches across the middle of the surface towards the greater sciatic notch. The *posterior gluteal line* begins at the crest two or three inches in front of the posterior superior spine and curves downwards to the greater sciatic notch.

Os Ischii.—The **ischium** is the thick prismatic part of the hip bone below and behind the acetabulum. In the upright sitting posture the body rests on the two ischia [*ἰσχίον* (ischion) = buttock. The adjective *ischiadic* has been reduced by time to *sciatic*].

The ischium has two ends, three borders, three surfaces, and a ramus.

The two **ends** are upper and lower. The **upper end** forms part of the acetabulum and is fused with the ilium and the pubis. The **lower end** is free and rough; the rough lower extremity of the ischium, together with the rough lower part of its dorsal surface, is called the **ischial tuberosity.** The **ramus** of the ischium is the compressed bar of bone that projects from the lower end of the ischium and fuses with a ramus of the pubis below the obturator foramen.

The **borders** of the ischium are anterior, posterior, and lateral. The **anterior border** forms one of the boundaries of the obturator foramen. The **posterior border** is continuous with the posterior border of the ilium at the lower part of the greater sciatic notch and extends to the lower end of the ischium; near its upper end a sharp triangular process, called the **ischial spine,** juts backwards and medially from it. The spine forms the lowest part of the boundary of the greater sciatic notch and the upper boundary of the **lesser sciatic notch,** which is the smooth shallow concavity between the ischial spine and tuberosity. The **lateral border** extends from the posterior margin of the acetabulum to the lower end of the ischium; its lower part is the lateral margin of the tuberosity; between the

tuberosity and the acetabulum it is almost obliterated by a short, wide, horizontal groove.

The **surfaces** of the ischium are dorsal, pelvic, and femoral. The **dorsal surface** is continuous with the dorsal surface of the ilium across the back of the acetabulum, and its lower part is occupied by the rough tuberosity. The **pelvic surface** is the

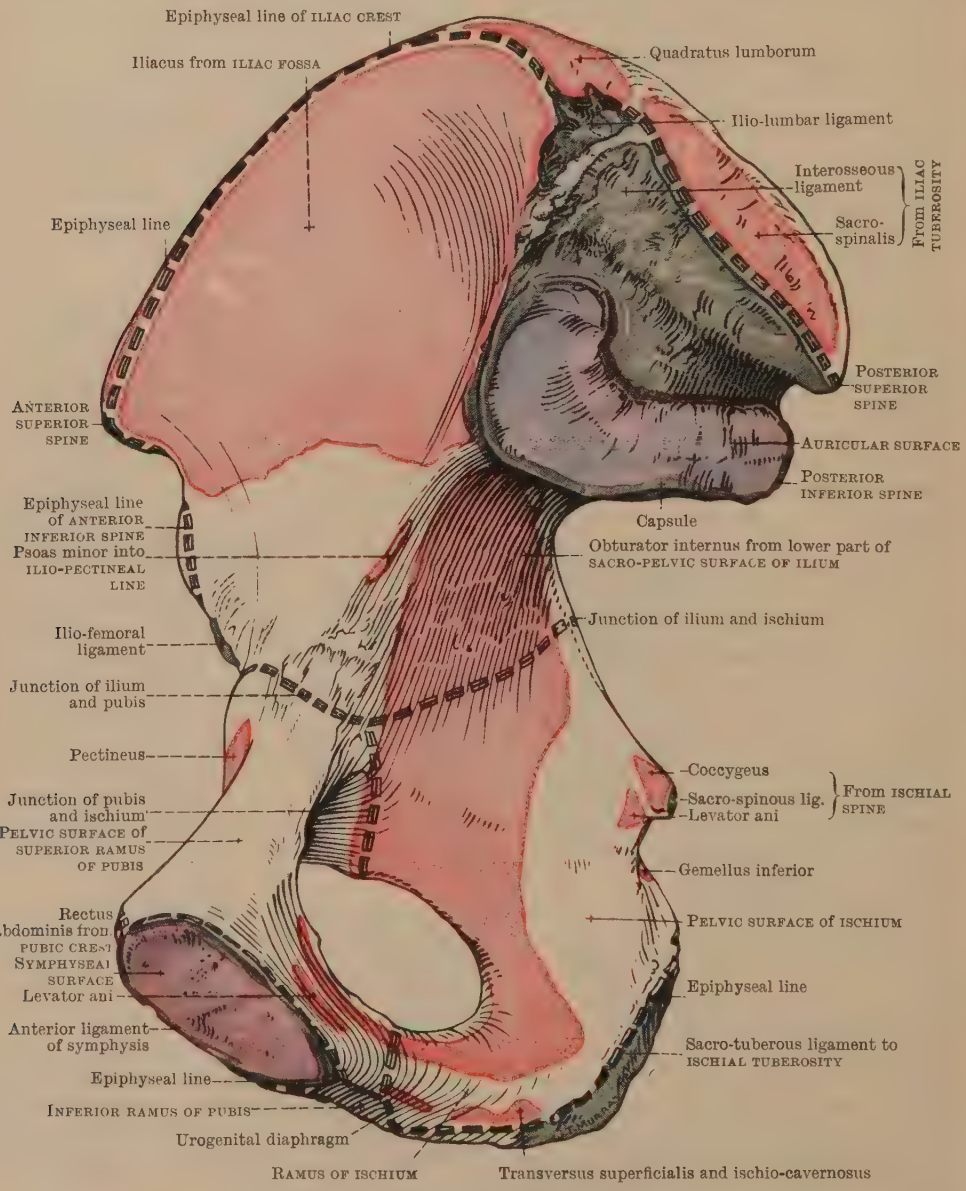

FIG. 215.—MEDIAL ASPECT OF RIGHT HIP BONE.

large smooth area between the anterior and posterior borders; it forms part of the side wall of the cavity of the pelvis minor, and is continuous superiorly with the sacro-pelvic surface of the ilium. The **femoral surface** is the flat area below the acetabulum; it looks towards the thigh.

Os Pubis.—The **pubis** lies in the anterior or lower wall of the pelvis, and can be felt at the lowest part of the front of the abdomen and at the upper end of the thigh where the medial side and the front of the thigh merge into each other. It is named from the region in which it lies. [The *pubis* is the region covered

with hair at the lowest part of the front of the abdomen: from *pubes* = the hair that appears at puberty.]

The pubis is divisible into an expanded compressed piece of bone, usually called the *body*, and two bars of bone called the *rami*, superior and inferior.

The **body** lies alongside the median plane in the pubic region, articulating with the body of the other pubis; the two are joined by a plate of fibro-cartilage, and the joint is called the symphysis pubis; the articulating border is called the *symphyseal border*. The body has two surfaces—anterior and posterior. The *posterior* or *pelvic surface* is smooth; it looks upwards into the cavity of the pelvis rather than backwards, and is closely related to the urinary bladder. The *anterior* or *femoral surface* looks downwards into the thigh rather than forwards, and is roughened for the attachment of thigh muscles. The upper border of the body is raised and bent forwards and downwards, and is called the **pubic crest.** The medial end of the crest, which joins the symphyseal border at an angle, is called the *pubic angle*; the lateral end is called the **pubic tubercle.** The upper part of the symphysis, the pubic crest, and the pubic tubercle can all be felt at the lower part of the abdomen; the tubercle is rather more than an inch from the median plane, and is often referred to as a landmark. When the hip bone is held in the position it occupies in the erect body, the pubic tubercle and the anterior superior iliac spine lie in one vertical plane, so that the hip bone is in its proper position when it is placed against a wall with only those two points touching, and the defective side of the acetabulum looking straight downwards. A fibrous band called the *inguinal ligament* stretches between the pubic tubercle and the anterior superior iliac spine. It can be felt in the living groin as a tense resisting cord along the floor of the curved groove that extends between those two bony points. Though called a "ligament" it is the lower edge of the aponeurosis of the external oblique muscle of the wall of the abdomen; it lies along the line where the front of the thigh joins the abdomen, and is encountered in the first steps of the dissection of the lower limb. [An *aponeurosis* is a tendon or sinew in the form of a wide sheet: ἀπό (apo) = from; νεῦρον (neuron) = *nervus* = a sinew (though now both *neuron* and *nervus* always signify *nerve*).]

The **inferior ramus** is the short compressed bar which begins at the lower part of the body of the pubis, and passes downwards, backwards, and in a lateral direction to meet and fuse with the ramus of the ischium; the position of their junction may be marked by a thickening or a ridge, but is often difficult to make out in an adult bone. The two fused rami form a bar of bone called the **conjoined rami** of ischium and pubis. The bar has two surfaces and two borders. The *inner surface* is divided lengthwise by a ridge into an upper and a lower part; the upper part looks into the pelvis; the lower part looks into the perineum and gives attachment to the crus of the penis or of the clitoris. The *outer surface* is directed towards the thigh and gives attachment to thigh muscles. The *upper border* is the lower boundary of the obturator foramen. The *lower border* can be felt in the boundary between the medial side of the thigh and the anterior part of the perineum. The conjoined rami of the right and left hip bones constitute the sides of an arch called the **pubic arch.**

The **superior ramus,** though named merely a "ramus," is the true pubic bone. It has two ends, three borders, and three surfaces.

The **ends** are medial and lateral. The **medial end** is wide and compressed, and is described above as the "body" of the pubis. The **lateral end** is expanded to form part of the acetabulum and fuses there with the ilium and the ischium. The *ilio-pectineal eminence,* in front of the acetabulum, marks the position of its union with the ilium.

The **borders** are superior, anterior, and posterior. The **superior border** begins at or near the pubic tubercle and extends to the upper part of the ilio-pectineal eminence; it is usually a sharp edge, and is called the **pectineal line** [*pecten* = a crest or comb]. At the ilio-pectineal eminence it is continuous with the lower smooth part of the medial border of the ilium; the two together are called the **ilio-pectineal line,** which forms a great part of the brim of the pelvis minor. The **anterior border** or *obturator crest* is the blunt ridge that begins near the pubic

tubercle and ends at the anterior margin of the acetabulum; it overhangs the obturator foramen. The **posterior border** is seen best from behind, *i.e.*, on the pelvic surface; it forms the anterior or upper boundary of the obturator foramen as seen from that point of view.

The **surfaces** of the superior ramus are named pectineal, pelvic, and obturator. The **pectineal surface** is the triangular area between the pectineal line and the obturator crest; the pectineus muscle arises from it; the femoral artery crosses its lateral end, but is separated from the bone by a muscle called psoas major. The **pelvic surface** is continuous with the pelvic surface of the body. The **obturator surface** is a broad oblique groove in the upper or anterior boundary of the obturator foramen; through that groove the obturator vessels and nerve pass out of the pelvis into the thigh.

Acetabulum.—The **acetabulum** is the large cup-shaped cavity on the lateral aspect of the hip bone [*acetabulum* = a vinegar cup]. It looks not only in a lateral direction, but also forwards and downwards. It articulates with the head of the femur to form the *hip joint*. The lower part of its wall is deficient, and the gap is called the **acetabular notch**; a fibrous band, called the *transverse ligament*, bridges across the notch and completes the rim. The floor of the acetabulum above the notch shows a large rough depression called the **acetabular fossa**. The rest of the inside of the cup is smooth and articular. The pubis forms about one-fifth of the acetabulum, the ischium rather more than two-fifths, and the ilium rather less than two-fifths.

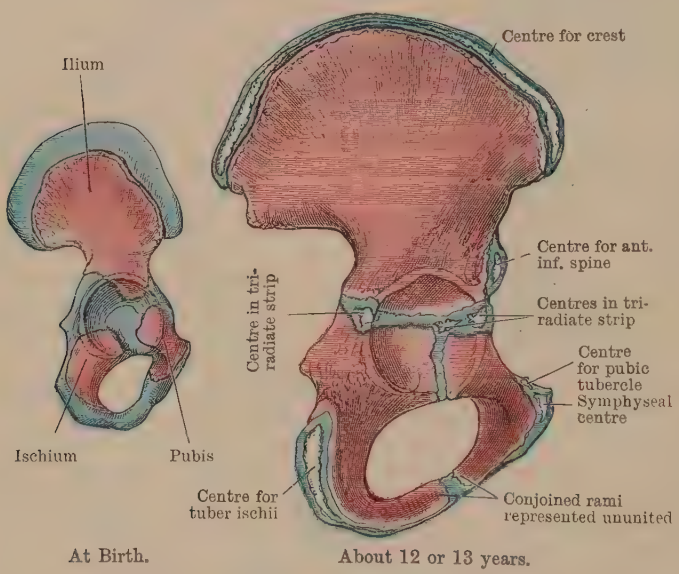

FIG. 216.—OSSIFICATION OF THE HIP BONE.

Foramen Obturatum.—The **obturator foramen** is bounded by the ischium and the pubis and their rami. It is almost completely closed up with a thin, strong membrane called the *obturator membrane*, from which the foramen gets its name [*obturare* = to close up]. The outer and inner surfaces of the membrane are directed, respectively, towards the thigh and towards the cavity of the pelvis.

The **nutrient foramina** are scattered here and there on the surface of the hip bone.

Ossification.—From *three* **primary** centres and several secondary centres.

Primary Centre appears for	**Ilium**, above greater sciatic notch, early in 3rd month.	**Ischium**, below acetabulum, in 4th month.	**Pubis**, in superior ramus, in 5th month.

At birth the larger part of each bone is ossified, including a portion of its acetabular end, but a great deal is still gristle, viz.: upper part of ilium, greater part of acetabulum, lower end of ischium, medial part of body of pubis, and the conjoined rami. By the tenth year most of the cartilage is ossified, that between the three bones at the *acetabulum* being reduced to a triradiate strip; and the *conjoined rami* are completely ossified and fused together. Secondary centres appear in the acetabulum at twelve, and in the other parts at puberty.

Secondary Centre.	Appears at	Epiphysis unites at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
Two or three for triradiate strip	12th year	17	Inside laterally, outside medially.
One or two for iliac crest including superior spines	Puberty	20-25	None.
For anterior inferior spine	Puberty	20-25	Outside.
For ischial tuberosity	Puberty	20-25	None.
For symphyseal part of pubis	Puberty	20-25	No joint cavity.

Occasionally small epiphyses, which appear and fuse at the same times as those in the list above, are present for the pubic tubercle, pubic angle, and ischial spine. The portions ossified from the centres in the acetabulum fuse with the nearest bone; *os acetabuli* is the name given to the part that joins the pubic bone.

Structure and Variations.—The hip bone is composed of spongy substance enclosed in compact substance, except in the centre of the iliac fossa and the floor of the acetabulum, where spongy bone is absent; occasionally the compact bone also is absent in one or other of those two situations. The bone is thickest and strongest above the acetabulum, between it and the auricular surface, for through that part the weight of the trunk is transmitted from the sacrum to the femur. The *os acetabuli* may remain a separate bone; the acetabular notch may be absent. The groove in the upper boundary of the obturator foramen is in rare cases converted into a tunnel. A separate articular facet may be present above the auricular surface, for articulation with a small facet on the back of the sacrum lateral to the first sacral foramen (Derry). The ischial and pubic rami sometimes fail to unite.

Pelvis.

The **pelvis** is the lower subdivision of the abdomen [*pelvis* = a basin], and the large crate that constitutes its bony framework is also called the pelvis. The bony pelvis is made up of the two hip bones and the portions of the backbone or vertebral column which are called the sacrum and the coccyx. The two hip bones form the sides of the pelvis and its ventral wall, the right and left pubic bones being joined together by the symphysis at the median plane in front; the sacrum and coccyx form its dorsal wall, the sacrum being wedged in between the hip bones and held in place by strong ligaments, while the coccyx lies below the sacrum between the hip bones and also is attached to them by ligaments.

The pelvis provides a large surface for the attachment of muscles, especially those which move the lower limb; it contains and protects the urinary bladder, some of the organs of reproduction, and part of the alimentary canal; but the chief use of the bony pelvis is to serve as a firm unyielding base for the trunk resting on the thighs. The curved or ring-like construction of the pelvic framework prevents its collapse under the weight of the body, which is borne at only two points on the framework—where the thigh bones articulate with the pelvis.

Inclinatio Pelvis.—The pelvis does not occupy the position in the body which is suggested by its stance when it is set on a table. Its upper part is tilted forwards, so that when the body is in the erect posture the pubic tubercles and the anterior superior iliac spines are all in one vertical plane, and the tip of the coccyx is on a level with the upper margin of the symphysis pubis; the *anterior* or ventral wall is therefore largely *inferior*, and the *posterior* or dorsal wall is largely *superior*. The tilt of the pelvis is called the *inclination of the pelvis*.

Foramina Ischiadica.—A wide interval separates the lower part of the hip bone from the coccyx and the lower part of the sacrum. The interval is crossed by two fibrous bands named the *sacro-tuberous* and *sacro-spinous ligaments*. They are such important parts of the pelvis that in many prepared skeletons they are

preserved. The **sacro-tuberous ligament** is a long, strong band which stretches from the sacrum and coccyx to the ischial tuberosity. The **sacro-spinous ligament** is a shorter, flatter band that stretches across the pelvic surface of the sacro-tuberous ligament from the sacrum and coccyx to the ischial spine. Those two ligaments convert the sciatic notches of the hip bone into foramina, named the

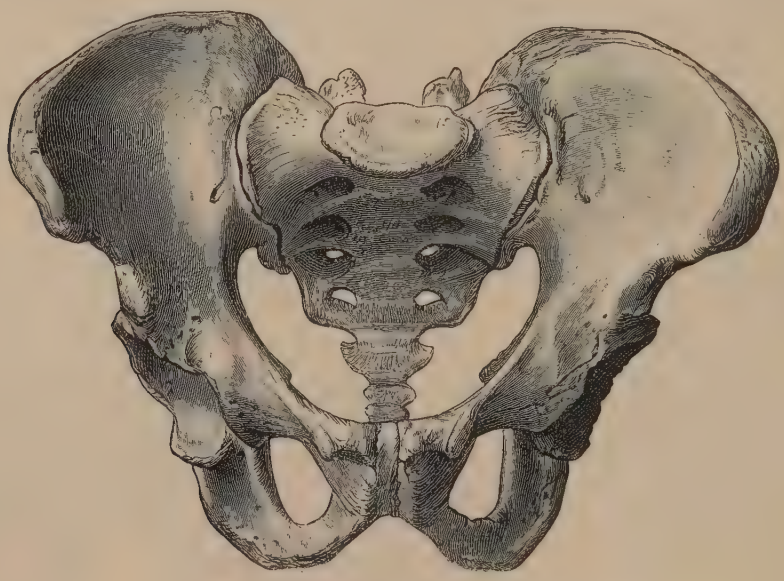

FIG. 217.—THE MALE PELVIS SEEN FROM THE FRONT.

greater sciatic foramen and the **lesser sciatic foramen,** through which muscles, nerves, and vessels pass between the pelvis and buttock. The dissector of the lower limb encounters both the ligaments and the foramina during the dissection of the gluteal region. (See Figs. 286, 287, p. 338.)

Arcus Pubis.—The **pubic arch** is the arch formed by the conjoined rami of

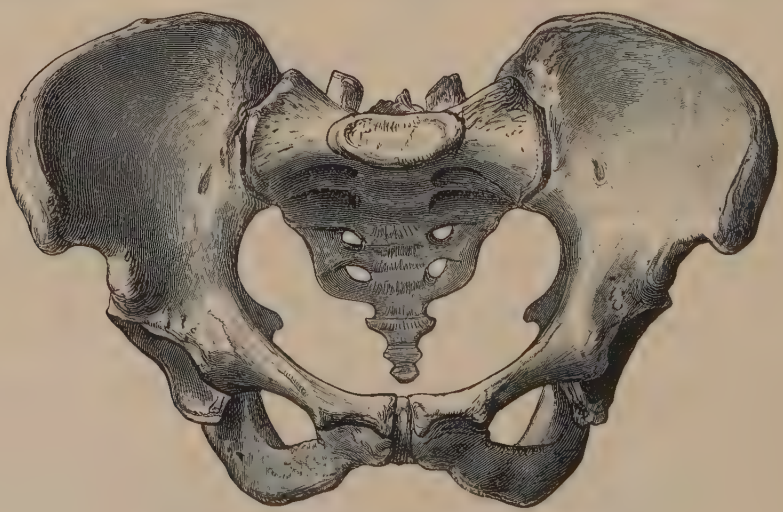

FIG. 218.—THE FEMALE PELVIS SEEN FROM THE FRONT.

ischium and pubis of the two sides. The apex of the arch is the lower margin of the symphysis pubis and is rounded off by a fibrous band called the *arcuate ligament,* the fibres of which curve from one side to the other just below the symphysis. The archway is to a large extent filled in by a sheet of muscle called the *uro-genital diaphragm,* which is covered on both upper and lower surfaces with fibrous

membrane or fascia; the inferior fascia is a strong membrane comparable to the obturator membrane.

Pelvis Major.—The pelvis is divided into the pelvis major and the pelvis minor. The **pelvis major** is the part above the level of the sacrum and the ilio-pectineal lines; it forms part of the walls of the abdomen proper.

Pelvis Minor.—The **pelvis minor** is the true pelvis. When reference is made to "the pelvis" in the description of muscles, viscera, etc., it is usually the pelvis minor only that is meant. The bones which form it are the sacrum and coccyx, the pubis, the ischium, and the lower part of the sacro-pelvic surface of the ilium.

The **cavity** of the pelvis minor is a short, wide canal or tunnel which is curved in general conformity with the curve of the sacrum and coccyx; in length it measures five or six inches along the sacrum and coccyx, but only one and a half or two inches along the symphysis pubis. The cavity is continuous with that of the abdomen proper at the *inlet* or **superior aperture** of the pelvis, the boundaries of which constitute the **brim** of the pelvis. The aperture is directed forwards rather than upwards, and its *boundaries* are: (1) the promontory of the sacrum in the median plane *behind*; (2) the upper margin of the symphysis pubis in the median plane *in front*; and, *on each side* from behind forwards, (3) the anterior margin of the ala of the sacrum, (4) the ilio-pectineal line, and (5) the crest of the pubis. The *outlet* or **inferior aperture** of the pelvis is *bounded* by: (1) the coccyx in the median plane *behind*; (2) the lower margin of the symphysis pubis in the median plane *in front*; and, *on each side* from behind forwards, (3) the sacro-tuberous ligament, (4) the lower end of the ischium, and (5) the side of the pubic arch. These are also the boundaries of the region called the *perineum*, which is shut off from the cavity of the pelvis by the urogenital diaphragm and two pairs of thin muscles called the levatores ani and the coccygei.

Planes and Axes of the Pelvis.—The **plane of the superior aperture** is the plane in which the sacral promontory and the upper margin of the symphysis pubis lie; owing to the inclination of the pelvis it forms an angle of about 60° with the horizontal. The **plane of the inferior aperture** is that in which the tip of the coccyx and the lower margin of the symphysis lie; it forms an angle of only 10° to 15° with the horizontal, because the symphysis is much shorter than the sacrum and coccyx. The **planes of the cavity** are a plane that passes through the middle of the third sacral vertebra and the middle of the symphysis pubis, and any number of planes set in intermediate positions between that plane and those of the apertures. The **axis of the superior aperture** is a line drawn at right angles to the centre of its plane; the line, if continued, would pass through the umbilicus and through the tip of the coccyx. The **axis of the inferior aperture** is a line drawn at right angles to the centre of its plane; if continued upwards the line would strike the sacral promontory. The **axis of the pelvis** is a line drawn through the centres of the planes of the cavity and the apertures; it is therefore curved and parallel to the curve of the sacrum and coccyx.

Diameters of the Pelvis.—The **intercristal diameter** is the distance from the outer lip of one iliac crest to that of the other where they are furthest apart. The **interspinous diameter** is the distance between the two anterior superior iliac spines. The **external antero-posterior diameter** is the distance between the tip of the spine of the first sacral vertebra and the upper margin of the symphysis pubis.

The **diameters of the pelvis minor** are of more importance.

Diameters of Superior Aperture.—*Antero-posterior* or conjugate: from the middle of the sacral promontory to the upper margin of the symphysis pubis. *Transverse*: across the aperture where it is widest. *Oblique*: from one sacro-iliac joint to the ilio-pectineal eminence of the other side.

Diameters of Cavity.—*Antero-posterior*: from the centre of the pelvic surface of the middle piece of the sacrum to the middle of the pelvic surface of the symphysis pubis. *Transverse*: across the cavity where it is widest. *Oblique*: from the posterior end of one sacro-iliac joint to the centre of the obturator membrane of the other side.

Diameters of Inferior Aperture.—*Antero-posterior*: from the tip of the coccyx to the lower margin of the symphysis pubis; it varies in the same pelvis, especially in the female, owing to the mobility of the coccyx. *Transverse*: across the aperture where it is widest. *Oblique*: from the point where the sacro-tuberous and sacro-spinous ligaments of one side cross each other to the junction of the pubic and ischial rami of the other side.

The first three diameters are slightly longer in a man's pelvis; but all the diameters of the pelvis minor are longer in a woman's pelvis than in a man's. Measurements vary in individuals of the same sex. In the following table the smaller figures are average measurements in inches and correspond to those given in Quain's *Anatomy*, 10th Edition; the large figures are millimetres, not the exact equivalents of the inches, but the nearest to them in round numbers (25 mm. is very slightly less than 1 inch).

	Female.			Male.		
Intercristal	11 ; 275			11¼ ; 280+		
Interspinous	9¼ ; 230+			9½ ; 235+		
External antero-posterior	7 ; 175			7¼ ; 180+		
Pelvis Minor.	Superior Aperture.	Cavity.	Inferior Aperture.	Superior Aperture.	Cavity.	Inferior Aperture.
Antero-posterior	4½ 110+	5 125	4-5 100-125	4 100	4¼ 105+	3¼ 80+
Transverse	5⅛ 130+	5 125	4⅞ 120−	5 125	4¾ 120−	3½ 85+
Oblique	5 125	5¼ 130+	4⅓ 110+	4¾ 120−	4⅓ 110+	4 100

Sexual Differences.—The pelvis of a woman differs from that of a man in many particulars, because the female pelvis is modified for the function of child-bearing. Distinctive sex characters are present in the fœtal pelvis, appearing as early as the third or fourth month of fœtal life; they are less marked in childhood; they become fully developed after puberty. The essential differences between male and female pelves are in the pelvis minor. The female pelvis minor is absolutely wider in all the diameters, especially in those of the inferior aperture, so that the cavity is less funnel-shaped; but the cavity is shorter. Nearly all the differences in detail are due to the fact that the cavity of the **pelvis minor** in the **female** is *roomier, less funnel-shaped,* and *shorter.* Most of the differences cannot be appreciated by a beginner unless he has at hand both a male and a female pelvis which he can compare; but the following difference will enable him to decide whether the specimen of pelvis or of hip bone which he is using for study is male or female: the **pubic arch** in the **female** is *wide* and its *apex is rounded*; it is usually wide enough to accommodate a right angle; in the male it is less than a right angle, and the apex is rather pointed.

The differences in detail are very numerous. The chief of them are that **in the female**—The bones are lighter and thinner, and muscular markings are less evident. The *ilium* is less everted and the *iliac fossa* is shallower. The **superior aperture** is larger, and is kidney-shaped rather than heart-shaped; its *plane* forms a wider angle with the horizontal, for the tilt of the pelvis is greater, so that the anterior superior iliac spines are even further forward than the pubic tubercles; the *sacral promontory* projects less, and the *pubic tubercles* are wider apart. The **cavity** is less funnel-shaped, is shorter, but is much roomier. The *sacrum* is shorter and wider, and its curve is said to be less uniform, being flatter above and more sharply turned forwards below. The **inferior aperture** is much larger. The *pubic arch* is wider and more rounded. The *coccyx* is more movable. The *sciatic notches* are wider and shallower; the *ischial spine* is less inturned. The *obturator foramen* is smaller and may be triangular in outline rather than oval. The *acetabula* are further apart and are smaller, especially relatively, for the head of the femur is smaller in a woman while the hip bone is larger. A pre-auricular sulcus is present just in front of the convex margin of the auricular surface of the ilium.

Growth of the Pelvis.—At birth, in either sex, the pelvis is relatively small; and so are the lower limbs, which are then only about a quarter of the length of the body. After birth the lower limbs grow much more rapidly than the rest of the body, especially after the first year when the child begins to learn to walk. The whole pelvis keeps pace with the lower limbs; it gives origin to a great number of the muscles that move the limbs, and grows concurrently with them to provide them with adequate attachments. At birth the pelvis minor is not big enough to hold the pelvic organs; the greater part of the urinary bladder and, in the female, the uterus and ovaries are in the abdomen proper; but by the sixth year the pelvis has grown large enough to contain them. The rate and manner of growth are similar in boys and girls till puberty, when the growth is modified to produce the distinctive sex characters of the adult pelvis.

Besides mere relative increase of size, there are other changes in the pelvis when the child, learning to walk, straightens out the lower limbs and adopts the erect attitude. The principal changes are: (1) The upper part of the pelvis is tilted forwards so that the sacro-vertebral angle, *i.e.*, the angle between the front of the sacrum and the last lumbar vertebra, becomes less obtuse. (2) The basal or upper part of the sacrum, now bearing the weight of the trunk obliquely, sinks

more deeply between the two hip bones, and that further accentuates the sacro-vertebral angle. (3) The sacrum becomes more curved also, for while the weight of the trunk bends the basal part downwards, the apical part is held down and prevented from tilting up by the sacro-tuberous and sacro-spinous ligaments. (4) At the same time the hip bone, where it bounds the pelvis minor, becomes curved outwards, and thus the pelvis minor is widened; for those parts of the two hip bones, at that time, resemble the limbs of the letter V, the apex being at the symphysis pubis; the sacrum lies between the upper ends of the limbs of the V, and the weight of the trunk is transmitted to them through the sacrum; they are fastened to the sacrum at their upper ends and to each other at the apex, *i.e.* at the symphysis pubis, and therefore, under the weight of the trunk, have to bend outwards in the middle. (5) The acetabulum becomes deeper to make the hip joint more stable. (6) The part of the ilium between the acetabulum and the auricular surface, through which the weight of the trunk is transmitted from sacrum to femur, grows stronger, and in consequence of its growth the iliac part of the ilio-pectineal line becomes better defined.

Attachments.—(A) **Of Structures encountered in the Dissection of the Lower Limb.**—The lateral end of the inguinal ligament is attached to the **anterior superior iliac spine.** The sartorius muscle arises from that spine and from part of the notch below; the tensor fasciæ latæ muscle from the spine and the adjoining two inches of the outer lip of the **iliac crest.** The lateral part of the fascia lata is attached to the whole length of the outer lip of the crest, its ilio-tibial tract being attached to the **tubercle of the crest**; the ilio-femoral ligament to the lower part of the **anterior inferior spine**; the straight head of the rectus femoris muscle from its upper part; the reflected head from the rough depression on the **dorsum ilii** just above the acetabulum; the gluteus minimus muscle from the area between the *inferior* and *anterior gluteal lines*; the gluteus medius from the area between the *anterior* and *posterior gluteal lines*; the gluteus maximus from the upper, rough part of the area behind the *posterior line* and from the *back* of the **sacrum** and *sacro-tuberous ligament*; the iliacus muscle from the **iliac fossa**; the piriformis muscle from the *pelvic surface* of the middle three pieces of the **sacrum**, and from the upper margin of the **greater sciatic notch** and the sacro-tuberous ligament, as the muscle emerges from the pelvis through the *greater sciatic foramen*; the obturator internus muscle from the side wall of the cavity of the pelvis, viz., the inner surface of the **obturator membrane**, the bone around the obturator foramen, especially the wide, flat area between the foramen and the greater sciatic notch, and the fibres converge on the tendon, which leaves the pelvis through the *lesser sciatic foramen*; the superior gemellus muscle from the **ischial spine** where it forms the upper boundary of the lesser sciatic foramen; the inferior gemellus from the **ischial tuberosity** where it forms the lower boundary. The sacro-spinous ligament stretches from the tip of the *ischial spine* to the side of the last piece of the *sacrum* and first piece of the *coccyx*. The sacro-tuberous ligament covers the dorsal surface of the medial and larger part of the sacro-spinous ligament; its upper end widens out to be attached to the side of the *coccyx* and *sacrum* and to the **posterior superior** and **posterior inferior iliac spine**; its lower end widens out to be attached to the medial margin and lower medial area of the **ischial tuberosity**, and sends a prolongation, called its *falciform process*, forwards along the inner surface of the *ischial ramus*. The quadratus femoris muscle arises from the *lateral margin* of the **ischial tuberosity.** The surface of the tuberosity is divided by a transverse line into an upper and a lower part, and each of those is divided into a lateral and a medial part. The tendon of the semimembranosus arises from the *upper lateral* area; the tendons of the semitendinosus and the short head of the biceps conjointly from the *upper medial* area; the adductor magnus muscle from the *lower lateral* area and from the lower part of the outer surface of the *conjoined rami*, the sacro-tuberous ligament being attached to the *lower medial* area.

The medial end of the inguinal ligament is attached to the **pubic tubercle**, and its expansion, called the lacunar ligament, to the medial inch of the **pectineal line.** The pectineus muscle arises from the *pectineal line* and *pectineal surface* of the **pubis**; the tendon of the adductor longus from the *femoral surface* of the body of the pubis, in the angle between the crest and the symphysis; the gracilis muscle from the margin of the *symphysis* and of the **inferior ramus**; the adductor brevis muscle from a broad strip lateral to the gracilis and below the adductor longus; the obturator externus muscle from the area below and in front of the obturator foramen and from the adjoining half of the **obturator membrane**, and as it winds backwards below the neck of the femur it lies in the wide groove below the acetabulum.

The fascia lata has a continuous attachment to the inguinal ligament, the lower lip of the pubic crest, the margin of the symphysis pubis, the lower margin of the conjoined rami, the medial margin of the ischial tuberosity, the medial margin of the sacro-tuberous ligament, the back of the sacrum and coccyx, and the whole length of the outer lip of the iliac crest.

The transverse ligament bridges across the *acetabular notch* and completes the rim of the acetabulum. The ligamentum teres femoris spreads out to be attached to the transverse ligament and the margins of the **acetabular notch** and **fossa.** A fibro-cartilaginous ring, called the labrum glenoidale, is attached to the *rim* and serves to deepen the cavity of the acetabulum and narrow its mouth. The fibrous capsule of the hip joint is attached to the labrum below and in front, to the bony rim above and behind, and to the rough strip above the acetabulum. The thickened parts of the capsule are attached as follows: the ilio-femoral ligament to the lower part of the *anterior inferior iliac spine*; the pubo-capsular ligament to the lateral end of the *obturator crest*; the ischio-capsular ligament to the *ischium* below the acetabulum.

(B) **Of Structures encountered in the Dissection of other Parts.**—The iliacus muscle arises from the upper and larger part of the floor of the **iliac fossa.** The fascia iliaca and part of the transversalis fascia are continuous with each other at the *inner lip* of the **iliac crest** above the

iliac fossa and are loosely attached to that part of the lip. Part of the transversus abdominis arises from the anterior half of the inner lip; part of the quadratus lumborum from the inner lip immediately behind the transversus, above the posterior part of the iliac fossa; a slip of the latissimus dorsi from the corresponding part of the *outer lip*. Part of the external oblique is inserted into the anterior half of the outer lip, and part of the internal oblique arises from the anterior half of the *intermediate line*. The ilio-lumbar ligament is attached to the upper end of the **medial border** of the ilium; the anterior ligament of the sacro-iliac joint to the convex margin of the **auricular surface**; the interosseous and short posterior sacro-iliac ligaments to the lower half of the **iliac tuberosity**; the lower part of the sacro-spinalis arises from the upper half, and from the back of the *sacrum*. The long posterior sacro-iliac ligament stretches from the **posterior superior iliac spine** to the side of the back of the sacrum half-way down; the sacro-tuberous ligament stretches from both *posterior spines* and from the side of the sacrum and coccyx to the lower part of the **ischial tuberosity** and the *ischial ramus*. The sacro-spinous ligament stretches from the tip of the **ischial spine**, across the pelvic surface of the sacro-tuberous ligament, to the side of the last piece of the sacrum and the first piece of the coccyx; the coccygeus muscle lies on the front of the sacro-spinous ligament and has the same attachments, the ligament being merely the degenerated dorsal fibres of the muscle. The piriformis muscle arises from the *pelvic surface* of the second, third, and fourth pieces of the **sacrum**, from the upper margin of the *greater sciatic notch*, and from the sacro-tuberous ligament; the obturator internus from the side wall of the pelvic cavity; the posterior fibres of the levator ani from the *ischial spine*, its anterior fibres from the *pelvic surface* of the **body of the pubis** below its middle, the greater part of the muscle from the fascia covering the obturator internus. The pubo-prostatic ligaments are attached to the pubis above the levator ani.

The fibro-cartilage of the symphysis pubis is attached to the **symphyseal border** or surface; the superior, anterior, posterior, and inferior pubic ligaments to the *margins* of that surface, the inferior ligament being called the arcuate ligament because on each side it curves backwards on to the inferior pubic ramus.

Part of the fascia transversalis is attached to the posterior or upper lip of the **pubic crest** and to the medial half of the **pectineal line**. The rectus abdominus arises from the crest in front of the fascia and from the anterior pubic ligament; the pyramidalis from the crest in front of the rectus. The falx inguinalis or conjoined tendon is attached to the anterior ligament of the *symphysis* below the rectus, to the *crest* in front of the pyramidalis, and to the *pectineal line* in front of the fascia transversalis; the reflex inguinal ligament (when present) to the medial half-inch of the pectineal line in front of the falx; the lower medial part of the external oblique aponeurosis to the anterior or lower lip of the pubic crest and to the anterior ligament of the pubis, below the falx inguinalis.

The inguinal ligament stretches from the anterior superior iliac spine to the **pubic tubercle** and, by means of the lacunar ligament, to the medial inch of the *pectineal line*, in front of the reflex ligament. One end of the loops of the cremaster muscle is attached to the pubic tubercle behind the inguinal ligament. The tendon of the psoas minor is inserted partly into the **ilio-pectineal line** and **eminence**.

The fascia of Colles (*i.e.*, the deeper membranous layer of the superficial fascia of the perineum) is attached to the lower margin of the **ischial ramus**. The crus penis or crus clitoridis is attached to the lower half of the *inner surface* of the **conjoined rami**, the lower half usually being grooved lengthwise for the lodgment of the crus. The ischio-cavernosus and transversus perinei superficialis arise from the posterior end of the groove. The urogenital diaphragm and its inferior fascia are attached to the ridge between the upper and lower halves of the surface; immediately above them the pubic part of the ridge gives attachment to the arcuate ligament, and the ischial part to the falciform process of the sacro-tuberous ligament. Fibres of the obturator internus arise from the upper half of the surface, *i.e.*, the strip between the ridge and the obturator foramen; the fascia covering that muscle blends with the falciform process, and gives attachment to the superior fascia of the urogenital diaphragm.

Femur.

The **femur** or thigh-bone is the longest and strongest and heaviest bone in the skeleton, and is between a third and a fourth of the length of the body. It has a shaft or **body** and **two ends**. It is so thickly covered with muscles that, in the living body, it can be palpated only at and near the ends. The beginner should at once proceed to distinguish the proximal end from the distal end, the front of the bone from the back, and the medial side from the lateral side. The larger end of the bone is the **distal** end, and it is partially divided into two, the wide notch between the two parts being on the **posterior** aspect; the globular head at the proximal end is on the **medial** side.

The **proximal end** includes the head, the neck, the greater trochanter and the lesser trochanter.

The **head** is smooth and is almost a sphere. It fits into the acetabulum to form the *hip joint*. On its medial aspect there is a rough, shallow pit to which

the apex of a triangular attached. [The name is not aptly chosen: *teres* = round.]

The **neck** is the thick bar that connects the head with the body of the bone in the region of the trochanters. It is nearly two inches long, is thinnest in the middle and widens towards each end, especially the end which joins the body, so that while the upper border is nearly horizontal the lower border is very oblique. The neck joins the body at an angle and is therefore liable to be broken; but a long neck joined to the shaft at an angle enables the femur to be moved freely and extensively, even though the head is deeply and stably articulated to the side of the pelvis.

The **greater trochanter** is the large, square prominence on the lateral aspect where the neck joins the shaft; its upper part stands up above the level of the adjacent part of the neck; its root is marked off from the shaft by a more or less horizontal ridge. It is the bone felt in front of the hollow on the side of the hip, and the body falls on it in a fall sideways; its upper border is on a level with the upper border of the symphysis pubis and with the centre of the hip joint. Many of the muscles of the gluteal region are inserted into the greater trochanter [τροχαντήρ (trochantēr) = a runner]. The rough pit on the medial side of the trochanter, where it joins the back of the neck, is called the **trochanteric fossa**.

fibrous band, called the ligamentum teres femoris, is

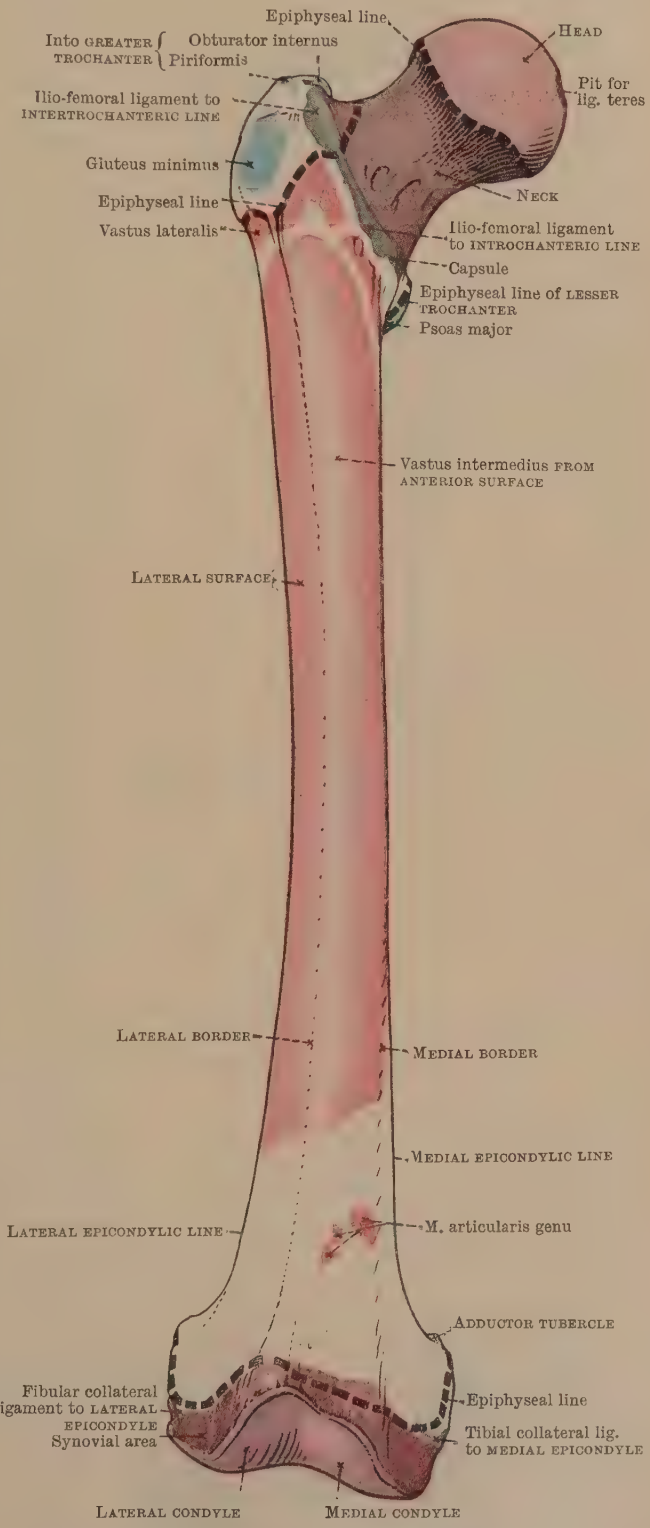

FIG. 219.—FRONT OF RIGHT FEMUR.

The **lesser trochanter** is the rounded, conical projection on the posterior

and medial aspect of the bone where the lower part of the neck joins the body.

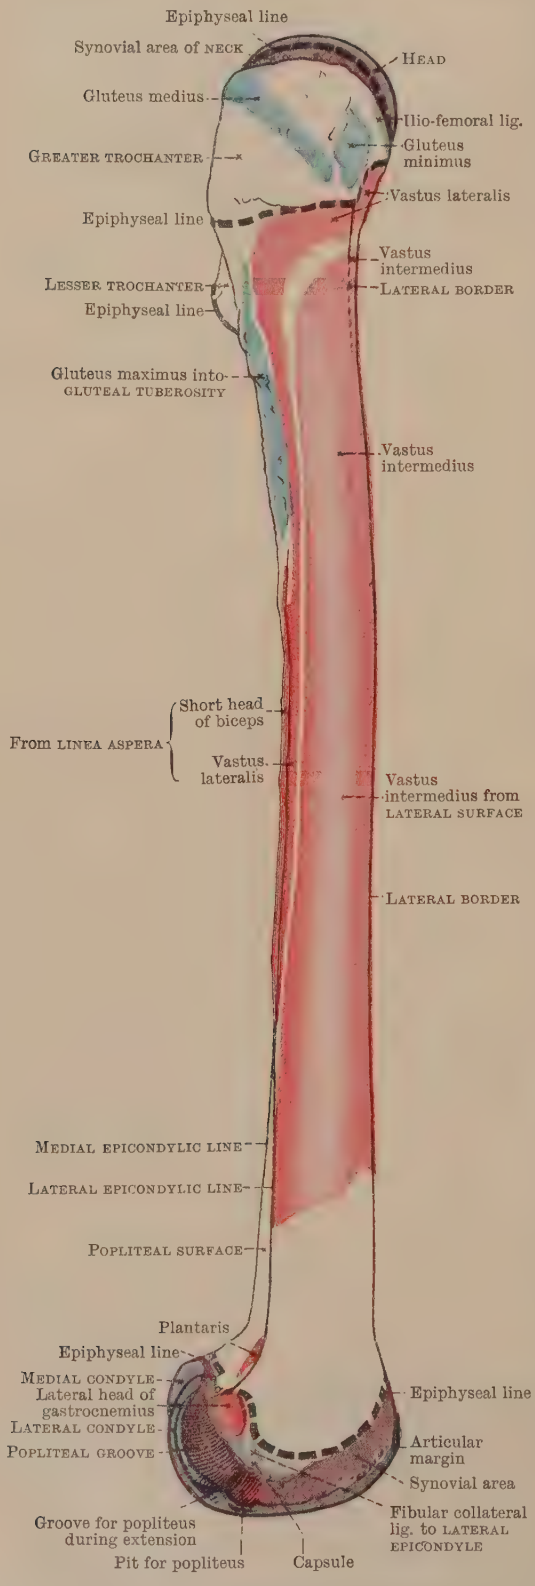

FIG. 220.—LATERAL ASPECT OF FEMUR.

The ridge connecting the lesser trochanter with the back of the greater trochanter is called the **trochanteric crest.** The low, rounded swelling on or alongside the crest, on the back of the trochanter major, is called the **quadrate tubercle** because part of the quadratus femoris muscle is inserted into it. The **intertrochanteric line** is the rough, broad line which extends from the upper part of the anterior surface of the greater trochanter towards the lesser trochanter, and marks the union of the front of the neck with the front of the body; though called "intertrochanteric" it does not reach the lesser trochanter, but becomes continuous with a faint ridge, called the *spiral line*, which winds to the back of the bone below the lesser trochanter.

The **distal end** of the femur consists of two large masses called *condyles*, which are separated posteriorly by a wide deep interval called the *intercondylar notch.*

Condyli.—Anteriorly the **condyles** are nearly in line with the front of the shaft, but they bulge backwards considerably beyond the plane of the shaft. The anterior, distal, and posterior aspects of each condyle are smooth and articular. The *anterior parts* of the two are joined together, forming a wide surface for articulation with the patella. This **patellar surface** is deeply concave from side to side; its lateral part is more prominent than the medial, and extends farther up, so that the proximal margin of the surface is sloping. The tibia articulates with the *distal surfaces* when the knee is extended, and with the *posterior surfaces* when the knee is flexed. The surfaces which form the sides of the intercondylar notch are rough for the attachment of strong fibrous bands, called the cruciate ligaments, which lie inside the knee joint and help to bind the femur and tibia together.

On the *lateral surface* of the **lateral condyle** there is a prominence, called the *lateral epicondyle,* much nearer the back of the bone than

the front; above it there is a pit or impression for the origin of the lateral head of the gastrocnemius; below it there is a pit for the origin of the tendon of the popliteus; a groove, in which the tendon lies when the knee is acutely flexed, runs upwards and backwards from the pit close alongside the articular margin. The **medial condyle** stands further away from the shaft than the lateral condyle does. Its medial surface is rough and convex; its most prominent part is called the *medial epicondyle*. On the uppermost part of the condyle there is a small, sharp prominence, called the **adductor tubercle** because the tendon of the adductor magnus is inserted into it.

The condyles can be felt as large prominences at the sides of the knee; the adductor tubercle can be felt at the most proximal part of the medial condyle, and is often used as a landmark; the tendon of the adductor magnus can usually be felt as it descends to the tubercle, but it is not the only tendon that can be felt at the medial side of the knee. When the knee is flexed, the patellar surface of the femur can be felt (or, at any rate, its lateral and medial margins), for the patella is drawn off it when the leg is bent; and a portion of the distal surface of each condyle can be felt at the side of the *ligamentum patellæ*, which is the thick broad band felt between the patella and the tibia.

Corpus Femoris. The **body** or shaft of the femur is thinnest in its middle third and widens towards each end, especially the distal end.

The **middle third** has

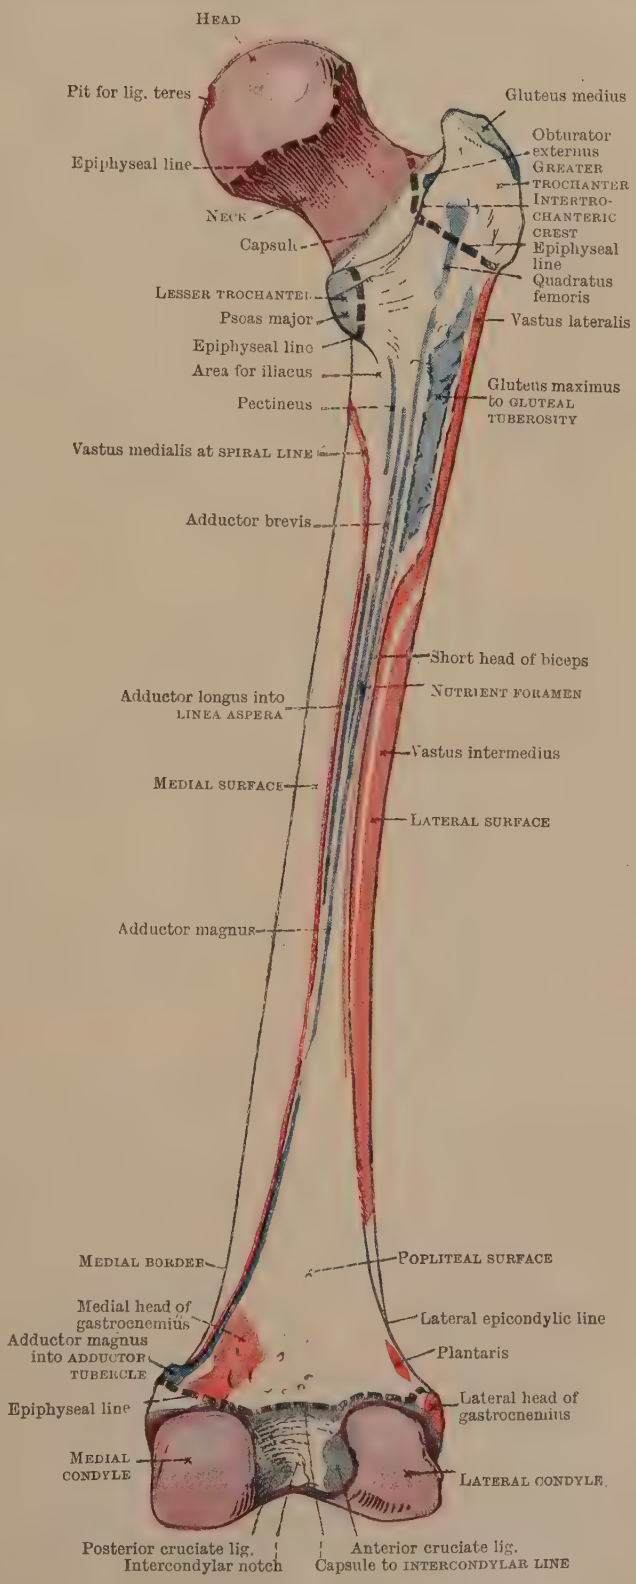

Fig. 221.—Back of Right Femur.

three surfaces and three borders. The *surfaces* are anterior, medial, and lateral; the *borders* are posterior, lateral, and medial.

The *lateral* and *medial borders* are blunt and ill-defined, so that the *anterior surface* is not sharply marked off from the *lateral* and *medial surfaces*; but the *posterior border*, which separates the medial surface from the lateral surface, is well-defined and rough, and is called the linea aspera.

The **linea aspera** is the rough ridge on the back of the femur, and it is limited to the middle third of the bone. Its margins are called its *lips—lateral* and *medial*; the lateral lip is the sharper and better defined of the two. At the proximal and distal ends of the linea aspera the lips diverge from each other and become continuous with ridges, bearing different names, on the proximal and distal thirds of the femur.

At the **proximal third** the *medial* lip becomes continuous with a narrow ridge, called the **spiral line**, which winds obliquely round the medial side of the femur on to the front of the bone and becomes continuous with the intertrochanteric line. The *lateral* lip becomes continuous with a long, broad, rough mark, called the **gluteal tuberosity**, which is situated on the back of the proximal third of the femur towards the lateral side, and extends from the linea aspera to the trochanter major; it receives its name because part of the gluteus maximus muscle is inserted into it. The proximal third of the body of the femur has therefore *four* surfaces: the three surfaces continuous with those of the middle third, and an additional, fourth surface—the *posterior surface*—between the gluteal tuberosity and the spiral line.

At the **distal third** of the femur the *lateral* lip of the linea aspera becomes continuous with the **lateral epicondylic line**, which extends as a well-defined line to the lateral condyle. The *medial* lip becomes continuous with the **medial epicondylic line**, which extends to the adductor tubercle, and may serve as a guide to the tubercle if it has not been identified already. The medial epicondylic line is never so well defined as the lateral, largely because it is worn down by the femoral vessels as they pass from the medial side of the thigh into the popliteal fossa and change their name to popliteal vessels. The distal third of the body of the femur also has *four* surfaces: anterior, medial, and lateral, continuous with those of the middle third, and a *posterior surface* between the epicondylic lines. The posterior surface is usually called the **popliteal surface**, because it forms a great part of the floor or anterior wall of the popliteal fossa; on its distal part, above the medial condyle, there is a rough, raised mark, about half an inch wide each way, from which the medial head of the gastrocnemius muscle arises.

The **nutrient foramen** of the femur is situated on or near the linea aspera, and is directed towards the proximal end.

Attachments.—The ligamentum teres is attached to the *pit* on the **head**. The capsule of the hip joint is attached to the back of the **neck** a finger's-breadth from the trochanter, to the upper and lower borders of the neck near the trochanters, and to the **intertrochanteric line**; the part of the neck within the capsule is clothed with synovial membrane. The uppermost fibres of the vastus medialis muscle arise from the lower half of the intertrochanteric line; the uppermost fibres of the vastus lateralis from the upper half of the line, and from the front and lateral aspect of the root of the **greater trochanter**. The gluteus minimus is inserted into the *front* of the greater trochanter, and is partly separated from it by a *bursa*; the gluteus medius into its *lateral surface* on a broad, oblique ridge that extends downwards and forwards from the posterosuperior angle; the surface in front of the ridge is separated from the gluteus medius by a *bursa*, and another *bursa* intervenes between the gluteus maximus and the surface behind the ridge; the piriformis into the *upper border*; the obturator internus and the gemelli into the *medial surface* above the neck; the obturator externus into the **trochanteric fossa**; the quadratus femoris into the **quadrate tubercle** and into a strip leading down from the tubercle for an inch; the psoas major into the **lesser trochanter**; the iliacus into the tendon of the psoas, the lesser trochanter, and the area below and in front of the trochanter.

Part of the gluteus maximus is inserted into the **gluteal tuberosity**, and part of the vastus lateralis arises from its lateral edge; part of the vastus medialis from the **spiral line**. The surface between the spiral line and the gluteal tuberosity gives insertion to four muscles: part of the iliacus (see above); the pectineus into a strip which begins lateral to the back of the root of the lesser trochanter and runs down to the linea aspera; the upper part of the adductor brevis into the same strip, behind or lateral to the pectineus; the uppermost fibres of the adductor magnus between the attachment of the adductor brevis and the gluteal tuberosity.

The **linea aspera** gives attachment to the following structures, named from medial to lateral

side: the origin of part of the vastus medialis; the medial intermuscular septum; the insertion of the adductor longus, in the whole length of the line or in the distal two-thirds only; the insertion of the lower part of the adductor brevis, in the proximal third of the line; the insertion of a part of the adductor magnus; the posterior intermuscular septum; the origin of the greater part of the short head of the biceps femoris; the lateral intermuscular septum; the origin of part of the vastus lateralis from the proximal half of the line, and of part of the vastus intermedius from the distal half.

From medial to lateral side the following structures are attached to the **epicondylic lines**: part of the vastus medialis from the proximal two-thirds of the **medial** line; the medial septum and part of the adductor magnus into the whole length, except where interrupted for the passage of the femoral vessels; the lower parts of the short head of the biceps, the lateral septum, and the vastus intermedius from the proximal two-thirds of the **lateral** line.

The greater part of the vastus intermedius arises from the proximal two-thirds or three-fourths of the **anterior** and **lateral surfaces** of the shaft; the slender bundles of the articularis genu muscle from the distal part of the anterior surface. The medial surface is covered by vastus medialis, but does not give attachment to any muscle.

The medial head of the gastrocnemius arises from the rough patch on the **popliteal surface** above the medial condyle; the plantaris from a small area above the lateral condyle; the lateral head of the gastrocnemius from an impression on the lateral surface of the **lateral condyle** and the adjoining distal end of the lateral epicondylic line; the tendon of the popliteus from the anterior end of the **popliteal groove**, and when the knee is extended it crosses the lower lip of the groove, which therefore bears a shallow notch near its anterior end. The fibular collateral ligament of the knee is attached to the *lateral epicondyle*; the anterior cruciate ligament to the posterior part of the *lateral wall* of the **intercondylar notch**; the posterior cruciate ligament to the anterior part of the *medial wall*; the tibial collateral ligament to the *medial epicondyle*. The tendon formed by the posterior part of the adductor magnus is inserted into the **adductor tubercle**.

The fascia lata blends with the periosteum of both condyles at the sides of the knee. The fibrous stratum of the capsule of the knee joint is attached to the **intercondylar line** (*i.e.* the upper or posterior margin of the intercondylar notch), to the bone immediately above the posterior parts of the condyles, to the lateral condyle between the popliteal groove and the epicondyle, and to the medial condyle just distal to the medial epicondyle. There is no definite fibrous stratum in front, and the synovial stratum is reflected off the quadriceps on to the femur about a finger's breadth above the patellar surface; but, by means of a wide communication with a large *bursa* that lies under cover of the quadriceps, the cavity of the knee joint extends upwards to a point at least three finger-breadths above the patella. The apex of the patellar synovial fold is attached to the anterior margin of the intercondylar notch.

Ossification.—The **primary** centre for body and neck appears at the seventh week of fœtal life. At birth the body is ossified, and ossification extends into the neck after birth.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For distal end	9th month of *fœtal* life	21	Outside.
For head	1st year	20	Inside.
For greater trochanter	2nd ,,	19	Outside (inside superiorly).
For lesser trochanter	12th ,,	18	Outside.

The presence of the centre in the cartilage at the distal end in a new-born child found dead is accepted as proof that the child had come to full time. The epiphyseal line at the distal end passes through the adductor tubercle, and just above the patellar surface, and along the intercondylar line. The epiphyses join at intervals of a year in the order conforming to their size.

Structure and Variations.—As in other long bones, the ends are composed of spongy substance enclosed in a shell of compact substance, and the shaft is a thick tube of compact bone enclosing a medullary cavity; the cavity begins opposite the lesser trochanter and ends about a handbreadth from the distal articular surface. A sheet of compact tissue branches off the posterior wall of the upper end of the cavity and extends upwards, through the spongy tissue under cover of the lesser trochanter, to blend with the compact tissue of the back of the neck; it is called the **calcar femorale**, from its appearance when seen in section; it strengthens the neck.

The **head** usually looks upwards and slightly forwards as well as medially. The pit is situated below and behind the centre of the head; blood-vessels from the ligamentum teres enter through it, so that the head gets a double blood supply; sometimes the pit is absent, resembling the condition in the orang.

The **neck** extends laterally, downwards and slightly backwards from the head. Its posterior surface is concave lengthwise and convex from above downwards; usually a shallow, horizontal groove can be seen on it, leading into the trochanteric fossa; the tendon of the obturator externus lies in the groove. Its anterior surface is nearly flat, and nearly in the same plane as the head and body. Near the head it often presents a smooth patch, produced by pressure against the ilio-femoral ligament. The neck is joined to the body at an angle which varies, but averages 125°.

The angle is less in the adult than in the child, and less in short-limbed people, especially in women; the proximal ends of the bodies of the two femora are separated by the width of the pelvis and by the length of the two necks, while the distal ends are in contact; therefore the body of the femur is oblique; the obliquity is more marked in short-limbed men, and still more so in women, for the pelvis is wider; and the greater the obliquity, the less is the angle. At the upper end of the **intertrochanteric line** there is often a rough prominence, called the *femoral tubercle*, for the attachment of the stronger part of the ilio-femoral ligament.

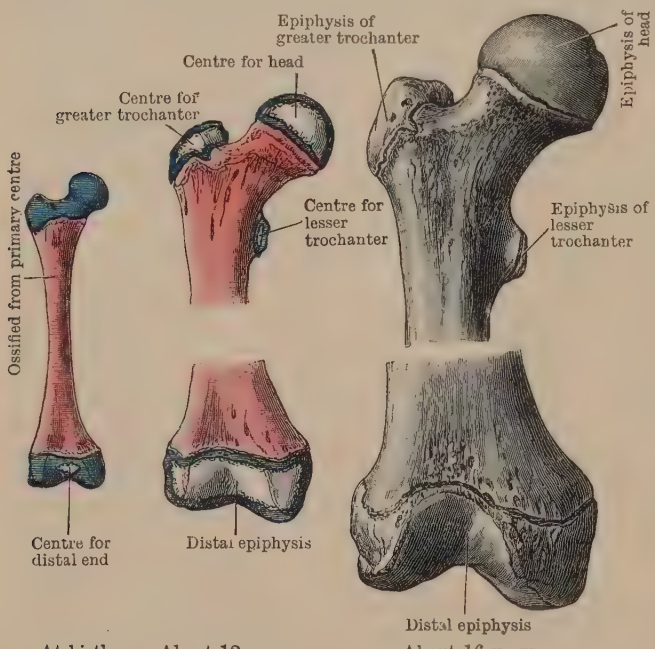

FIG. 222.—OSSIFICATION OF THE FEMUR.

Sometimes part of the **gluteal tuberosity** is so raised that it makes a prominent excrescence, easily felt in the living person, comparable to the **third trochanter** which is always present on the thigh-bone of a horse. Sometimes the tuberosity is represented by a depression called the *hypo-trochanteric fossa*.

The **body** of the femur is slightly twisted; it is curved, with the convexity forwards, and that partly accounts for the fulness of the front of the thigh; the degree of curvature varies considerably. The **linea aspera** may be a prominent keel; or it may be absent, as it is in apes. The proximal and distal parts of the body are rather compressed from before backwards; a femur showing an exaggerated degree of compression is called **platymeric**; the condition is more common in the femora of prehistoric races.

The distal surfaces of the **condyles** articulate partly with the proximal end of the tibia and partly with two crescentic pieces of fibro-cartilage, called the lateral and medial menisci [*μηνίσκος* (mēniscos) = a crescent], which lie within the knee joint between the femur and tibia; faint grooves, made by the anterior edges of the menisci, separate the *distal* articular surfaces from the *patellar* surface. The distal surfaces of the condyles are on the same horizontal plane when the femur is held in its proper oblique position, and therefore the medial condyle juts further downwards when the bone is held perpendicular. The medial condyle is narrower than the lateral, and is curved. The area for articulation with the patella in extreme flexion of the knee can sometimes be seen on the medial condyle where it bounds the anterior part of the inter-condylar notch.

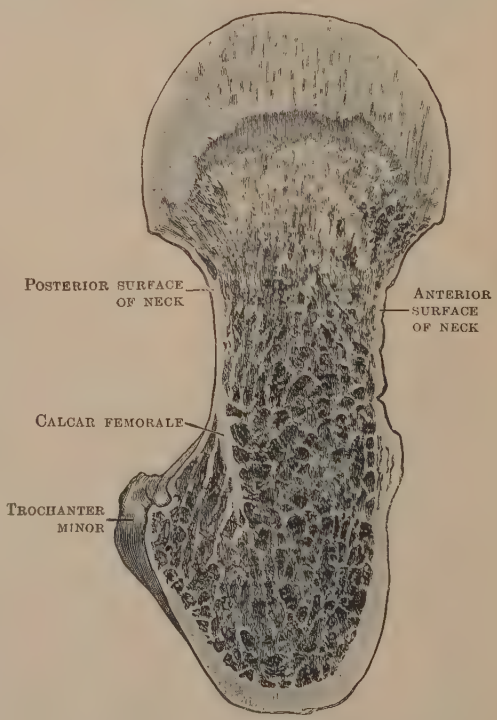

FIG. 223.—SECTION THROUGH HEAD AND NECK OF FEMUR TO SHOW CALCAR FEMORALE.

Patella.

The **patella** or knee cap or knee pan [*patella*, diminutive of *patina* = a pan] lies in the front of the knee, and articulates with the femur. It is a small compressed bone, measuring nearly two inches each way. The **posterior surface** is largely occupied by an oval *facet* for articulation with the femur; the

facet is divided by a blunt ridge into a larger lateral part, and a smaller medial part, which correspond to the sloping sides of the patellar surface of the femur. The **anterior surface** is triangular in outline; the *apex* of the triangle points towards the leg, and is on a level just above the plane of the knee joint, when the joint is extended; the base of the triangle is the anterior margin of the *base of the patella, i.e.*, its thick proximal border.

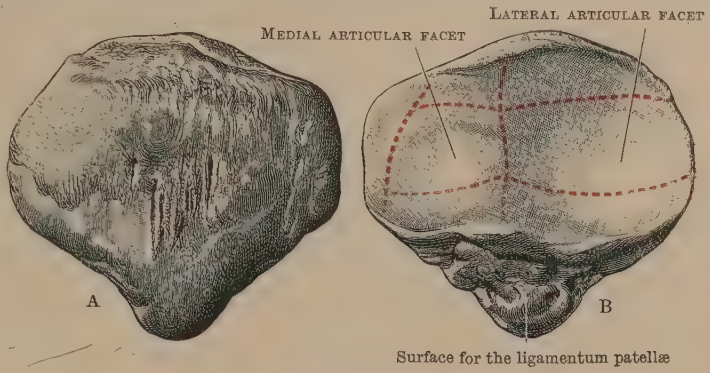

Fig. 224.—The Right Patella.
A. Anterior Surface. B. Posterior Surface.

The **patella** is the largest of the *sesamoid* bones; it lies in the tendon of the quadriceps femoris—the large four-headed muscle of the front of the thigh—and, playing against the patellar surface of the femur, it increases the leverage of the muscle when the muscle contracts to move the leg. The distal part of the quadriceps tendon is called the *ligamentum patellæ*—a strong, broad band that stretches from the patella to the tibia, and on which the body partly rests in the kneeling posture. When the knee is extended and the muscles are relaxed, the patella can be moved from side to side fairly freely, and to some extent also downwards; when the knee is flexed the quadriceps muscle, including the ligamentum patellæ, is put on the stretch, the patella is jammed hard against the femur and is immovable.

Attachments.—The three vasti and the rectus femoris are inserted into the base or proximal border; vastus lateralis and medialis, respectively, into the lateral and medial margins also. The ligamentum patellæ is attached to the apex and adjoining part of the posterior surface, but the greater part of the rough surface below the articular facet is related to fat and the synovial membrane of the knee.

Ossification.—The patella is cartilaginous at birth. Ossification, usually from a single centre, begins about the third year, and is completed about puberty.

Structure and Variations.—The patella is composed of spongy tissue enclosed in a shell of compact tissue. Cases have been noted in which the patella was absent; its absence is said to be hereditary and transmitted in the female line. A case has been recorded in which the patella was divided into a large upper part and a smaller lower part imbedded in the ligamentum patellæ; and separate epiphyseal nodules have been found in the lateral margin of the patella (Holland, *Jour. Anat.*, 1921).

Tibia.

The **tibia** or shin-bone [*tibia* = shin-bone] comes next in size after the femur, and is between a fourth and a fifth of the length of the body. It is the medial and larger of the two bones of the leg, and can be felt through the skin in all its length. It is a long bone, possessing a **body** or shaft and **two extremities.** The most outstanding border of the body is the **anterior** border; the **distal** end is the smaller end; and on the **medial** side of the distal end there is a stout blunt projection which is called the *medial malleolus.*

The **proximal end** is large and expanded to support the distal end of the femur, and is bent slightly backwards; it includes two imperfectly separated condyles and a tuberosity.

The **tuberosity** is the low elevation on the anterior aspect where the proximal end joins the anterior border of the shaft; its distal part is rough; its proximal part is smooth and rounded, and gives attachment to the ligamentum patellæ.

The two **condyles** make up nearly the whole of the proximal end of the tibia; they are separated *posteriorly* by a wide, shallow depression called the **popliteal notch**; *anteriorly*, above the tuberosity, they are united by a more or less flattened surface concealed behind the ligamentum patellæ; in the kneeling posture the body rests on the ligamentum patellæ and the anterior aspects of the two condyles. The *proximal surface* of each condyle is large, oval and smooth; it articulates with the corresponding condyle of the femur; the more central part of the surface articulates directly with the femur, but the more peripheral part is separated from

the femur by a semilunar fibro-cartilage, called a *meniscus*. Between the articular surfaces of the two condyles there is a broad, rough strip, rising near its middle into a rough tubercle called the **intercondylar eminence**, and the depressions in front of and behind the eminence are called the *anterior* and *posterior* **intercondyloid fossæ**, the posterior fossa being continuous with the popliteal notch.

On the *posterior* aspect of the **medial condyle** there is a rough, horizontal groove for the insertion of part of the tendon of the semimembranosus muscle. The **lateral condyle** stands more abruptly away from the shaft than the medial does, so that it has a *distal surface* separated from the lateral surface by a curved line or ridge to which a thick band of fascia, called the *ilio-tibial tract*, is attached. On the posterior part of the distal surface there is a flat, circular **facet** for articulation with the head of the fibula; on the anterior part of the *lateral surface* there is usually quite a well-marked impression for the attachment of the anterior part of the ilio-tibial tract. Both the condyles can be felt through the skin at the sides of the knee.

The **distal end** of the tibia has five surfaces—anterior, posterior, lateral, medial, and distal.

The **anterior surface** is smooth and rounded, and can be felt indistinctly through the skin and the tendons which descend from the front of the leg to the foot.

The **medial surface** is subcutaneous, and from it there juts downwards a short, broad, thick projection, called the **medial malleolus**, which is the well-known prominence, both felt and seen, on the medial side of the ankle [*malleolus* = a small hammer]. The distal border of the malleolus is occupied by a well-marked pit for the attachment of an exceedingly strong fibrous band named, from its shape, the *deltoid ligament* [Δ = the Greek capital letter *delta*]; the lateral surface of the malleolus is smooth and articulates with the medial surface of the talus or ankle bone.

The **posterior surface** lies deeply under cover of a pad of fat and the tendo calcaneus—*i.e.*, the stout sinew felt above the heel. The surface is on the same plane as the back of the malleolus, which can be felt. Where it merges into the back of the malleolus there is a distinct vertical groove which lodges the tendons of the tibialis posterior and flexor digitorum longus; nearer the lateral side there is an indistinct groove which lodges the tendon of the flexor hallucis longus.

The **lateral surface** is occupied by a wide triangular depression, the apical part of which extends on to the body; it is called the **fibular notch** because the distal part of the fibula lies in it; the fibula is usually in actual contact with the distal smooth part, but is bound to the rough proximal part by a very short but very thick interosseous ligament.

The **distal surface** is square and smooth, concave from before backwards, slightly convex from side to side, and broader in front than behind; it articulates with and rests upon the upper surface of the talus, which is the first bone of the tarsus.

Corpus Tibiæ.—The **body** or shaft is thinnest about the junction of the middle and distal thirds; it becomes thicker towards the distal end and still more so towards the proximal end. It has three borders and three surfaces. The *borders* are anterior, medial, and lateral; the *surfaces* are posterior, lateral, and medial.

The **anterior border** or *anterior crest* is the shin of the leg. It is the most prominent of the borders; it begins at the tuberosity and extends sinuously to the anterior margin of the medial malleolus; it can be felt from end to end in the living leg. Every one is familiar with it; small notches, the result of accidental impacts, may be felt in it.

The **medial border** is a smooth, blunt margin that extends from near the back of the medial condyle to the back of the medial malleolus; it also can be felt from end to end.

The **lateral border** is a distinct, sharp line, but is not prominent. It is traced more easily from below upwards; it extends from the apex of the fibular notch to the distal aspect of the lateral condyle, some distance in front of the facet for the head of the fibula. It is usually called the **interosseous crest** because it gives attachment to the interosseous membrane—a strong, wide, fibrous sheet which stretches between the tibia and the fibula.

The **medial surface**, between the anterior crest and the medial border, is smooth and can be felt through the skin; it is continuous with the medial malleolus at the distal end; at its proximal end it is slightly roughened for the attachment of certain tendons and ligaments which overlie it.

The **lateral surface** is situated between the anterior and interosseous crests,

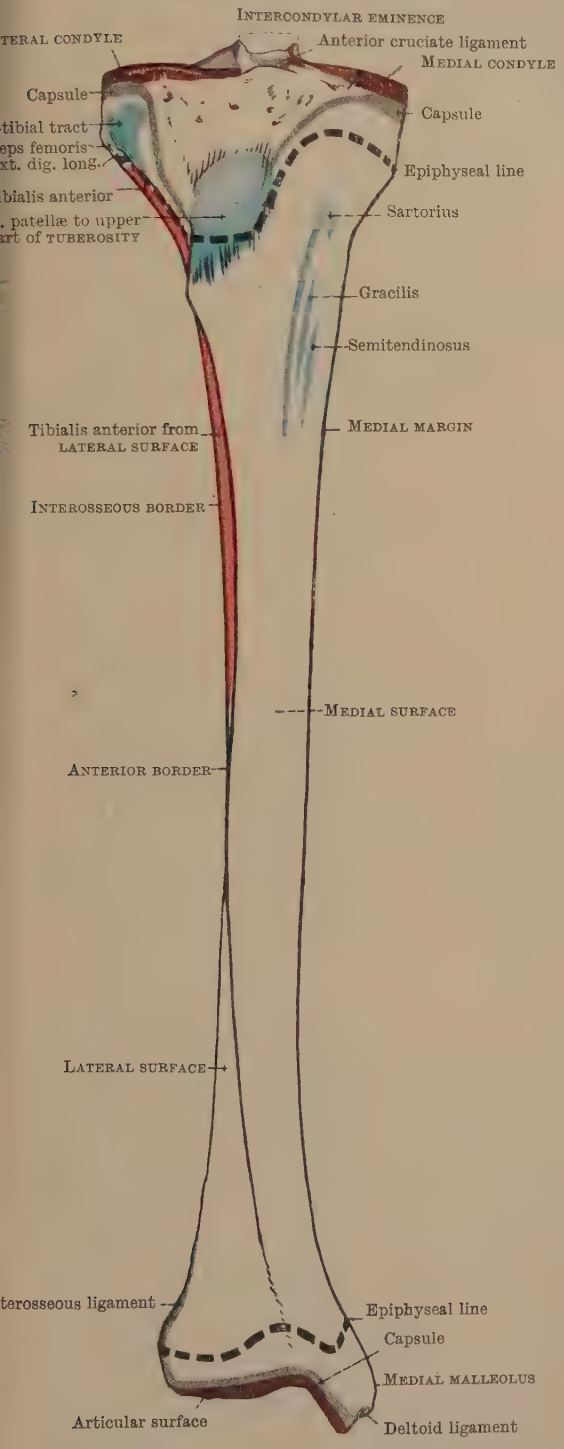

FIG. 225.—ANTERIOR ASPECT OF RIGHT TIBIA.

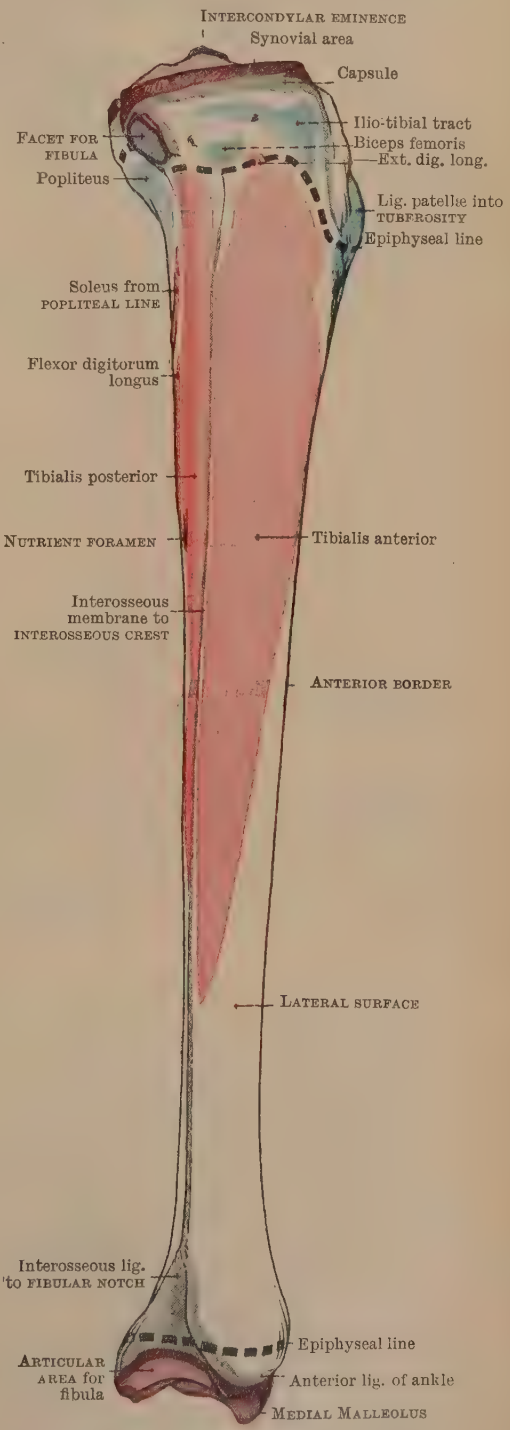

FIG. 226.—LATERAL ASPECT OF RIGHT TIBIA.

and, owing to the direction of the distal parts of those borders, it turns forwards to become continuous with the front of the distal end of the tibia.

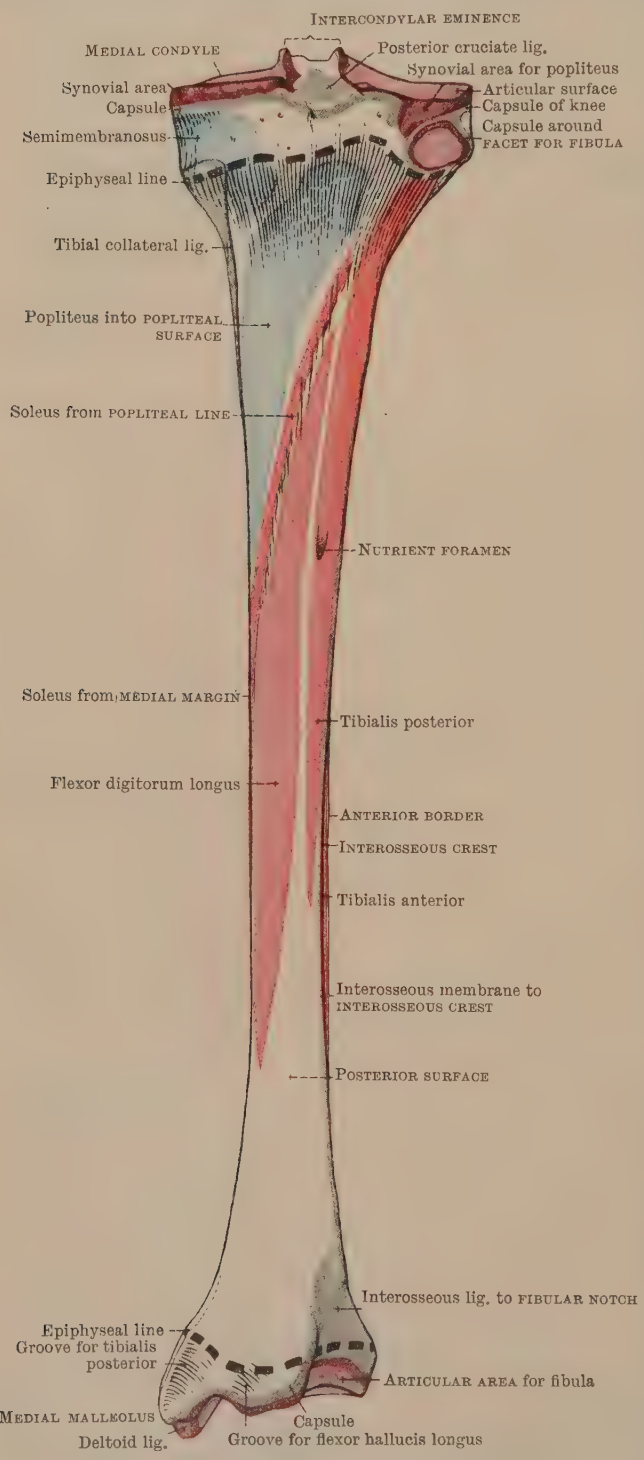

FIG. 227.—POSTERIOR ASPECT OF RIGHT TIBIA.

The **posterior surface** is situated between the medial border and the interosseous crest; its proximal part encroaches on the lateral aspect of the bone owing to the position of the proximal part of the crest. The proximal third of the posterior surface is crossed by an oblique ridge, called the **popliteal line**, which begins near the facet for the head of the fibula and runs in a medial and distal direction towards the medial border. The part of the surface above the line is called the **popliteal surface** of the tibia; the popliteus muscle, which lies in the distal part of the floor of the popliteal fossa, is inserted into the popliteal surface. The part of the surface below the popliteal line is usually imperfectly subdivided into medial and lateral parts by a more or less *vertical line*, which is blunt and often ill-defined.

The **nutrient foramen** is situated near the popliteal line and is directed towards the distal end.

Attachments.—The articular capsule of the knee joint is attached to the circumference of the **condyles** just below the margins of the articular surface; the capsule of the proximal tibio-fibular joint to the circumference of the **facet for the fibula**; the cruciate ligaments and the horns of the crescentic menisci to the rough strip between the condyles, in the following order from before backwards: anterior horn of medial meniscus and anterior cruciate ligament to the *anterior intercondyloid fossa*, the horns of the lateral meniscus to the front and back of the *intercondyloid eminence*, the posterior horn of the medial meniscus to the *posterior intercondyloid fossa*, the posterior cruciate ligament to the same fossa and to the *popliteal notch*. The fascia lata to the sides of both *condyles*; its ilio-tibial tract to the ridge and impression on the *lateral condyle*. Below that ridge, on the overhanging, distal surface of

the condyle, a few fibres of the biceps femoris are inserted, in front of the facet for the fibula, and a few fibres of the peroneus longus, extensor digitorum longus, and tibialis anterior muscles take origin. Part of the tendon of the semimembranosus is inserted into the medial part of the horizontal *groove* on the back of the *medial condyle* and into the rough area distal to the groove; and the ligamentum patellæ into the smooth, proximal part of the **tuberosity** of the tibia.

The tibial collateral ligament of the knee is attached to a rough patch about two inches long and half an inch wide on the *medial surface of the* **body**, just in front of the proximal part of the medial border. The tendons of the semitendinosus, gracilis, and sartorius, in that order from behind forwards, have linear insertions into the area immediately in front of that rough patch. The tendon of the popliteus, as it emerges from the knee joint, lies in a smooth, shallow groove on the back of the lateral condyle, and, becoming fleshy, it widens out to be inserted into the **popliteal surface**. Part of the soleus arises from the **popliteal line** and the middle third of the *medial border*; the flexor digitorum longus from the proximal two-thirds of the *medial area* of the **posterior surface**; part of the tibialis posterior from the *lateral area*; and the fascia covering the tibialis posterior is attached to the *vertical line*; the interosseous membrane to the *interosseous crest*; the fascia of the leg to the *medial border* and to the *anterior crest*; the transverse ligament of the leg to the distal part of the anterior crest.

The cruciate ligament of the ankle is attached to the *anterior* border of the **medial malleolus**; the deltoid ligament to the *distal* border; the ligamentum laciniatum to the *posterior* border; the posterior ligament and inferior transverse ligament of the ankle joint to the *posterior* border of the **distal end**; the anterior ligament to the *anterior* border; the interosseous tibio-fibular ligament to the rough floor of the **fibular notch**; the anterior and posterior ligaments of the lateral malleolus to the prominent anterior and posterior *margins* of the distal part of the notch.

Ossification.—The **primary** centre appears at the seventh week of fœtal life. At birth only the ends are cartilaginous.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For proximal end	Birth	21	Outside.
For distal end	2nd year	18	Outside.

The *proximal* epiphyseal centre appears shortly after birth and sometimes shortly before birth. The *epiphyseal line* extends downwards in front to include the greater part of the tuberosity. Occasionally there are additional epiphyseal centres for the tuberosity and the medial malleolus.

Structure and Variations.—The structure is like that of the other long bones. The medullary cavity falls short of each end by two or three inches.

Tibiæ which show compression from side to side are called **platyknemic**; the condition is more common in prehistoric and savage people than among modern Europeans. Exaggerated *retroversion* of the proximal end is said to be due to the habit that some people have of walking with the knees slightly bent. The parts of the articular surface of a condyle that articulate with the meniscus and with the femur respectively may be indicated by a difference in texture or in colour. In people who habitually squat rather than sit there may be a "pressure" facet on the anterior margin of the distal end, due to contact with the neck of the talus in the squatting posture.

Fibula.

The **fibula** or splinter bone is the lateral and smaller bone of the leg. It is almost as long as the tibia but is very slender, and it has slightly expanded ends. In some animals it is pointed at one end—hence its name [*fibula* (from figibula) = a pin or skewer; the equivalent word in Greek is περόνη (peronē), hence the names *peroneus* and *peroneal* given to muscles, vessels, and nerves related to the fibula].

The fibula has a shaft or **body** and **two extremities**; it is thickly covered with muscles except at its proximal and distal ends, and is not easily palpated except at the ends. The **proximal** end is knob-like; the distal end is compressed from side to side and is triangular in outline; on the **medial** side of the distal end there is a large, nearly flat, triangular facet; the **posterior** aspect can be recognised from the fact that there is a pit *behind* the lower part of the facet.

The **proximal end** is called the *head* of the fibula. The anterior, posterior, lateral, and medial surfaces of the **head** are identified more easily after the surfaces of the body and distal end have been recognised; the medial part of the *proximal surface* bears a *facet* of considerable size for articulation with the lateral condyle of the tibia; a stunted projection, called the **apex** of the head or styloid process, stands up from the junction of the *lateral* and *posterior* surfaces. The

head is felt as a hard knob well back on the lateral aspect of the leg, on a level with the tuberosity of the tibia. If the finger is passed round to its posterior surface a big nerve, called the *common peroneal nerve*, can be felt and rolled between the finger and the bone; it is felt most easily when the knee is bent to a right angle and the muscles are relaxed. The part of the shaft immediately adjoining the head is called the **neck** of the fibula and can also be felt; the nerve inclines downwards and forwards from the back of the head and ends on the lateral aspect of the neck, and is most liable to injury there.

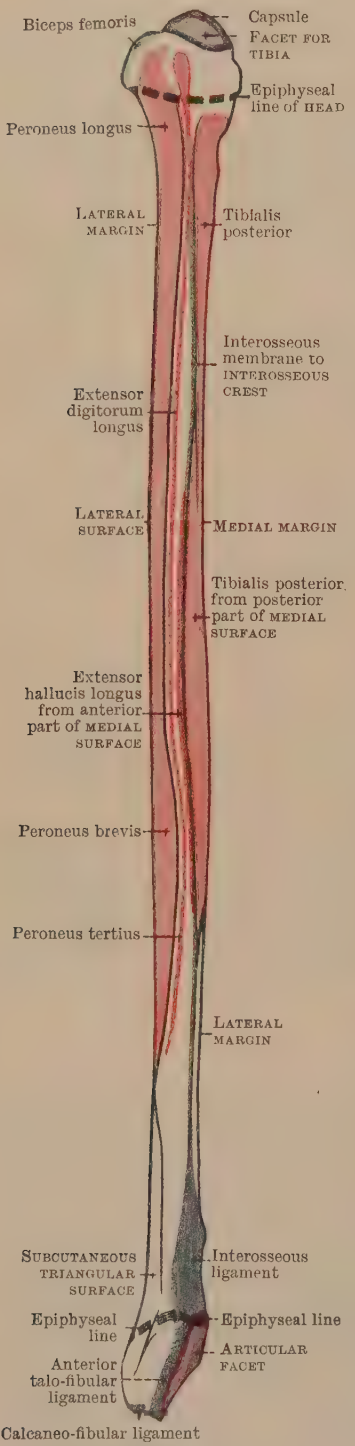

Fig. 228.—Anterior Aspect of Right Fibula.

The **distal end** is called the *lateral malleolus*. It is the outstanding prominence on the lateral side of the ankle. It articulates with the lateral surface of the distal end of the tibia, but projects downwards beyond the tibia, articulating with the lateral surface of the talus; the talus is therefore gripped between the two malleoli.

The **lateral malleolus** has four surfaces—lateral medial, anterior, and posterior. The **lateral surface** is subcutaneous. The **medial surface** bears a large articular *facet*; the malleolus projects so far beyond the tibia that only the proximal edge of the facet articulates with the tibia; practically the whole of it articulates with the talus. The pit behind and distal to the facet is sometimes called the *digital fossa* because it can accommodate the tip of the little finger. The rough mark on the shaft, just above the facet, lies in the fibular notch of the tibia and is bound to its floor by an interosseous ligament. The **anterior surface** is narrow from side to side, convex from above downwards, and slightly roughened. The **posterior surface** is wider and flatter than the anterior; the tendon of the peroneus brevis lies on it and often grooves it longitudinally, and the tendon of the peroneus longus lies on that of the brevis.

The **body** or shaft of the fibula, though slender, is strongly ridged and grooved, but the ridges and grooves are not all alike in all fibulæ. Like the other long bones, the fibula is twisted, but, as it is slender and its surfaces narrow, the torsion has a greater apparent effect in altering the directions in which the surfaces look than it has in thicker bones. Therefore the identification of the surfaces and borders of the shaft of the fibula presents difficulties to the beginner and takes up time out of all proportion to its importance, for the shaft of the fibula is merely a stanchion for the attachment of muscles and fasciæ and the interosseous membrane; the fibula does not support the body, since it does not articulate with the femur, and, being closely bound to the tibia at each end, it does not serve independently as a lever in the movements of the leg.

Corpus Fibulæ.—The **body** of the fibula is described as having three borders and three surfaces. The *borders* are anterior, medial, and lateral. The *surfaces* are posterior, lateral, and medial. But an additional border, called the interosseous crest, divides the medial surface into an anterior part and a

posterior part; and there is an additional, small "triangular subcutaneous surface" not included in any of the three surfaces named above.

The **triangular subcutaneous surface** should be identified first. It is a narrow triangular area,

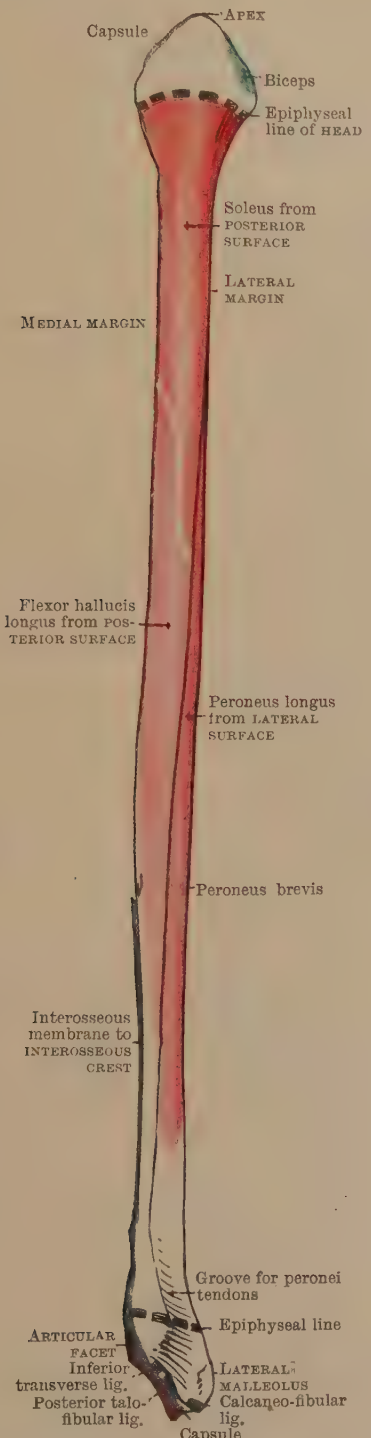

Fig. 229.—Posterior Aspect of Right Fibula.

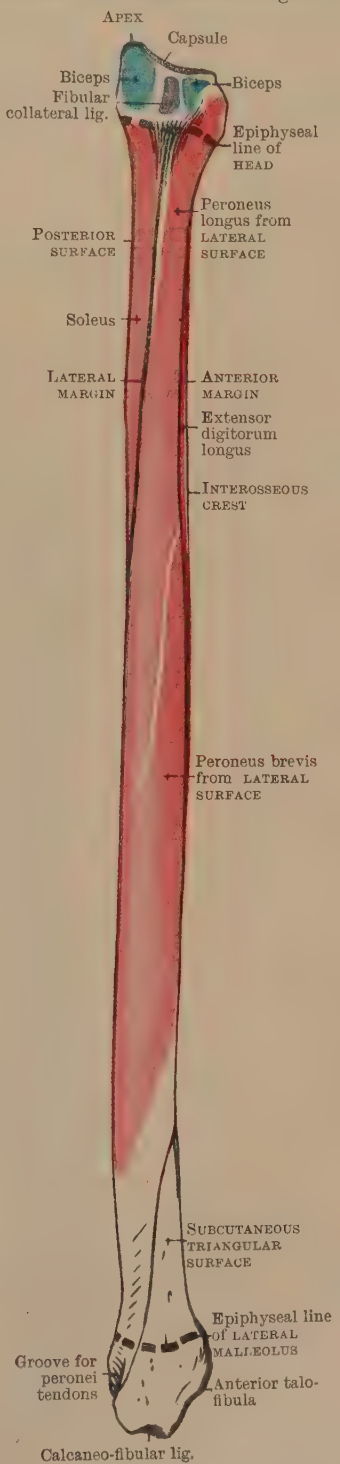

Fig. 230.—Lateral Aspect of Right Fibula.

about two inches long, on the distal part of the body; its base is continuous with the lateral surface of the lateral malleolus, and both the malleolus and the triangular surface are easily identified through the skin.

Crista Anterior.—The **anterior border** or **crest** is located most easily at the *apex* of the triangular subcutaneous surface, where it bifurcates to enclose that surface; from that point it passes proximally to the neck as a sharp even line.

Crista Interossea.—The **interosseous crest** should be located next. It is medial to the anterior border, and should be looked for first in the distal third of the body, where there is nearly always an interval of a quarter of an inch or so between it and the anterior border. Its distal end runs into the rough triangular patch above the medial surface of the malleolus. When traced towards the neck it is apt to be lost, for in many fibulæ it approaches the anterior border or crest so closely that the two almost merge into one, and even when the two crests remain quite distinct there is seldom more than a twelfth of an inch interval between them near the neck. The interosseous crest is never a strongly marked line though the interosseous membrane is attached to it.

Crista Medialis.—The **medial border** should be looked for next; it is medial to and behind the interosseous crest, and in some fibulæ it is the most outstanding ridge on the bone. It begins at the neck, but, instead of running the whole length of the shaft like the other borders, it joins the interosseous crest three or four inches from the distal end; it should be located there first and traced towards the neck.

Crista Lateralis.—The **lateral border** is the remaining ridge on the fibula, and is usually well defined. It begins at the neck and ends at the posterior margin of the medial surface of the malleolus.

Facies Lateralis.—The **lateral surface** is that which lies mainly between the lateral border and the anterior border, but its distal fourth or fifth lies between the lateral border and the subcutaneous triangle, and, owing to the twist of the fibula, it becomes continuous with the *posterior* surface of the malleolus.

Facies Posterior.—The **posterior surface** lies between the lateral border and the medial border in the proximal two-thirds or so of the bone; but, since the medial border does not reach the distal end, the distal part of the surface lies between the lateral border and the interosseous crest, and, owing to the twist, it becomes continuous with the medial surface of the malleolus.

Facies Medialis.—The **medial surface** is the remaining surface; it is divided by the interosseous crest into an anterior and a posterior part. The *anterior part* lies between the anterior border and the interosseous crest; towards the distal end it is about a quarter of an inch in breadth; near the neck it may be reduced to a mere line. The *posterior part* lies between the interosseous crest and the medial border, and therefore is found only in the proximal two-thirds of the bone; its proximal part is often crossed by an oblique ridge which extends from above downwards and backwards, and may be mistaken for the proximal part of the medial border.

The **nutrient foramen** of the fibula is situated usually on the posterior surface, about the junction of the proximal and middle thirds, and is directed towards the distal end; it may be situated near the distal third.

Attachments.—The greater part of the tendon of the biceps is inserted into the **head**, in front of the apex. The fibular collateral ligament of the knee is attached to the head under cover of the biceps tendon; the capsule of the proximal tibio-fibular joint to the margins of the *facet*; the ilio-tibial tract to the *lateral aspect* of the head. The muscles that arise from the proximal part of the shaft take origin also from the adjoining surfaces of the head.

The peroneus longus arises from the head and the proximal two-thirds of the *lateral surface* of the body; the peroneus brevis from the distal two-thirds, overlapping the longus anteriorly in the middle third; part of the soleus from the head and the proximal third of the *posterior surface*; the flexor hallucis longus from the distal two-thirds; part of the tibialis posterior from the head and the *posterior part of the medial surface*; the extensor digitorum longus from the head and the proximal two-thirds of the *anterior part*; the peroneus tertius from the distal third; and, medial to those two, the extensor hallucis longus from the middle three-fifths. The interosseous membrane is attached to the *interosseous crest*; the fascia covering the tibialis posterior to the *medial border*; the posterior intermuscular septum to the *lateral border*; the anterior intermuscular septum to the greater part of the *anterior border*; the deep fascia of the leg to the *margins of the subcutaneous surface*, including the lig. transversum cruris attached to its anterior margin; the interosseous ligament to the rough area above the facet at the distal end.

The anterior and posterior ligaments of the **lateral malleolus** are attached to the corresponding margins of the facet; the anterior talo-fibular ligament to the *anterior surface* of the malleolus near its tip; the calcaneo-fibular ligament to the *tip*; the posterior talo-fibular ligament and the inferior transverse ligament of the ankle joint to the **digital fossa**; the superior retinaculum of the peroneal tendons to the margins of the *posterior surface* of the malleolus.

Ossification.—The **primary** centre appears at the seventh week of fœtal life. Only the ends are cartilaginous at birth.

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For distal end	2nd year	18-20	Medial part inside, lateral part outside.
For proximal end	4th ,,	20-25	Outside.

Structure and Variations.—The structure is like that of other long bones. The medullary canal extends from the neck to a point about three inches from the tip of the malleolus. The fibula is occasionally absent or incompletely developed. The facet on the head may be double or may be absent.

Tarsus.

The term **Tarsus** originally included nearly the whole foot [ταρσός (tarsos)= the part of the foot between the toes and the heel], but it is now applied only to

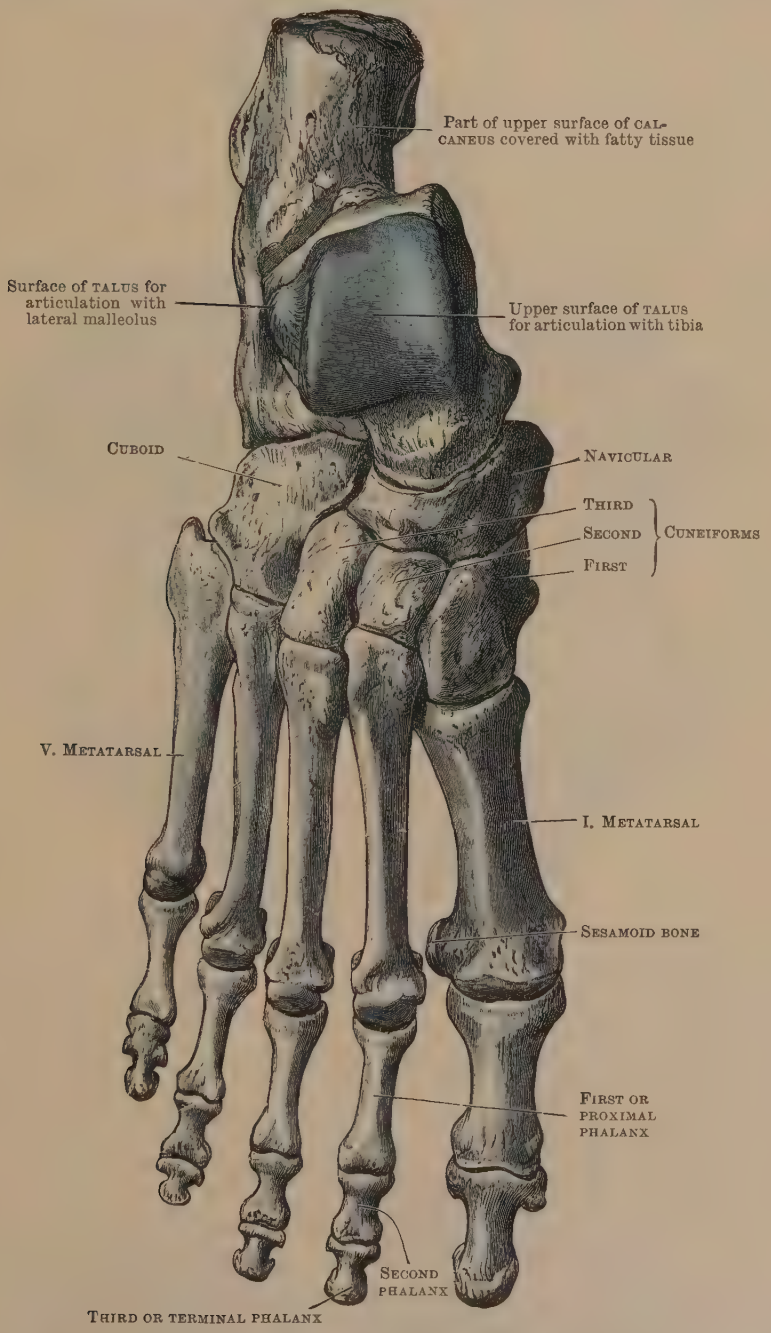

FIG. 231.—UPPER OR DORSAL SURFACE OF BONES OF RIGHT FOOT.

the posterior half of the foot, the skeleton of which consists of seven bones called tarsal bones.

The **tarsal bones** are closely bound together by ligaments. They are arranged in two rows, with an intermediate bone between the rows. There are two bones in the first row; they are the largest of the tarsal bones and are named the **talus** and the **calcaneus**; they are placed not side by side, but the talus on

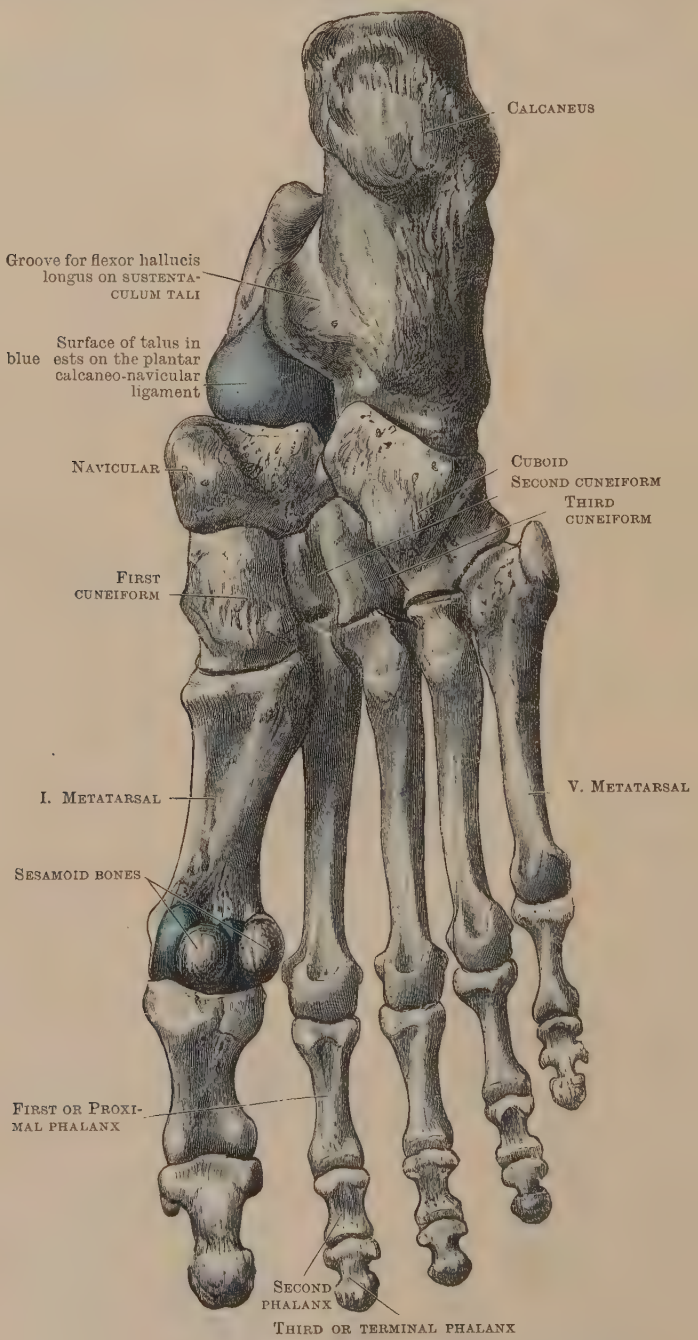

Fig. 232.—Lower or Plantar Surface of Bones of Right Foot.

the top of the calcaneus. The second or distal row comprises four bones placed side by side—three **cuneiform** bones and, lateral to them, the **cuboid** bone. The intermediate bone is called the **navicular**; it is placed between the talus and the three cuneiform bones.

All the tarsal bones are more or less cuboidal in shape, and each is therefore

described as having six surfaces—anterior, posterior, superior, inferior, lateral, and medial.

A knowledge of the characters of the individual bones is more necessary in the case of the tarsus than in the case of the carpus.

Calcaneus.

The **calcaneus** is the bone of the heel [*calcaneum* (allied to calx) = the heel]. It is the largest of the tarsal bones, being nearly three inches in length and about half of that in thickness.

The *anterior* and *posterior surfaces* are the ends of the bone. The anterior surface is smooth and concavo-convex, and articulates with the cuboid bone; the posterior surface is rough, and the tendo calcaneus is inserted into a specially roughened strip across the middle of the surface.

The *superior surface* is distinguished from the others because it has a large, oval, smooth facet about its middle; the facet is for articulation with the body of

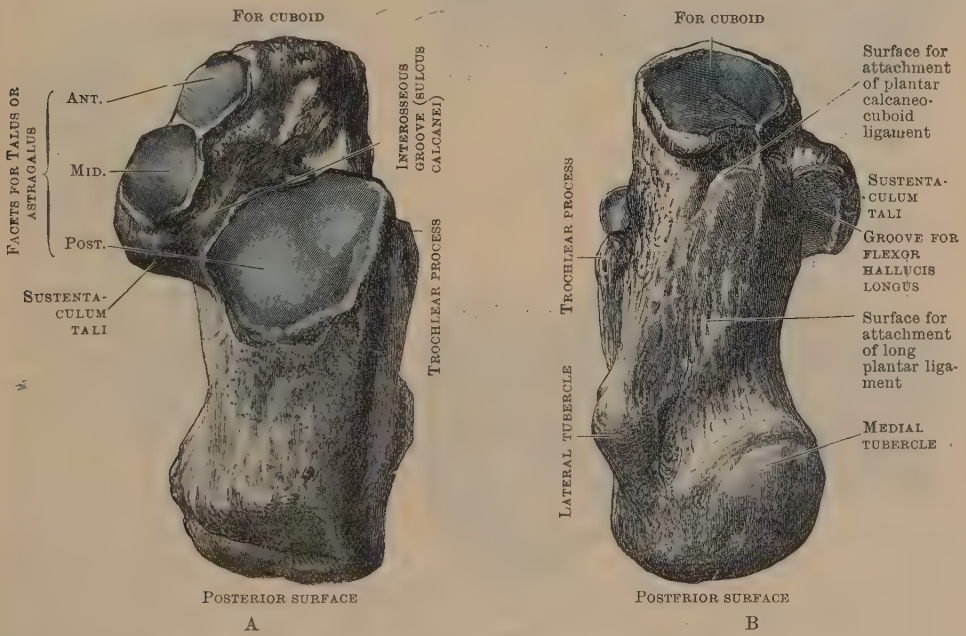

Fig. 233.—Right Calcaneus. A, seen from above; B, seen from below.

the talus. In front of the facet there is a rough groove for the attachment of a strong interosseous ligament that binds the talus and calcaneus together. In front of the lateral part of that groove there is a rough, fairly flat area, and at the anterior and medial corner of the area there is usually a small facet for articulation with the head of the talus. In front of and medial to the medial part of the groove there is a projecting shelf of bone, called the **sustentaculum tali** because part of the talus rests on it; the upper surface of the sustentaculum is smooth for articulation with the talus; its lower surface is occupied by a shallow groove in which the tendon of the flexor hallucis longus is lodged as it runs forwards into the sole of the foot; the thick, rough medial border of the sustentaculum can be felt in the living body as an ill-defined bony resistance directly below the medial malleolus.

The *inferior surface* is rough. At its anterior part there is a low, rounded eminence called the **anterior tubercle** of the calcaneus. At its most posterior part there are two blunt, rounded prominences called the **lateral** and **medial tubercles** or processes of the calcaneus; the medial tubercle is the larger of the two. When the calcaneus is laid on the table it rests on the three tubercles; but that is not its position in the foot: when the sole is on the ground the calcaneus is placed so that it rests on the backs of the lateral and medial tubercles, *i.e.*, on the lower,

sloping part of the posterior surface, and the anterior part of the bone is raised up from the ground.

The *medial surface* is markedly concave owing to the projection of the medial tubercle and the sustentaculum. The *lateral surface* is slightly convex and is rough. On the anterior half of the surface, in some specimens, there is a small but well-marked tubercle called the **trochlear process**; the tendons of the peroneus longus and brevis cross the surface obliquely, the longus below the tubercle, the brevis above it, and produce shallow grooves on the bone. Except for the strips covered by those two tendons, the whole of the lateral surface is subcutaneous and can be felt in the living foot.

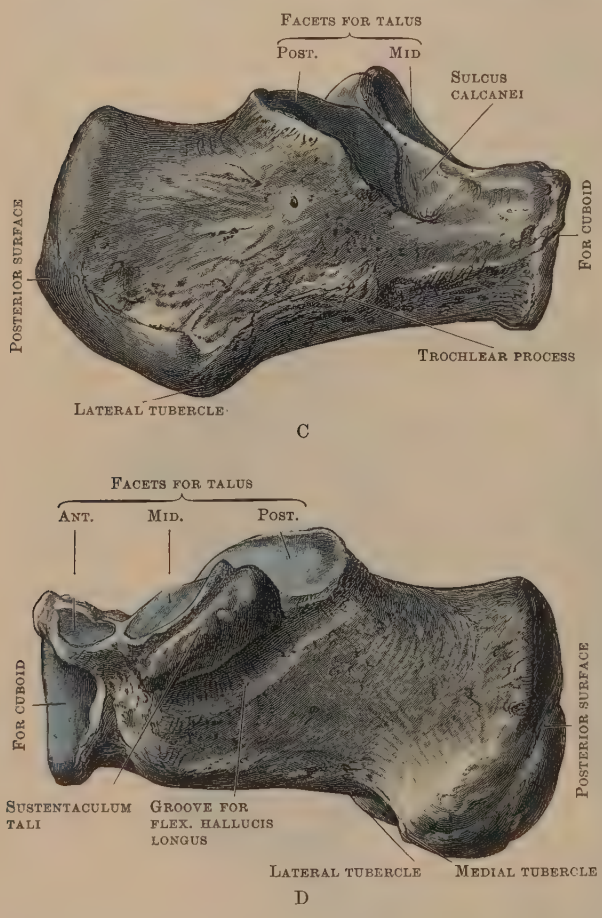

FIG. 234.—RIGHT CALCANEUS. C, Lateral side; D, Medial side.

Attachments.—The tendo calcaneus is inserted into the rough strip across the middle of the *posterior surface*, and is separated from the upper part of the surface by a *bursa*; the lower part of the surface is covered with the fatty pad on which the heel rests. The calcaneo-fibular ligament is attached to the middle of the *lateral surface*; the inferior peroneal retinaculum to the margins of the grooves which lodge the peroneal tendons. The ligamentum laciniatum and the thick, middle part of the plantar aponeurosis are attached to the **medial tubercle**, and parts of the abductor hallucis and flexor digitorum brevis arise from it; the abductor digiti quinti from both **medial and lateral tubercles**. The plantar calcaneo-cuboid ligament is attached to the **anterior tubercle**; the long plantar ligament to the wide area on the *inferior surface* behind the anterior tubercle; the lateral head of the quadratus plantæ arises from the lateral edge of that area, and the large medial head from the *medial surface*. The deltoid ligament and the plantar calcaneo-navicular ligament are attached to the medial margin of the **sustentaculum tali**, and a slip from the tendon of the tibialis posterior is inserted into it.

The following structures, after they leave the back of the leg and turn forwards into the sole of the foot, are related to the sustentaculum tali: the tendon of the tibialis posterior lies above it, between it and the medial malleolus; the tendon of the flexor hallucis longus lies on its grooved lower surface; the tendon of the flexor digitorum longus lies on its medial margin; the posterior tibial vessels and the tibial nerve lie between the tendons of the flexor digitorum and flexor hallucis.

The capsule of the talo-calcanean joint is attached to the margins of the large oval *facet* on the *upper surface*; the wide, saddle-shaped area behind the facet is covered with the fatty fibrous tissue in front of the tendo calcaneus; the groove in front of the facet gives attachment to the strong interosseous talo-calcanean ligament; the rough flat area in front of the lateral end of the groove gives attachment to the stem of the ligamentum bifurcatum, the stem of the ligamentum cruciatum cruris, and some fibres of origin of the extensor digitorum brevis; and the dorsal calcaneo-cuboid ligament is attached to the upper and lateral margins of the *anterior surface*.

Talus.

The **talus**, or witch bone, or ankle bone is next to the calcaneus in size, and has large smooth articular facets on several of its surfaces. It rests on the upper surface of the calcaneus, directly below the distal end of the tibia; it is gripped

between the two malleoli, and with them and the distal end of the tibia it form the *ankle joint* [*talus* = the ankle bone].

The bulkier part of the talus is called the *body*; the smooth and rounded end is the anterior part of the bone, and is called the *head*; the rough, slightly constricted part between the head and the body is called the *neck*.

The *superior surface* of the **body** is a large face for articulation with the distal end of the tibia. It is convex from before backwards, slightly concave from side to side, and is narrower behind than in front; it is sometimes called the **trochlea**. The *inferior surface* has two facets with a deep groove between them. The posterior facet is large, concave, and oval, and articulates with the large oval facet on the upper surface of the calcaneus. The anterior facet is on body, neck, and head; it articulates with the sustentaculum tali, and with the facet on the anterior part of the upper surface of the calcaneus; the facet on the talus varies in its extent, and the part on the head may lie separate from the rest.

17. GROOVE FOR FLEXOR HALLUCIS LONGUS.
18. MEDIAL TUBERCLE.

The *medial surface* can be distinguished from the lateral surface because it is nearly all rough, and is flush with the medial side of the neck. Near the upper margin there is a comma-shaped facet for articulation with the medial malleolus.

The *lateral surface* stands away from the neck, and is nearly all occupied by a large facet for articulation with the lateral malleolus.

The *posterior surface* is very small. It is crossed by a fairly broad, oblique groove which lodges the tendon of the flexor hallucis longus. When the talus and calcaneus are placed together properly, that groove is continuous with the groove for the same tendon on the lower surface of the sustentaculum tali. The projection on the lateral side of the groove is called the **posterior tubercle** of the talus, and that on the medial side is called the **medial tubercle**.

The *anterior surface* is the convex, smooth surface of the **head**; it articulates with the navicular bone. The facet on the lower surface of the head for articulation with the anterior part of the upper surface of the calcaneus is usually continuous with the facet that articulates with the sustentaculum tali. The lower part of the medial side of the head articulates not with a bone, but with a ligament called the plantar calcaneo-navicular or "spring" ligament, which

stretches between the sustentaculum tali and the plantar surface of the navicular bone; a faint ridge often marks off that area from the rest of the articular surface of the head.

When the talus and the calcaneus of the same foot are placed together properly, their anterior surfaces are almost in the same transverse vertical plane, and the anterior surface of the talus is medial to that of the calcaneus as well as above it; the anterior surfaces of the talus and the calcaneus articulate respectively with the navicular and the cuboid, and the two joints are spoken of together as the *transverse tarsal joint.* The movements of inversion and eversion of the foot take place largely at the transverse tarsal joint. **Inversion** is the movement whereby the medial border of the foot is lifted up, and the sole looks towards the median

plane. **Eversion** is the movement whereby the lateral border of the foot is lifted up, and the sole looks in a lateral direction. When the foot is extended so that it is almost in line with the leg, and is inverted, the head of the talus can be both felt and seen as a distinct prominence about an inch in front of and below the ankle joint, and the body of the talus also may be felt near the lateral malleolus.

Attachments.—The anterior ligament of the ankle joint and the dorsal talo-navicular ligament are attached to the *upper surface* of the **neck**; the anterior talo-fibular ligament to the *lateral surface*; a part of the deltoid ligament to the *medial surface* of both neck and **body**; the capsule of the talo-calcanean joint to the margins of the large oval facet on the *lower surface* of the body; the interosseous talo-calcanean ligament to the *groove* in front of that facet; the posterior ligament of the ankle joint to the upper part of the *posterior surface*; the posterior talo-fibular ligament to the **posterior tubercle.** The talus does not give attachment to any muscle or tendon. When the talus and calcaneus are placed together, the grooves which give attachment to the interosseous ligament form a tunnel, called the **sinus tarsi.**

Os Cuboideum.

The **cuboid** bone may be picked out from the other smaller tarsal bones because of its more cubical shape. It lies in the lateral margin of the foot in front of the calcaneus.

The *anterior* and *posterior surfaces* can be distinguished from the other surfaces because each of those two is wholly covered with an articular facet. The posterior surface is concavo-convex and sloping; it articulates with the calcaneus. The

anterior surface also slopes and is nearly flat; it is subdivided by a faint vertical ridge into two parts which articulate with the bases of the fourth and fifth metatarsal bones.

The *superior* or *dorsal surface* is distinguished from the others because it is nearly flat and is rough, having no articular facet. Owing to the slope of the dorsum of the foot from medial to lateral border, the upper surface of the cuboid is flush not with the upper surface of the calcaneus but with the lateral surface, when the bones are placed together properly. The *inferior* or *plantar surface* is rough and uneven. Close to its anterior margin it is crossed by a fairly deep groove which lodges the tendon of the peroneus longus as it crosses the sole of the foot; the posterior boundary of the groove is a broad prominent ridge called the **tuberosity.**

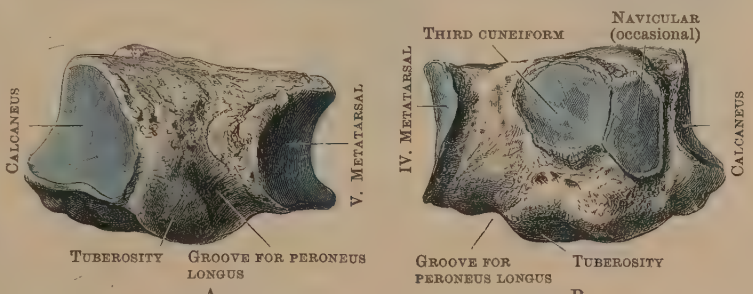

Fig. 237.—Right Cuboid Bone. A, Lateral Side; B, Medial Side.

The *lateral surface* is the smallest of all the surfaces, owing to the slope of the anterior and posterior surfaces. It is formed by the lateral ends of the groove and ridge seen on the plantar surface; at the lateral end of the ridge there is often a smooth facet produced by contact with a sesamoid bone or cartilage which lies in the substance of the peroneus longus tendon as the tendon turns from the lateral surface of the cuboid on to its plantar surface. The *medial surface* is large and rather uneven; about its middle there is a facet for articulation with the third cuneiform bone; and behind that facet, and continuous with it, there may be another, smaller facet for articulation with the navicular bone.

Attachments.—Dorsal, plantar, and interosseous ligaments, binding the **cuboid** to neighbouring bones, are attached to the rough parts of its surfaces. The long plantar ligament is attached to both *lips* of the **groove** on the *plantar surface* and holds the peroneus longus tendon in place. A slip from the tendon of the tibialis posterior is inserted into the medial part of the groove; and a slip of the flexor hallucis brevis arises from the medial part of the area behind the ridge.

Os Naviculare Pedis.

The **navicular bone** is readily identified because one of its two large surfaces is markedly concave—hence its name, from a fancied resemblance to a boat. It lies in the medial side of the foot in front of the talus, and is compressed from before backwards.

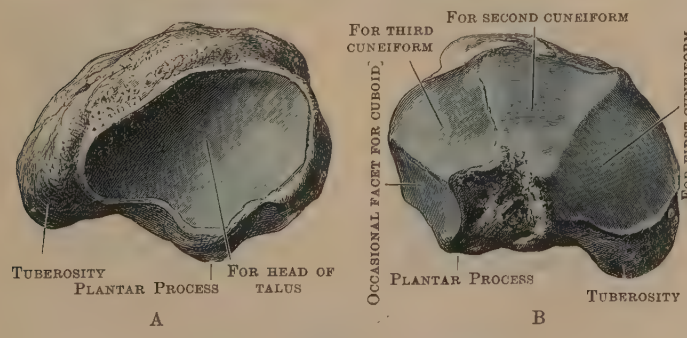

Fig. 238.—Right Navicular Bone.
A, Posterior aspect; B, Anterior aspect.

The *posterior surface* is the large, smooth, concave surface, and articulates with the head of the talus. The *anterior surface* also is smooth, but it is slightly convex, and it is mapped out by faint ridges into three areas for articulation with the three cuneiform bones. The *superior* or *dorsal surface* is rough and is convex in its longer measurement. The *inferior* or *plantar surface* also is rough,

but it is much smaller than the dorsal surface and is very uneven; its most prominent point is sometimes called the **plantar process.**

The *medial surface* is modified into a rough projection, called the **tuberosity** of the navicular bone, which can be felt on the medial side of the foot about an inch below and in front of the medial malleolus, and is much used as a landmark; when shoes are worn the tuberosity is on a level with the upper margin of the shoe. The *lateral* surface is not marked off from the superior surface by any definite line; it is small and usually rough, but may be faceted to articulate with the cuboid bone.

Attachments.—Dorsal and plantar ligaments are attached to the rough parts and bind the **navicular** bone to adjacent bones. The most important of those is the plantar calcaneo-navicular ligament, which stretches from its *plantar surface* to the sustentaculum tali. The anterior fibres of the deltoid ligament are attached to the **tuberosity,** which receives also a great part of the tendon of the tibialis posterior.

Ossa Cuneiformia.

The three **cuneiform** bones are wedge-shaped [*cuneus* = a wedge]. They lie side by side in front of the navicular bone; they are named by number, **first, second,** and **third,** from medial to lateral side, and each articulates with the metatarsal bone of corresponding number. Their anterior and posterior surfaces are occupied by smooth articular facets. The first cuneiform is the largest and most important of the three; the second is the smallest and is the most definitely wedge-shaped.

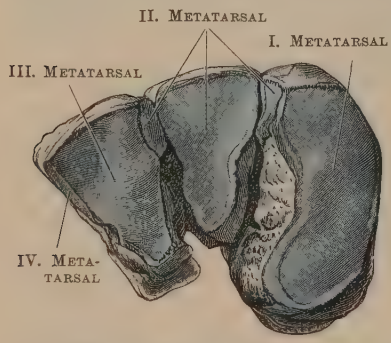

Fig. 239.—Anterior Surfaces of the three Cuneiform Bones of the Right Foot.

The **first cuneiform** lies in the medial side of the foot between the navicular bone and the first metatarsal. The *anterior surface* is kidney-shaped in outline, the concave edge being its lateral margin; it articulates with the base of the first metatarsal bone. The *posterior surface* is concave and pear-shaped, with the stalk of the pear upwards; it articulates with the navicular bone. The *lateral surface* is uneven and slightly concave; it has facets near its posterior and upper margins for articulation with the second cuneiform and with the medial side of the base of the second metatarsal bone. The *medial surface* is the largest of the surfaces and is rough. It can be felt in front of the tuberosity of the navicular, and, in conformity with the shape of the medial side of the foot, it is convex from above downwards. At the most anterior and lowest part there is a smooth impression, resembling a facet, for the insertion of the greater part of the tendon of the tibialis anterior. The *inferior* or *plantar surface* is the rough base of the wedge. The *superior* or *dorsal surface* is reduced to a border—the edge of the wedge—between the lateral and medial surfaces, and it slopes downwards and backwards, because the posterior surface is smaller than the anterior.

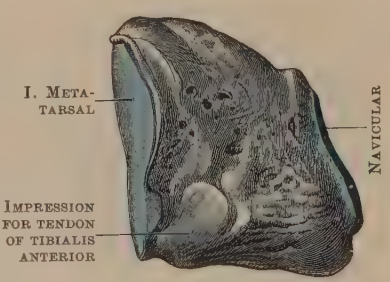

Fig. 240.—Right First Cuneiform (Medial Side).

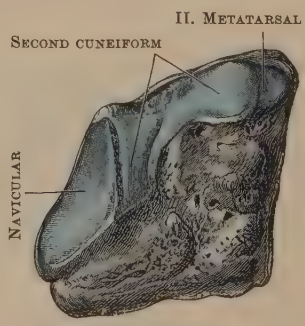

Fig. 241.—Right First Cuneiform (Lateral Side).

Second Cuneiform.—The *superior* or *dorsal surface* is square in outline, rough and nearly flat, and is the base of the wedge. The *inferior* or *plantar surface* is reduced to a rough border between the medial and lateral surfaces, and is the edge of the wedge. The *anterior* and *posterior surfaces* are triangular in outline: the anterior is slightly convex and articulates with the base of the second metatarsal bone; the posterior is slightly concave and articulates with the navicular bone. The *medial surface* has a facet along its upper border and another along its posterior border, both for articulation with the first cuneiform; the rest of the surface is rough. The *lateral surface* has a facet along its posterior border for articulation with the third cuneiform, and the rest of it is rough. The facet along the upper border distinguishes the medial surface from the lateral surface; the facets along the posterior borders enable one to distinguish the posterior surface from the anterior, if that has not been done already.

Fig. 242. — Right Second Cuneiform (Medial Side).

Fig. 243. — Right Second Cuneiform (Lateral Side).

The **third cuneiform** is larger than the second cuneiform, provided that both specimens come from the same skeleton. A beginner may have difficulty in distinguishing the third cuneiform of a small foot from the second of a large foot, for the two bones are not unlike in general appearance.

The *superior* or *dorsal surface* is oblong in outline, rough and nearly flat, and is the base of the wedge. The *inferior* or *plantar surface* is reduced to a rough, thick border between the medial and lateral surfaces, and is the edge of the wedge. The *anterior surface* is all covered with a facet for articulation with the base of the third metatarsal bone, and is nearly triangular in outline. The upper and larger part of the *posterior surface* is covered with a quadrangular facet for articulation with the navicular bone, and the small, lower part is rough. The *medial surface* has a narrow facet along its posterior border for articulation with the second cuneiform, and usually two small facets along its anterior border for articulation with the lateral side of the base of the second metatarsal bone; the rest of the surface is rough. The *lateral surface* is usually wider from before backwards than the medial surface; it has a small facet at its anterior border for articulation with the medial side of the base of the fourth metatarsal bone, and a large facet in its upper posterior corner. That facet distinguishes the lateral surface from the medial surface, distinguishes the third cuneiform from the second, and enables one to identify the posterior surface, for it lies close to the posterior border; it articulates with the cuboid bone. The rest of the lateral surface is rough.

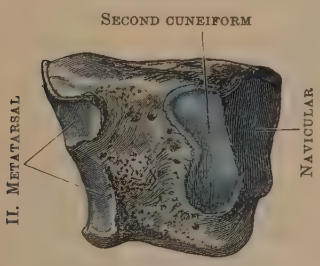

Fig. 244.—Right Third Cuneiform (Medial Side).

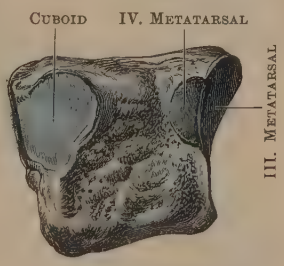

Fig. 245.—Right Third Cuneiform (Lateral Side).

When the three cuneiform bones are fitted together their posterior surfaces are nearly flush, for they all articulate with the front of the navicular bone. The second cuneiform is shorter than the other two, so that a gap is left, between the first and the third, in front of the second. The base of the second metatarsal bone fits into the gap, so that it articulates posteriorly with the second cuneiform, and at the sides with the first and the third—an arrangement which increases the stability of the foot, but adds to the difficulty of amputating the foot at the tarso-metatarsal joints. The second and third cuneiform bones are placed edge downwards and are of less depth than the first; therefore the plantar surfaces of the cuboid bone and the first cuneiform are not far apart.

Attachments.—The three **cuneiform** bones are united to each other and to adjacent bones by dorsal, plantar, and interosseous ligaments. A large part of the tendon of the tibialis posterior is inserted into the posterior part of the *plantar surface* of the **first** cuneiform, and it sends slips to the plantar surfaces of the **other two.** The greater part of the tendon of the tibialis anterior is

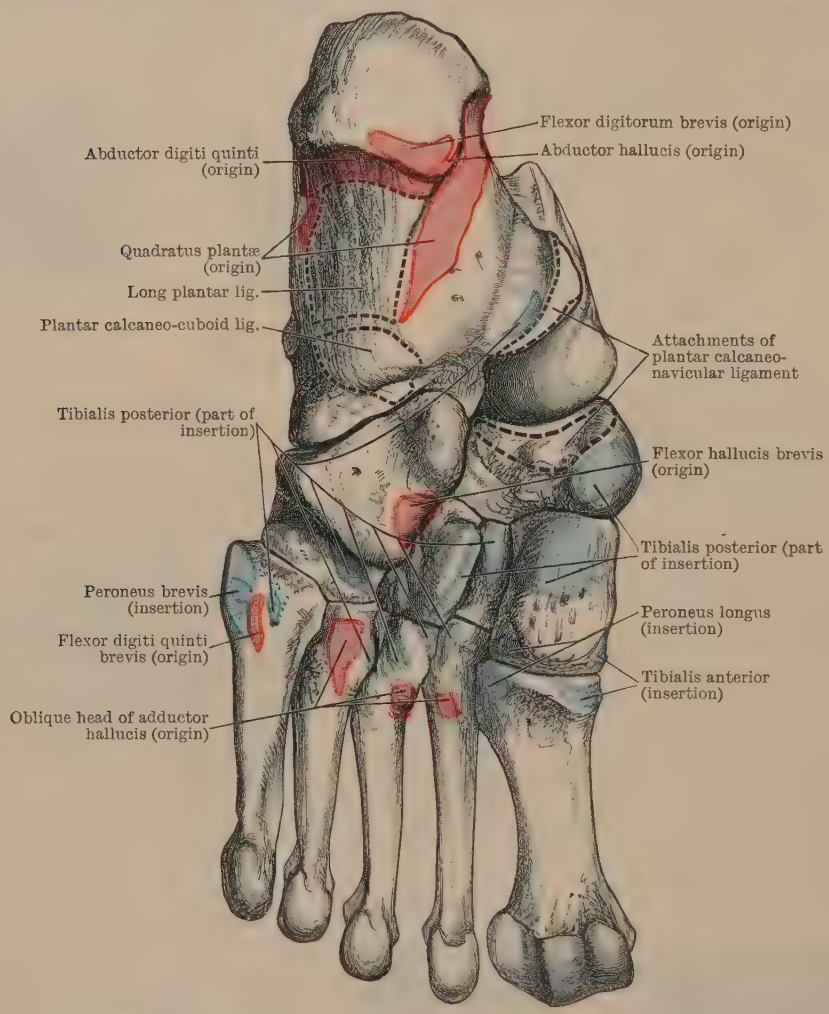

Fig. 246.—Muscle-Attachments to Left Tarsus and Metatarsus (Plantar Aspect).

inserted into an impression situated low down and far forward on the *medial surface* of the **first** cuneiform, and the smaller part of the peroneus longus tendon is inserted into an impression at the corresponding point on its *lateral surface.* The first cuneiform therefore receives parts of the tendons of the tibialis anterior, tibialis posterior, and peroneus longus, while the second and third cuneiform bones get only slips from the tibialis posterior.

Metatarsus.

The **metatarsus** lies in front of the tarsus, and is the skeleton of the anterior or distal half of the foot proper [μετά (meta) = next after]. It consists of five separate **metatarsal bones**, one corresponding to each toe. They are named by number—*first, second,* etc., beginning with the one corresponding to the big toe. Each metatarsal is a miniature long bone, possessing a **body** or shaft and **two ends.** Each of them is slightly concave lengthwise on its inferior or plantar surface; the rounded end is the **anterior** or distal end, and is called the *head*; the **posterior** end is larger, and is called the *base.*

The corresponding bones of the hand are called *metacarpal bones*; they are not unlike metatarsal bones, and a beginner may mistake a metacarpal bone for a

metatarsal. The metatarsal bones are more flattened from side to side than the metacarpals, and a metacarpal has on its dorsal surface a long, flat, triangular area, the base of which is at the head of the bone, while the metatarsal bones have no such area. The metatarsals are about three inches long, and are rather longer than the metacarpals, if the bones are from the same skeleton. The first metatarsal and first metacarpal are distinguished by their size: the first metatarsal is the thickest of all those bones, and the first metacarpal is the shortest.

Basis.—The **bases** of the metatarsal bones are firmly bound to the tarsus by ligaments, and their *posterior surfaces* articulate with the tarsus, forming *tarso-metatarsal joints*. The bases of the lateral four are tightly bound to each other and articulate *side by side*, forming *inter-metatarsal joints*; the base of the first sometimes articulates with that of the second.

Capitulum.—The **heads** articulate with the proximal row of phalanges, forming *metatarso-phalangeal joints*. The sides of the heads have pits and tubercles for the attachment of the collateral ligaments of those joints. The articular part extends much further on to the plantar surface than on to the dorsum, because when the toe is *flexed*, *i.e.*, moved towards the sole, the base of the phalanx articulates with the plantar surface of the head of the metatarsal; when the toe is *extended* it is in straight line with the metatarsal, and the base of the phalanx articulates with the distal surface of the head. *Dorsiflexion* or *hyper-extension* is the movement of bending the toe upwards out of line with the metatarsal; the degree to which it is possible varies in different people but is never great, and therefore the articular surface of the head extends very little on to the dorsum.

Os Metatarsale Primum.—The **first metatarsal bone** can be felt in all its length in the medial side of the foot. Its **base**, looked at end on, is kidney-shaped, and the notched or concave side is the *lateral* side. It articulates with the first cuneiform bone. The **head** is slightly compressed from above downwards, and has two well-marked grooves on its lower or *plantar* surface, for articulation with two small sesamoid bones. The **body** is three-sided; its surfaces are dorsal, plantar, and lateral, and can be identified by reference to the head and base.

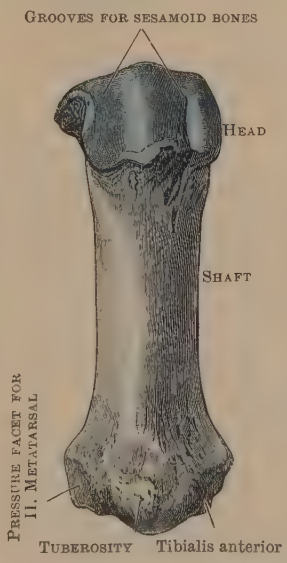

Fig. 247.—First Right Metatarsal Bone (Plantar Aspect).

Fig. 248.—Fifth Right Metatarsal Bone (Dorsal Aspect).

Os Metatarsale Quintum.—The **fifth metatarsal bone** is easily distinguished from the others because it is compressed from above downwards, has a relatively small **head**, and has a large **tuberosity** on the *lateral* side of the **base**. The whole length of the bone can be felt in the lateral border of the foot, and the tuberosity makes the prominence, seen as well as felt, about midway between the heel and the little toe. The posterior surface of the base articulates with the cuboid.

A line drawn from the base of the first metatarsal to the tuberosity of the fifth slants backwards, and corresponds fairly closely to the position of the tarso-metatarsal joints. Therefore those joints and the posterior surfaces of the bases of the lateral four metatarsals slope backwards from medial to lateral side; consequently, the lateral surface of a metatarsal is longer than the medial surface and can be distinguished from it at a glance.

The **second** and **third metatarsal bones** are very much alike. They are compressed from side to side in all their length; the posterior surface of the base is nearly triangular in outline and articulates with the cuneiform bone of corresponding number. But they can be distinguished if the *lateral* surface of the base is examined: the lateral surface of the **second** has two facets, an upper and a lower, separated by a horizontal groove, and one or both of the facets are double; for the base of the second metatarsal fits in between the first and third cuneiform bones, articulating with them, and the lateral surface articulates also with the base of the third metatarsal.

The **head** and **body** of the **fourth metatarsal bone** resemble those of the second and third,

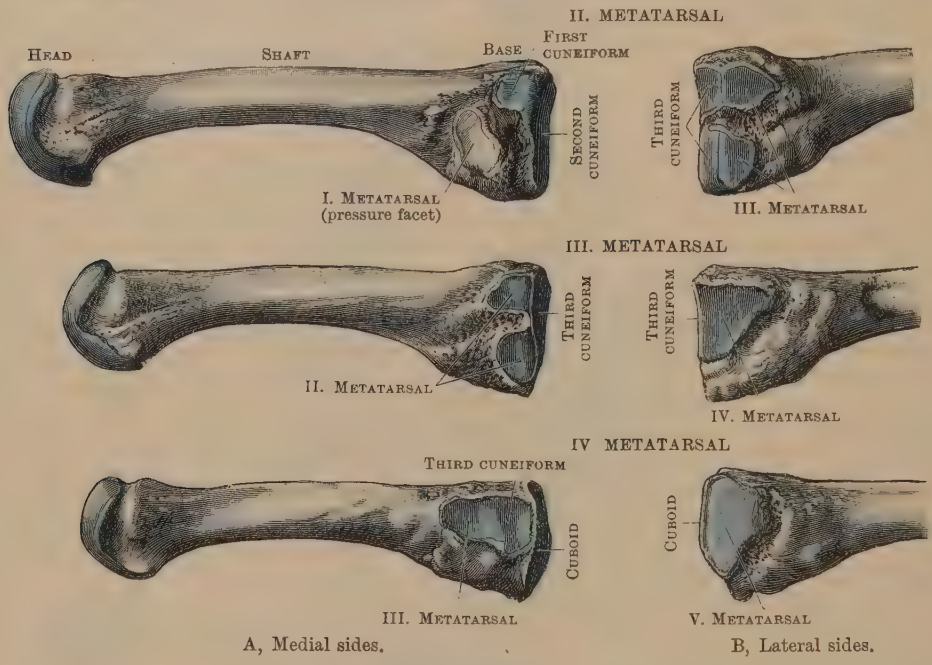

FIG. 249.—VIEW OF THE BASES AND SHAFTS OF THE SECOND, THIRD, AND FOURTH METATARSAL BONES OF THE RIGHT FOOT.

but the base is more irregular, is more cuboidal in shape, and its posterior surface, which articulates with the cuboid, is more nearly square in outline. The *lateral surface* of the **base** has a large facet bounded by an oblique groove; in that respect it resembles the lateral surface of the third, but the medial surfaces are quite different: the *medial surface* of the **third** has two small facets, an upper and a lower; the *medial surface* of the **fourth** has a large facet which is usually subdivided, for it articulates not only with the base of the third metatarsal but also with the lateral surface of the third cuneiform bone.

Attachments.—In the case of *each metatarsal*, collateral ligaments pass from the sides of the **head** to the sides of the base of the first phalanx, and the plantar accessory ligament closes in the metatarso-phalangeal joint below, being attached loosely to the plantar surface of the metatarsal just behind the head, and firmly to the plantar surface of the base of the phalanx, while the extensor tendon takes the place of a dorsal ligament. Dorsal, plantar and interosseous ligaments bind the **bases** to each other and to the tarsus.

Slips of the long plantar ligament are attached to the plantar surfaces of the **bases** of the *second*, *third*, and *fourth* metatarsals; slips of the tibialis posterior tendon are inserted into those bases, and the oblique head of the adductor hallucis arises from them. One head of a dorsal interosseous muscle arises from each side of the **body** of each of those three bones, and the first and second plantar interosseous muscles arise respectively from the third and fourth.

The smaller part of the tendon of the tibialis anterior is inserted into an impression on the medial side of the **base** of the *first* metatarsal bone near the sole, and the greater part of the peroneus longus tendon into an impression at the corresponding point on the lateral side; one head of the first dorsal interosseous muscle arises from the lateral surface of the **body**.

The peroneus brevis tendon is inserted into the tuberosity on the **base** of the *fifth* metatarsal; the peroneus tertius tendon into the dorsal surface of the base; part of the flexor digiti quinti brevis arises from the plantar surface. The third plantar interosseous muscle arises from the plantar surface of the **body**, and one head of the fourth dorsal interosseous from the medial surface.

Phalanges Digitorum Pedis.

Each **phalanx** is a miniature long bone, possessing a **body** or shaft and **two ends** [φάλαγξ (phalanx) = a round log or roller]; the **proximal** end is the larger end

and is called the *base*; the **distal** end is called the *head*. The first phalanx of a toe is about the same length as the second phalanx of a finger, but it can be picked out from among phalanges of fingers because its base is larger, and its body is relatively more attenuated; the first phalanx of the great toe, on the contrary, is thicker than any other phalanx. The second and third phalanges of the toes are so greatly reduced in length that they cannot be mistaken either for the first phalanx of a toe or for the phalanges of fingers.

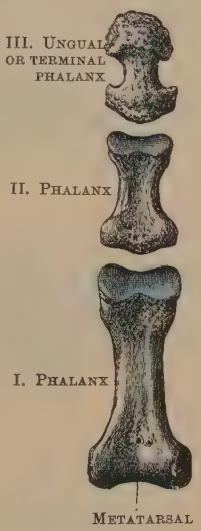

Fig. 250.—Phalanges of a Toe (Plantar Aspect).

The **first phalanx** of a toe is a little more than an inch in length, and is slightly concave lengthwise on its inferior or *plantar surface*. The **base** is expanded and is concave on its proximal surface for articulation with the rounded head of the metatarsal. The **body** is thin, being compressed from side to side near the base, and from above downwards near the head. The **head** is pulley-shaped and articulates with the base of the second phalanx; the articular part extends on to the plantar surface but scarcely at all on to the dorsum, for dorsiflexion is a limited movement, while flexion is free, and the middle joint of the toes in many people who have worn boots since infancy is in a permanent position of flexion.

The **second phalanx** is very short, usually less than half an inch in length, and it may be a mere nodule of bone. The **base** articulates with the head of the first phalanx and is therefore the reverse of a pulley: it has two concave smooth areas with a low vertical smooth ridge between them. The **body** is convex on its dorsal surface and either flat or concave on its plantar surface; but it may be difficult to distinguish the surfaces if the phalanx is stunted. The articular part of the **head** is a shallow pulley, and as it extends some distance on to the plantar surface it is a guide to the surfaces.

The **third phalanx** also is very small. The **base** articulates with the head of the second phalanx and is relatively expanded. The **body** is constricted, the **head** is expanded and is very rough on its plantar surface.

The **great toe** has only two phalanges. The **first** resembles the first phalanx of the other toes and **second** resembles the third; but they are much larger in every way than the phalanges of other toes. In an adult great toe the medial side of the base of a phalanx is larger than the lateral side, so that the toe inclines towards the other toes; the inclination is not an abnormality due to wearing pointed boots, but it may be exaggerated by the use of boots that do not fit.

Owing to the slant of the joints between the tarsus and metatarsus and to the fact that the toes are progressively shorter from the second to the fifth, the nail of the little toe is about the level of the root of the big toe; the root of the little toe or fifth metatarso-phalangeal joint is the yielding prominence on the lateral border of the widest part of the foot, and usually bulges out the side of the shoe a little in front of the middle, and, being so far back, is apt to be mistaken for the base of the metatarsal bone.

Attachments.—The plantar accessory and the collateral ligaments of the metatarso-phalangeal joints and interphalangeal joints are attached to the **bases** and the **heads**; the fibrous flexor sheaths that hold the flexor tendons in their place on the toes are attached to the **bodies**.

The abductor hallucis is inserted into the medial side of the **base** of the **first phalanx** of the *big toe*; the adductor hallucis into the lateral side; the flexor hallucis brevis into both sides; the medial tendon of the extensor digitorum brevis into the dorsum. The flexor brevis and abductor digiti quinti are inserted into the lateral side of the base of the first phalanx of the *little toe*; the third plantar interosseous and the fourth lumbrical into the medial side. Plantar and dorsal interossei and lumbricales are inserted into the sides of the base of the first phalanx of the *other three toes*.

The **base** of the **second phalanx** of the *great toe* receives the insertion of the tendons of the long flexor and extensor on the plantar and dorsal aspects respectively. A tendon of the flexor digitorum brevis is inserted into the sides of the **body** of the **second phalanx** of each of the *other toes*, and a slip of the extensor expansion into the dorsum of its base. The **base** of each **third phalanx** gives insertion to a tendon of the flexor digitorum longus on its plantar surface, and the rest of the extensor expansion on its dorsal surface.

Arches of the Foot.—The bones of the tarsus and metatarsus do not lie in a horizontal plane, but are arranged in the form of a half-dome, with longitudinal and transverse arches, so that the foot rests posteriorly on the lower part of the back of the calcaneus, anteriorly on the heads of the metatarsal bones, and at the lateral border slightly on the fifth metatarsal bone, while at the medial border it is raised well away from the ground.

The dome and its arches are due primarily to the shape of the bones with which the framework of the foot is built, and they are maintained by the ligaments that bind the bones together and by the muscles, tendons, and fasciæ of the foot, their chief support being the tendons of the tibialis posterior and peroneus longus, which cross the sole obliquely from opposite sides.

The advantages given by the arches of the foot are that the weight of the body is distributed over the foot (compare the use of arches above windows in the wall of a big building), the height of the body is slightly increased, springiness is given to the step, shocks received in running and jumping are broken; and a

Fig. 251.

A. About the end of the third month. The primary centres of all the metatarsals are shown, as well as the centres for the phalanges of the great toe and the terminal phalanx of the third toe.

B.[1] A little later. The centres for the terminal phalanges of the medial four toes are seen, as well as the centres for the first phalanges of the great and second toe.

C. About the fourth month. The centres for all the terminal phalanges, as well as those of the first row, are well ossified.

D. About the fifth month. In this the centre for the second phalanx of the second toe has already made its appearance.

[1] This specimen displays the occurrence of anomalous centres within the tarsus the significance of which is not apparent. The appearance is not due to any defect in the plate, but recurred in repeated radiographs.

space is provided in which the soft parts of the sole of the foot may lie free from pressure.

The muscles and tendons may become inefficient owing to malnutrition; the strain of upholding the arches under the weight of the body then becomes too much for the ligaments; they stretch, and the arches sink down gradually, till a condition of flat-foot or splay-foot is established, the bones altering in shape to fit each other in their modified positions in the flattened arch.

Ossification of Bones of Foot.—**Tarsus.** Each tarsal bone has one *primary* centre.

	Calcaneus.	Talus.	Cuboid.	Third Cuneiform.	Second Cuneiform.	First Cuneiform.	Navicular.
Primary centre appears at	6th month of fœtal life	8th month of fœtal life	Birth	1st year	2nd year	3rd year	4th year

The calcaneus alone has a *secondary* centre. It appears in the eighth year for the part of the bone that bears the medial and lateral tubercles. Ossification of all the tarsal bones is completed after puberty. The posterior process of the talus may have a separate centre, and the process may develop as an independent bone called the *os trigonum*.

Metatarsus.—A *primary* centre for each metatarsal appears in the ninth week of fœtal life. They are well ossified at birth. A *secondary* centre for each appears as follows:—

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For *base* of first	2nd year	18	Outside.
For *head* of others	2nd-4th year	18	Outside.

Phalanges.—Each has a *primary* centre for body and head; the base of each is ossified from a secondary centre. (See next page.)

FIG. 252.—RADIOGRAPHS OF THE FŒTAL FOOT.

1. About fifth month. No ossification in the tarsus visible.
2. About sixth month. Appearance of a nucleus for the calcaneus.
3. About seventh month. Nucleus for calcaneus well developed.

4 and 5. About eighth month. Centre for talus, as well as for calcaneus, is now seen.

6. About birth. Centres for the talus and calcaneus are well developed; there is also a considerable centre for the cuboid, and the centre for the third cuneiform has appeared.

FIG. 253.—RADIOGRAPH OF THE HAND AT BIRTH.

It will be noticed that whilst the primary centres for the metacarpus and phalanges are well ossified, the carpus is still entirely cartilaginous.

FIG. 254.—RADIOGRAPH OF THE FOOT AT BIRTH.

The centres for the calcaneus and talus are well developed, the centre for the cuboid is quite distinct, and in this instance the third cuneiform is already commencing to ossify.

Primary Centre for	Ungual Phalanx.	First Phalanx.	Second Phalanx.
Appears	At end of 3rd month	At end of 4th month	6th month—birth

Secondary Centre.	Appears at	Epiphysis fuses at	Relation of Epiphyseal Line to Capsule of Neighbouring Joint.
For base	4th year	16-18	Outside.

Structure and Variations.—The *tarsal* bones are composed of spongy tissue enclosed in compact tissue. The *metatarsal* bones and the *phalanges* have the structure of long bones. The bones are arranged in two columns. The lateral column is formed by the calcaneus, the cuboid, the fourth and fifth metatarsal bones, and the phalanges of corresponding digits; the medial column consists of the talus, the navicular, the three cuneiform bones, the medial three metatarsal bones, and the phalanges of corresponding digits.

The **calcaneus** occasionally articulates with the navicular. The sustentaculum tali may be a separate bone, and so may be the trochlear process. The articular surface for the medial malleolus on the **talus** extends on to the neck in an infant. Occasionally in an adult talus there is a small facet for the tibia on the medial part of the upper surface of the neck, probably due to the ankle joint being often in a state of extreme flexion. The *os trigonum*, when present, may be quite separate, or joined to the body of the talus by cartilage. An ossicle may be present between the talus and dorsal surface of navicular, and another on the dorsum between the talus, calcaneus, navicular, and cuboid. The tuberosity of the **navicular** is sometimes a separate bone. The **first cuneiform bone** may be divided into a dorsal and a plantar part. In rare cases a little separate ossicle is found between the posterior parts of the dorsal surfaces of the first and second cuneiform bones. Division of the **cuboid** has been recorded. The tuberosity of the base of the **fifth metatarsal** may be separate; as also the part of the base of the **first** into which the peroneus longus is inserted. A separate ossicle may be found between the bases of the first and second metatarsals. Fusion of **phalanges** is not uncommon, especially in the little toe.

Ossa Sesamoidea.

Sesamoid bones are imbedded in tendons, but there is usually one surface free and smooth for articulation. The largest sesamoid bone is the **patella**. The *flexor hallucis brevis* has two little sesamoid bones in its tendons of insertion. They are about the size of half of a marrowfat pea; they should not be mistaken for the pisiform bone of the hand, for they are compressed and oval. They play against the grooves on the plantar surface of the head of the first metatarsal bone, and they add to the size and firm consistence of the parts below the first metatarso-phalangeal joint—that is, the medial part of the ball of the foot; the medial sesamoid may be divided transversely, and sometimes there is a minute nodule between the two. Occasionally there are minute sesamoid bones at the *other metatarso-phalangeal joints* and at the *interphalangeal joint* of the big toe and other interphalangeal joints. A sesamoid bone or cartilage is usually present in the tendon of the *peroneus longus* as it crosses the lateral aspect of the cuboid bone to enter the sole. The tendon of the *tibialis posterior* is thickened at the point where it glides over the spring ligament and enters the sole; the thickening has sometimes the character of a sesamoid cartilage. More seldom, a sesamoid bone is present in the *tibialis anterior* close to its insertion, in the *psoas major* as it passes over the pubic bone, in the lateral head of the *gastrocnemius* as it crosses the lateral condyle of the femur, and in the *gluteus maximus* as it overlies the greater trochanter.

DEVELOPMENT AND MORPHOLOGY OF THE LIMBS.[1]

The limbs appear in the Human embryo about the third week as small buds on the sides of the body near the cephalic and caudal ends of the trunk. Each of them is derived from several trunk segments; for the upper limb contains branches from spinal nerves, from the fourth cervical to the second thoracic inclusive; and the lower limb contains branches from the last thoracic nerve, the five lumbar nerves, and the upper four sacral nerves. The buds arise from the ventro-

[1] It is not possible to do more than touch upon the subject in a general text-book.

lateral part of the trunk, and the nerves of a limb are derived from the anterior rami of the spinal nerves.

Each bud has two surfaces and two borders. At first the surfaces look ventrally and dorsally; the ventral aspect corresponds to the flexor surface of the adult limb, and the dorsal aspect to the extensor surface; the borders of each bud look headward and tailward, and are named **pre-axial** and **post-axial**, respectively. (Figs. 103-108, pp. 80, 81).

During the second month slight constrictions appear in the elongating buds at positions which correspond to the elbow and the wrist, the knee and the ankle; and grooves appear on the dorsal surfaces of the extremities of the buds, indicating the subdivision into digits. At the same time, the central or axial mesoderm of the bud passes through a pro-cartilage stage, and chondrifies to form the cartilage models of the limb bones. Chondrification begins in the roots of the limbs and spreads towards the digits, leaving unchondrified intervals where joints are to be formed. The cartilage developed along the pre-axial border of the forearm becomes the radius, and the pre-axial digit becomes the thumb; in the leg and foot the pre-axial cartilage and digit become the tibia and the great toe; similarly, the ulna and little finger, the fibula and little toe are developed at the post-axial borders of the respective limbs. Therefore, the thumb, the radius, and the lateral epicondyle of the humerus are serially homologous with the great toe, the tibia, and the medial epicondyle of the femur, if it is granted that the pre-axial borders of the two limbs are serially homologous.

During the third month the embryo—now called the *fœtus*—begins to assume the "fœtal position," which is one of flexion at all the joints, notably those of the limbs; the wrist and the elbow are flexed and the upper arm is bent tailwards along the side of the thorax; the ankle is flexed and the foot is turned medially, the knee is flexed and the thigh is inclined headwards along the abdomen. At the same time the upper and lower limbs are rotated around their long axes. The *lower limb* is rotated through an angle of 90°, so that the pre-axial border, which originally looked headwards, looks towards the median plane; but the rotation is not completed till after birth. The *upper limb* is rotated in the opposite direction, so that the pre-axial border is turned away from the median plane; therefore the flexor surface is the anterior aspect of the upper limb while it is the posterior aspect of the lower limb. The movement is not so complete in the upper limb as in the lower; for only in the supine position, which is an unnatural position, is the flexor surface of the upper limb directed straight forwards. The rotation takes place partly at the shoulder joint and the hip joint, and partly in the shafts of the bones; some assert and others deny that the rotation involves also the dorsal part of the limb girdles.

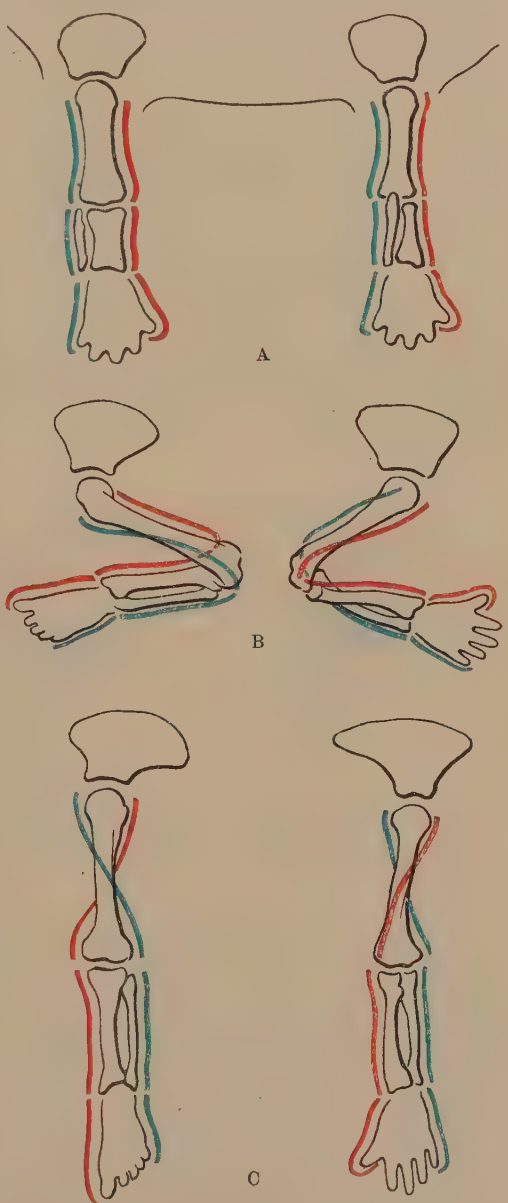

FIG. 255.—DIAGRAM TO ILLUSTRATE THE HOMOLOGIES OF THE BONES OF THE LIMBS.

The two limb buds of an embryo prior to flexion and rotation. The anterior or pre-axial border is coloured red; the posterior or post-axial border, blue. B. After the assumption of the fœtal position. Flexion and rotation have now taken place. The red and blue lines indicate the altered position of the pre-axial and post-axial borders. C. The fully developed limbs with the flexor aspects directed towards the reader. The coloured lines indicate the effect of the torsion of the upper segment of the limb through quarters of a circle.

The homology between the limb bones of Man and those of other animals, and the serial homology or homo-dynamy between the bones of the two limbs in Man are fairly clear except in the case of the limb girdles.

Limb Girdles.—The homologies of the parts of the girdles have become obscured owing to

the structural alterations that have occurred in order to adapt the two limbs to their different functions. Even in quadrupedal animals the functions of the fore and the hind limbs are not quite the same, though both are used for support and locomotion; the fore limb is at the same time adapted for *pull* and the hind limb for *push* (Rabl); therefore the pelvic girdle is more consolidated than the shoulder girdle. The modifications from the primitive type are more varied and more profound in the case of the shoulder girdle, and began so long ago in phylogenetic development that in Man there is no evidence in ontogenetic development of how they came about.

The primitive, fundamental limb girdle is a curved bar of cartilage imbedded in the muscular substance of the side of the trunk at right angles to the long axis of the trunk. The cartilage is divisible into a dorsal part and a ventral part by means of an articulation of the middle of its lateral surface with the cartilage of the free portion of the limb.

In higher vertebrates the *ventral part* of the developing cartilage of the **pelvic girdle** is divided into two bars, a cephalic and a caudal; the cephalic bar corresponds to the pubis, the caudal bar to the ischium. The *dorsal part* is undivided and corresponds to the ilium.

The **shoulder girdle** does not show such a uniform arrangement. The *dorsal part*, however, does not undergo grave modification; it corresponds to the blade of the scapula and may be regarded as homologous with the ilium.

The *ventral part* is subdivided to a varying extent in different vertebrates, and the names given to subdivisions have been "coracoid," "epicoracoid," "metacoracoid," "precoracoid," and "subcoracoid," different names having sometimes been given by different writers to the same subdivision. In **amphibians** the developing ventral part is divided into two portions, a caudal

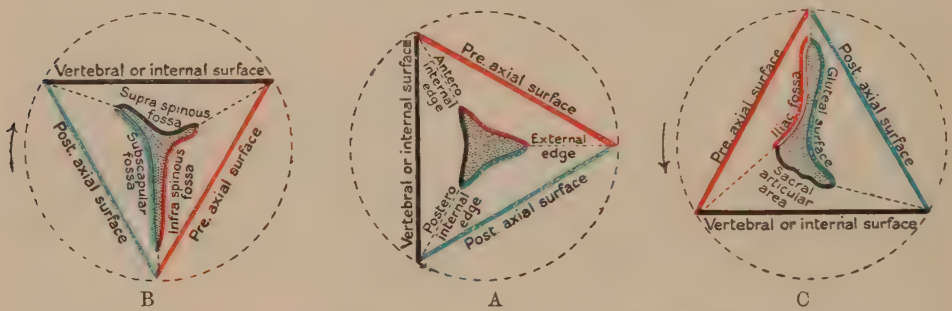

FIG. 256.—DIAGRAM TO ILLUSTRATE THE HOMOLOGOUS PARTS OF THE SCAPULA AND ILIUM, ACCORDING TO FLOWER.

A, Ideal type; three-sided rod. B, Scapula rotated forward through a quarter of a circle (90°), so that the primitive medial or vertebral surface is now directed forwards. C, Ilium rotated backwards through a quarter of a circle so that the primitive medial surface is now directed backwards. In the diagram the primitive medial or vertebral surface of each figure is coloured black, the pre-axial surfaces red, and the post-axial surfaces blue.

portion named the **coracoid**, and a cephalic portion named the **precoracoid**, which, as development proceeds, is overlaid by a clavicle of dermal or membranous origin. In man the clavicle was at one time (Gegenbauer) regarded as a bone ossified from a primordial cartilage, possibly homologous with the precoracoid; and the ventral part of the primitive shoulder girdle was considered to be represented by the clavicle and the coracoid process, those two parts being equivalent to the pubis and the ischium respectively. The view that the clavicle was precoracoid in origin was abandoned, but has been recently revived only to be refuted a second time; and at the present state of knowledge it is as well not to attempt to establish homodynamy of parts of the shoulder girdle with the ischium and pubis.

The theories and facts regarding the problem have been reviewed recently by Hanson (*Anat. Record*, 1919, 1920), who has clarified the nomenclature that has arisen around the subject. The type adopted as a standard for comparison is not the amphibians but the **Permian reptiles**, which were relatives of the ancestors of the Mammals; in them there were three elements in the ventral part of the girdle, which Hanson names **metacoracoid**, **precoracoid**, and **epicoracoid**. His summary of the evidence goes to prove that: (1) The coracoid process of Man and the coracoid of other mammals represents part of the precoracoid of Permian reptiles, and corresponds, therefore, with the coracoid of living reptiles. (2) The part of the scapula ossified from the "subcoracoid" centre is not derived from the ventral part of the girdle, as has been asserted by some, but is merely an epiphyseal ossification. (3) The clavicle is not derived, even in part, from the precoracoid cartilage, but is of membranous origin, and the cartilage which develops after the clavicle has begun to ossify is of a secondary or accessory character and not part of the primordial cartilage of the girdle.

The clavicle is peculiar among limb bones in its mode of ossification (see Fawcett, *Jour. Anat.*, 1913). It is ossified from two primary centres which appear in two portions of mesodermal tissue which are at the pro-cartilaginous stage. When the tissue intervening between those two portions also becomes pro-cartilage the two centres fuse together to form one centre, from which the ossifying process spreads into the cartilage that appears at the ends of the bone rudiment.

Attempts have been made to demonstrate homologies between the several parts of the scapula

and ilium. Flower's scheme, which is the most generally accepted, assumed a primitive or ideal type bone with dorsal and ventral *ends*, pre-axial, post-axial, and vertebral or medial *surfaces*, postero-medial, antero-medial, and lateral *borders*, and postulated that the rotation of the limbs involved the scapular and iliac parts of the limb girdles in the directions indicated by the arrows in the diagram. The dorsal end is, in the case of the scapula, the vertebral border, and in the ilium it is the iliac crest ; the ventral end is respectively the glenoid cavity of the scapula and the acetabular end of the ilium. The diagram sufficiently indicates the homologies of the surfaces and borders under Flower's scheme.

Humphry assumed that the girdles were not involved in the rotation of the limbs, and the second diagram expresses the homologies he ascribed to scapula and ilium. It may be noted in that diagram that the anterior border of ilium (between gluteal surface and iliac fossa), which gives origin to the rectus femoris, corresponds to the crest of the scapular spine (between the supra-spinous and infraspinous fossæ) and not to the axillary border of the scapula (between the sub-scapular and infraspinous fossæ), which gives origin to the homologous muscle—the long head of the triceps. But Humphry explained that those muscles arose from the lateral surface of the bone (an attachment partly retained by the human rectus femoris) and in the rotation of the free part of the limb, the rectus femoris attachment was turned forward on to the anterior border, while the triceps was turned on to the posterior border (the axillary border in Man is the posterior or caudal border in quadrupeds).

Humerus and Femur.—Owing to the rotation of the limbs in opposite directions, the greater tubercle, the posterior surface of the body and the lateral epicondyle of the humerus correspond respectively to the lesser trochanter, the anterior surface, and the medial epicondyle of the femur.

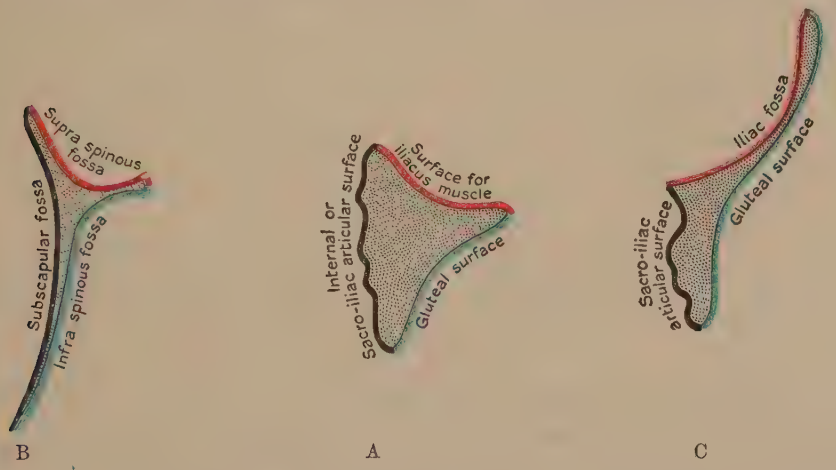

FIG. 257.—DIAGRAM TO ILLUSTRATE THE HOMOLOGOUS PARTS OF THE SCAPULA AND ILIUM, ACCORDING TO HUMPHRY.

A, Primitive rod-like ilium of kangaroo, prismatic on section. B, Scapula. C, Ilium. The corresponding surfaces are similarly coloured.

Bones of Forearm and Leg.—The radius corresponds to the tibia, and the ulna to the fibula. There is nothing in the lower limb, however, to correspond to the olecranon, and nothing in the upper limb to correspond to the patella. Those two parts are not homologous ; but they are analogous, for each of them gives insertion to the extensor tendon and gives the extensor muscle more leverage for its action.

In the **hand and foot** the homology or homodynamy of metacarpus with metatarsus, thumb and fingers with toes is obvious, the radial side of the hand corresponding with the tibial side of the foot.

The homologies of the carpal and tarsal bones are not so clear ; they are given in the following table, together with the more generalised type from which they are evolved :—

Type.	Hand.	Foot.
Radiale (Tibiale)	= Os naviculare (body)	= Talus.
Intermedium	= Os lunatum	= Absent, or Os trigonum (?).
Ulnare (Fibulare)	= Os triquetrum	= Calcaneus.
Centrale	= Absent, or fused with Navicular	= Navicular, less its tuberosity.
Carpale (Tarsale), i.	= Os multangulum majus	= First Cuneiform.
Carpale (Tarsale), ii.	= Os multangulum minus	= Second Cuneiform.
Carpale (Tarsale), iii.	= Os capitatum	= Third Cuneiform.
Carpale (Tarsale), iv. }	= Os hamatum	= Cuboid, plus the peroneal sesamoid.
Carpale (Tarsale), v. }		

The pisiform is omitted from the table, since it is now generally regarded as being a vestige of an additional digit placed post-axial to the little finger (digitus post-minimus). Its homologue

in the foot is by some considered as fused with the calcaneus. The tuberosity of the navicular, formed, according to Manners Smith, of three elements, of which the sesamoid bone in the tendon of the tibialis posterior may be one, is to be regarded as the homologue of the pre-axial sesamoid in the hand, which probably fuses with the navicular to form its tuberosity. The peroneal sesamoid probably corresponds to the hamulus (sometimes an independent ossicle) of the os hamatum. Similarly, on the pre-axial border of the hand and foot, vestiges of a suppressed digit (prepollex and prehallux) may occasionally be met with. The frequent occurrence of an increase in the number of digits seems to indicate that phylogenetically the number of digits was greater than at present, and included a prepollex or prehallux, and a digitus post-minimus.

In Man the lower limbs have been modified for the whole office of support and locomotion, and the upper limbs have undertaken more varied and specialised functions, including that of prehension; the lower limbs are increased in strength and length and are constructed with the view of stability, while mobility is the aim achieved in the upper limb. The elements of the lower limb girdle are welded into one bone which is firmly jointed to its fellow and to the backbone, and, with the adoption of the erect attitude, it assumes the special human characteristic of wide expansion of the ilia to support the abdominal viscera.

In order to be free and movable, the shoulder girdle is not built into the wall of the body cavity. The scapula is only loosely connected with the axial skeleton by muscles; the clavicle is joined to the sternum by a freely movable joint; and, further, those two constituents of the girdle are not fused but are connected by a movable joint. To obtain greater freedom and range of movement, the upper limb, including the ventral part of the scapula, becomes further removed from the trunk, and the scapula loses the support received through the union of the coracoid element with the sternum, as in birds, reptiles, and, to some extent, in lowest mammals. As a substitute for that support the clavicle is evolved as a new element; in its most specialised form, as in Man, it gives strength and stability to the girdle, keeps the upper limb removed from the trunk so that the movements are unhampered, and, being itself a movable fulcrum, it enlarges the range of movement.

The head of the humerus articulates with the shallow glenoid fossa and is connected with the scapula by a lax capsule; in the case of the femur, the presence of a long neck set at an angle to the shaft removes the limb from the trunk and enables the limb to have a wide range of movement, but the head of the femur articulates with a deep cup and is held firmly in place by a strong capsule.

The power of supination and pronation gives a varied mobility to the upper limb which the lower limb does not possess, though that is in some degree compensated for by the fact that, at the knee-joint, movements of rotation, as well as flexion and extension, can take place, while the elbow-joint is a simple hinge. But at the wrist-joint, movement can take place around two axes, while the ankle joint is a very stable articulation at which only hinge movements can take place, except when it is extended.

The hand, as a prehensile organ, has its phalanges increased in length and the carpus reduced; the opposability of the thumb metacarpal enables the hand to grasp cylindrical objects firmly, and the opposable fifth metacarpal enables it to grasp spherical objects. In the foot, strength and stability are required; the tarsal bones are large, and, having to sustain the weight of the body, the tarsus and metatarsus are built in the form of an arch; the foot does not have the prehensile function which it discharges in Apes, and therefore the digits are short and none of them is opposable.

MEASUREMENTS AND INDICES EMPLOYED IN PHYSICAL ANTHROPOLOGY.

(1) Craniometry.

The various groups of Mankind display in their physical attributes certain features which are more or less characteristic of the stock to which they belong. Craniology deals with the differences among them so far as they affect the skull. The method whereby the differences are recorded involves the accurate measurement of the skull in most of its details. Such procedure is included under the term *craniometry*. Here only the outlines of the subject are briefly referred to; fuller information on the subject may be obtained from the works of Broca, Topinard, Flower, and Turner.

The races of Man display great variations in regard to the size of the skull. Apart altogether from individual differences and the proportion of head-size to body-height, it may be generally assumed that the size of the skull in the more highly civilised races is much in excess of that of lower types. The size of the head is intimately correlated with the development of the brain. By measuring the capacity of the cranial cavity we can form some estimate of the size of the brain. The **cranial capacity** is determined by filling the cranial cavity with some suitable material and then taking the cubage of its contents. Various methods are employed, each of which has its advantage. The use of liquids, which of course would be the most accurate, is rendered impracticable, without special precautions, owing to the foramina. As a matter of practice, it is found that leaden shot, glass beads, or seeds of various sorts are the most serviceable. The results obtained by any of those methods display a considerable range of variation. For purposes of classification and comparison, skulls are grouped according to their **cranial capacity** into the following varieties:—

Microcephalic skulls are those with a capacity below 1350 c.c., and include such well-known races as Andamanese, Veddahs, Australians, Bushmen, Tasmanians, etc. [μικρός (micros) = small; κεφαλή (cephalē) = head.]

Mesocephalic skulls range from 1350 c.c. to 1450 c.c., and embrace examples of the following varieties: American Indians, Chinese, some African Negroes. [μέσος (mesos) = middle.]

Megacephalic skulls are those with a capacity over 1450 c.c., and are most commonly met with in the more highly civilised races: Mixed Europeans, Japanese, etc. [μέγας (megas) = big.]

Apart from its size, the form of the cranium has been regarded as an important factor in the classification of skulls; though whether the differences in shape have not been unduly emphasised in the past is open to question.

The relation of the breadth to the length of the skull is expressed by means of the **cephalic index**, which records the proportion of the maximum breadth to the maximum length of the skull, assuming the latter equal 100, or—

$$\frac{\text{Max. breadth} \times 100}{\text{Max. length}} = \textbf{Cephalic index.}$$

The results are classified into three groups:—

1. **Dolichocephalic**, with an index below 75: Australians, Kaffirs, Zulus, Eskimo, Fijians.
2. **Mesaticephalic**, ranging from 75 to 80: Europeans (mixed), Chinese, Polynesians (mixed).
3. **Brachycephalic**, with an index over 80: Malays, Burmese, American Indians, Andamanese. [βραχύς (brachys) = short; δολιχός (dolichos) = long.]

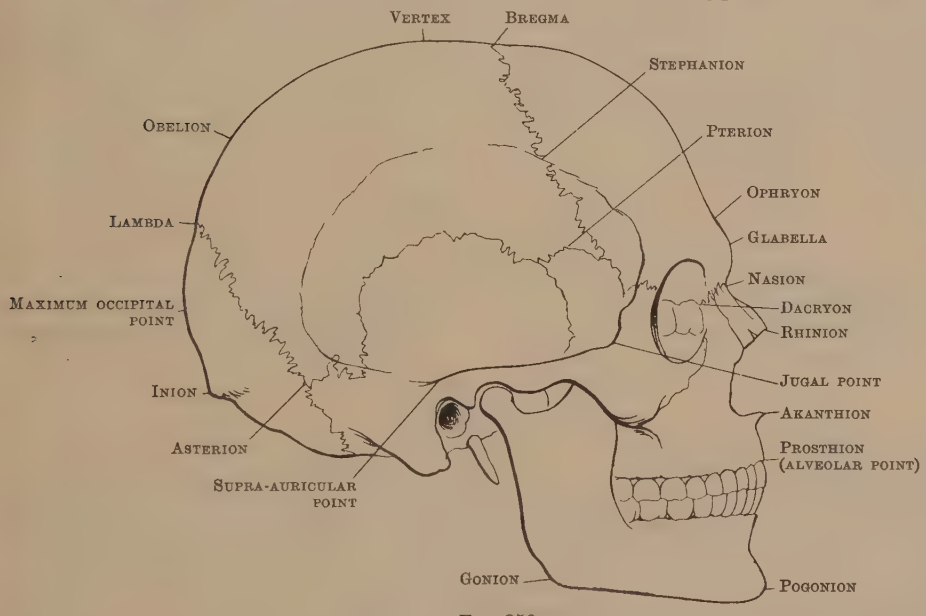

FIG. 258.

The more important of the points from which measurements are taken are included in the subjoined table:—

Nasion.—The middle of the naso-frontal suture.
Glabella.—A point midway between the two superciliary ridges.
Ophryon.—The central point of the narrowest transverse diameter of the forehead, measured from one temporal line to the other.
Inion.—The external occipital protuberance.
Maximum Occipital Point.—The point on the squamous part of the occipital in the sagittal plane most distant from the glabella.
Opisthion.—The middle of the posterior margin of the foramen magnum.
Basion.—The middle of the anterior margin of the foramen magnum.
Bregma.—The point of junction of the coronal and sagittal sutures.
Rhinion.—The most prominent point at which the nasal bones touch one another.
Alveolar Point or Prosthion.—The centre of the anterior edge of the alveolar margin of the maxilla.
Subnasal Point.—The middle of the inferior border of the piriform (anterior nasal) aperture at the root of the anterior nasal spine.
Akanthion.—The most prominent point on the nasal spine.
Vertex.—The summit of the cranial vault.
Obelion.—A point on the sagittal suture, between the parietal foramina.
Lambda.—The meeting-point of the sagittal and lambdoid sutures.

Pterion.—The region of the antero-lateral fontanelle, where the angles of the frontal, parietal, squamous part of the temporal, and great wing of sphenoid lie in relation to one another. As a rule, the sutures are arranged like the letter H, the parietal and great wing of sphenoid separating the frontal from the squamous temporal. In other cases the form of the suture is like an X; whilst in a third variety the frontal and squamous part of the temporal articulate with each other, thus separating the great wing from the parietal.

Asterion is the region of the postero-lateral fontanelle, where the lambdoid, parieto-mastoid, and occipito-mastoid sutures meet.

Stephanion.—The point where the coronal suture crosses the temporal line.

Dacryon.—The point where the vertical lacrimo-maxillary suture meets the fronto-maxillary suture at the medial angle of the orbit.

Jugal Point.—Corresponds to the angle between the frontal process and the temporal process of the zygomatic bone.

Supra-auricular Point.—A point immediately above the middle of the orifice of the external acoustic meatus close to the edge of the posterior root of the zygoma.

Gonion.—The lateral side of the angle of the mandible. [*γωνία* (gōnia) = a corner.]

Pogonion.—The most prominent point of the chin as represented on the mandible. [*πώγων* (pōgōn) = the beard.]

The measurements of the length of the skull may be taken between a variety of points—the nasion, the glabella, or the ophryon in front, and the inion or the maximum occipital point behind. Or the maximum length alone may be taken without reference to any fixed points. In all cases it is better to state precisely where the measurement is taken. The maximum breadth of the head is very variable as regards its position; it is advisable to note whether it occurs above or below the parieto-squamosal suture. The inter-relation of these measurements as expressed by the cephalic index has been already referred to. The width of the head may also be measured from one asterion to the other (**bi-asterionic width**) or by taking the **bi-stephanic diameter.**

The height of the cranium is usually ascertained by measuring the distance from the basion to the bregma. The relation of the height to the length may be expressed by the **height** or **vertical index**, thus—

$$\frac{\text{Height} \times 100}{\text{Length}} = \textbf{Vertical index.}$$

Skulls are classified in accordance with the relations of length and height as follows:—

Tapeinocephalic, index below 72.		**Chamæcephalic**, index up to 70.
Metriocephalic, index between 72 and 77.	or	**Orthocephalic**, index from 70·1 to 75.
Acrocephalic, index above 77 (Turner).		**Hypsicephalic**, index 75·1 and upwards (Kollmann, Ranke, and Virchow).

[*ταπεινός*] (tapeinos) = low; *χαμαί* (chamai) = on the ground. *μέτριος* (metrios) = moderate, middle; *ὀρθός* (orthos) = straight, right. *ἄκρος* = highest; *ὕψι* (hypsi) = on high.]

The **horizontal circumference** of the cranium, which ranges from 450 mm. to 550 mm., is measured around a plane cutting the glabella or the ophryon anteriorly, and the maximum occipital point posteriorly. The **longitudinal arc** is measured from the nasion in front to the opisthion behind; if the basi-nasal length and the distance between the basion and the opisthion are added to that, we have a record of the vertico-median circumference of the cranium. The frontal, parietal, and occipital portions of the superior longitudinal arc may be measured separately, and the length of each compared with the length of the arc and with each other.

The measurements of the skeleton of the face are more complex, but, on the whole, of greater value than the measurements of the cranium. In the *face* the characteristic features of race are best observed, and the osseous structure most accurately records the form and proportions of the living.

The form of the face varies, like that of the cranium, in the relative proportions of its length and breadth. Generally speaking, a dolichocephalic cranium is associated with a long face, whilst the brachycephalic type of head is correlated with a rounder and shorter face. This rule, however, is not universal, and there are many exceptions to it.

The determination of the facial index varies according to whether the measurements are made with or without the mandible in position. When the mandible is in place the length is measured from the ophryon or the nasion above to the mental tubercle below, and compared with the maximum bi-zygomatic width. This is referred to as the **total facial index**, and is obtained by the formula—

$$\frac{\text{Ophryo-mental length} \times 100}{\text{Bi-zygomatic width}} = \textbf{Total facial index.}$$

More usually, however, owing to the loss of the mandible, the proportions of the face are expressed by the **superior facial index**, which is determined by comparing the ophryo-alveolar or naso-alveolar length with the bi-zygomatic width, thus—

$$\frac{\text{Ophryo-alveolar length} \times 100}{\text{Bi-zygomatic width}} = \textbf{Superior facial index.}$$

The terms **dolichofacial** or **leptoprosope** and **brachyfacial** or **chamæprosope** have been employed to express the differences thus recorded. [λεπτός (leptos) = thin, delicate, refined; πρόσωπον (prosōpon) = the face.]

Uniformity in these measurements, however, is far from complete, since many anthropologists compare the width with the length = 100.

The proportion of the face-width to the width of the calvaria is roughly expressed by the use of the terms **cryptozygous** and **phænozygous** as applied to the skull. In cryptozygous skulls the zygomatic arches are concealed, when the skull is viewed from above, by the overhanging and projection of the sides of the cranial box; in phænozygous skulls, owing to the narrowness of the calvaria, the zygomatic arches are clearly visible. [κρυπτός (cryptos) = hidden; φαίνω (phainō) = cause to appear, *in passive* = appear.]

The projection of the face, so characteristic of certain races (Negroes for example), may be estimated on the living by measuring the angle formed by two straight lines, the one passing from the middle of the external acoustic meatus to the lower margin of the septum of the nose; the other drawn from the most prominent part of the forehead to the incisor teeth. The angle between those two lines is called the **facial angle** (Camper), and ranges from 62° to 85°. The smaller angle is characteristic of a muzzle-like projection of the lower part of the face. The larger angle is the concomitant of a more vertical profile. The degree of projection of the maxilla in the macerated cranium is most commonly expressed by employing the **gnathic** or **alveolar index** of Flower. This records the relative proportions of the basi-alveolar and basi-nasal lengths, the latter being regarded as = 100, thus—

$$\frac{\text{Basi-alveolar length} \times 100}{\text{Basi-nasal length}} = \textbf{Gnathic index.}$$

The results are conveniently grouped into three classes:—

Orthognathous, index below 98: including mixed Europeans, ancient Egyptians, etc.
Mesognathous, index from 98 to 103: Chinese, Japanese, Eskimo, Polynesians (mixed).
Prognathous, index above 103: Tasmanians, Australians, Melanesians, various African Negroes. [γνάθος (gnathos) = the jaw.]

Unfortunately, however, little reliance can be placed on the results obtained by this method, since it takes no account of the proportion of the third or facial side of the gnathic triangle. (See Thomson and MacIver, *Races of the Thebaid*, Oxford: Clarendon Press, 1905.)

The form of the piriform aperture in the macerated skull is of much value from an ethnic standpoint, as it is so intimately associated with the shape of the nose in the living. The greatest width of the aperture is compared with the nasal height (measured from the nasion to the lower border of the aperture) and the **nasal index** is thus determined:—

$$\frac{\text{Nasal width} \times 100}{\text{Nasal height}} = \textbf{Nasal index.}$$

Skulls are—

Leptorrhine, with a nasal index below 48: as in mixed Europeans, ancient Egyptians, American Indians, etc.
Mesorrhine, with an index ranging from 48 to 53: as in Chinese, Japanese, Malays, etc.
Platyrrhine, with an index above 53: as in Australians, Negroes, Kaffirs, Zulus, etc. [πλατύς (platys) = wide, flat; ῥίς (rhis) = nose.]

The form of the orbit varies considerably in different races, but is of much less value from the standpoint of classification. The **orbital index** expresses the proportion of the orbital height to the orbital width, and is obtained by the following formula:—

$$\frac{\text{Orbital height} \times 100}{\text{Orbital width}} = \textbf{Orbital index.}$$

The orbital height is the distance between the upper and lower margins of the orbit at the middle; whilst the orbital width is measured from a point where the ridge which forms the posterior boundary of the lacrimal groove meets the fronto-lacrimal suture (Flower), or from the dacryon (Broca), to the most distant point on the lateral margin of the orbital opening.

The form of the orbital aperture is referred to as—

Megaseme, if the index is over 89;
Mesoseme, if the index is between 89 and 84;
Microseme, if the index is below 84. [σῆμα (sēma) = a sign or signal.]

The variations met with in the form of the palate and dentary arcade may be expressed by the **palato-maxillary index** of Flower. The length is measured from the alveolar point to a line drawn across the posterior borders of the maxillæ, whilst the width is taken between the outer borders of the alveolar arch immediately above the middle of the second molar tooth. To obtain the index, the following formula is employed:—

$$\frac{\text{Palato-maxillary width} \times 100}{\text{Palato-maxillary length}} = \textbf{Palato-maxillary index.}$$

For purposes of classification Turner introduced the following terms :—

Dolichuranic, index below 110.
Mesuranic, index between 110 and 115.
Brachyuranic, index above 115. [*οὐρανός* (uranos) = the vault of heaven, any vault, the roof of the mouth.]

As is stated elsewhere, the size of the teeth has an important influence on the architecture of the skull. Considered from a racial standpoint, the relative size of the teeth to the length of the cranio-facial axis has been found by Flower to be a character of much value. The dental length is taken by measuring the distance between the anterior surface of the first premolar and the posterior surface of the third molar of the upper jaw.

To obtain the **dental index** the following formula is used :—

$$\frac{\text{Dental length} \times 100}{\text{Basi-nasal length}} = \textbf{Dental index.}$$

Following the convenient method of division adopted with other indices, the dental indices may be divided into three series, called respectively—

Microdont, index below 42 : including the so-called Caucasian or white races.
Mesodont, index between 42 and 44 : including the Mongolian or yellow races.
Megadont, index above 44 : comprising the black races, including the Australians.

Many complicated instruments have been devised to take the various measurements required, but for all practical purposes the calipers designed by Flower or the *compas glissière* of Broca are sufficient.

As an aid to calculating the indices, the tables published in the *Osteological Catalogue of the Royal College of Surgeons of England*, Part I., Man ; *Index-Tabellen zum anthropometrischen Gebrauche*, C. M. Furst, Jena, 1902 ; or the index calculator invented by Waterston, will be found of much service in saving time.

(2) Indices and Measurements of other Parts of the Skeleton.

In addition to the indices employed to express the proportions of the cranial measurements, there are others similarly made use of to convey an idea of the proportions of different parts of the skeleton. The following may be mentioned as those in most common use :—

Scapula.—At birth the form of the human scapula more closely resembles the mammalian type in that its breadth, measured from the glenoid cavity to the vertebral border, is greater in comparison with its length than in the adult. This proportion is expressed as follows :—

$$\frac{\text{Breadth from glenoid cavity to vertebral border} \times 100}{\text{Length from medial to inferior angle}} = \textbf{Scapular index.}$$

The index ranges from 87 in African pygmies, who therefore have proportionately broader scapulæ, to 61 in Eskimos. The average European index is about 65.

Hip Bone.—The relation of the breadth of this bone to its height is computed as follows :—

$$\frac{\text{Iliac breadth} \times 100}{\text{Ischio-iliac height}} = \textbf{Innominate index.}$$

Man, as compared with the apes, is distinguished by possessing proportionately broader and shorter hip bones. The index in man ranges from 74 to 90.

Pelvis.—The form of the human pelvis is characterised by an increased proportionate width and a reduced proportionate height or length. The relation of these diameters is expressed by the formula :—

$$\frac{\text{Ischio-iliac height} \times 100}{\text{Greatest breadth between the outer lips of the iliac crests}} = \textbf{Pelvic breadth-height index.}$$

The average index for white races is 73.

Pelvic Cavity.—The measurements usually taken are those of the superior aperture. In man there is a proportionate increase in the transverse diameter as compared with lower forms :—

$$\frac{\text{Antero-posterior diameter (conjugate) from mid-point of sacral promontory to the upper margin of pubic symphysis} \times 100}{\text{Greatest transverse width between ilio-pectineal lines}} = \textbf{Pelvic or brim index.}$$

Turner has classified the indices into three groups :—

Dolichopellic, index above 95 : Australians, Bushmen, Kaffirs.
Mesatipellic, index between 90 and 95 : Negroes, Tasmanians, New Caledonians.
Platypellic, index below 90 : Europeans and Mongolians generally. [*πέλλα* (pella) = a bowl or pail.]

Vertebral Column.—A characteristic feature of man's vertebral column is the pronounced lumbar curve associated with the erect posture in the living. Apart from the consideration of the interposition of the intervertebral fibro-cartilages between the segments, the bodies of the

lumbar vertebræ influence and react on the curve by exhibiting differences in their anterior and posterior vertical diameters. Advantage has been taken of this to endeavour to reconstruct the lumbar curve from the dried and macerated bones, but it must be borne in mind that habitual posture or increased range of movements may yield results which are possibly misleading. Thus, there is reason for believing that the squatting position, when habitually adopted, may give rise to a compression of the anterior parts of the bodies of the vertebræ, suggesting an absence of or flattening of the lumbar curve, which in fact did not exist during life.

The quality of the curve is estimated from the macerated bones by an index which is computed as follows :—

$$\frac{\text{Sum of posterior vertical diameters of the bodies of the five lumbar vertebræ} \times 100}{\text{Sum of anterior vertical diameters of the bodies of the five lumbar vertebræ}} = \textbf{General lumbar index.}$$

The results are classified as follows :—

Kyrtorrhachic, index below 98, displaying a forward convexity : includes Europeans generally, and Chinese. [κυρτός (kyrtos) = curved, convex ; ῥάχις (rhachis) = the lower part of the back.]

Orthorrhachic, index between 98 and 102, column practically straight : includes examples of Eskimo and Maori.

Koilorrhachic, index above 102, displaying a forward concavity : includes Australians, Negroes, Bushmen, and Andamanese. [κοῖλος (koilos) = hollow, concave.]

Sacrum.—Man's sacrum is characterised by its great breadth in proportion to its length, Those relations are expressed as follows :—

$$\frac{\text{Greatest breadth of base of sacrum} \times 100}{\text{Length from middle of promontory to middle of anterior inferior border of fifth sacral vertebræ}} = \textbf{Sacral index.}$$

The diverse forms are grouped as follows :—

Dolichohieric, index below 100, sacra longer than broad : includes Australians, Tasmanians, Bushmen, Hottentots, Kaffirs, and Andamanese.

Platyhieric, index above 100, sacra broader than long : includes Europeans, Negroes, Hindoos, North and South American Indians. The average European index is 112·4 for males, 116·8 for females. [ἱερός (hieros) = sacred.]

Thorax.—The diameters are taken at the level of the xiphisternal joint.

$$\frac{\text{Transverse diameter} \times 100}{\text{Antero-posterior diameter}} = \textbf{Thoracic index.}$$

The index is usually lower in the female, the form of the thorax being more rounded.

Limb Bones.—The proportionate length of the limb bones to each other and to the body height is of practical interest. It is a matter of common knowledge that the forearms of Negroes are proportionately longer than those of Europeans. Great differences, too, are met with in the absolute and proportionate length of the lower limbs, nor must the relation of these to body height be overlooked. An enumeration of the more important of these indices, and the manner of their computation, will suffice. The proportion of the length of the radius to the length of the humerus is expressed as follows :—

$$\frac{\text{Length of radius} \times 100}{\text{Length of humerus}} = \textbf{Radio-humeral index.}$$

Subdivided into three groups :—

Brachykerkic, index less than 75 : includes Europeans, Lapps, Eskimo. [κερκίς = κνήμη—see below ; but also meant *radius*.]

Mesatikerkic, index between 75 and 80 : Chinese, Australians, Polynesians, Negroes.

Dolichokerkic, index above 80 : Andamanese, Negritoes and Fuegians, Simiidæ in general.

The proportion of the length of the tibia to the femur is computed by the formula—

$$\frac{\text{Length of tibia from surface of condyle to articular surface for talus} \times 100}{\text{Oblique length of femur}} = \textbf{Tibio-femoral index.}$$

Subdivided into two groups :—

Brachyknemic, index 82 and under : includes Europeans and Mongolians generally.

Dolichoknemic, index 83 and over : includes Australians, Negroes, Negritoes, American Indians. [κνήμη (knēmē) = the leg.]

The proportion of the length of the upper limb to that of the lower limb is obtained thus :—

$$\frac{\text{Lengths of humerus + radius} \times 100}{\text{Lengths of femur + tibia}} = \textbf{Intermembral index.}$$

A comparison between the relative lengths of the upper segments of the limbs is obtained by the following formula :—

$$\frac{\text{Length of humerus} \times 100}{\text{Length of femur}} = \textbf{Humero-femoral index.}$$

Platymeria (see p. 266) [$\mu\eta\rho\acute{o}s$ (mēros) = thigh].—The amount of compression of the femur is estimated as follows :—

$$\frac{\text{Sagittal diameter of shaft immediately distal to lesser trochanter} \times 100}{\text{Transverse diameter of shaft immediately distal to lesser trochanter}} = \textbf{Platymeric index.}$$

Platyknemia (see p. 271).—The degree of compression of the tibia is estimated by the formula—

$$\frac{\text{Transverse diameter of shaft at level of nutrient foramen} \times 100}{\text{Antero-posterior diameter of shaft at level of nutrient foramen}} = \textbf{Platyknemic index.}$$

The index ranges from 60 in a Maori tibia to 80 to 108 in modern French tibiæ.

For further information relating to the measurements and indices used by physical anthropologists, the reader is referred to Topinard's *Éléments d'anthropologie* ; Sir W. Turner's *Challenger Memoirs*, Part 47, vol. xvi. ; and Duckworth's *Morphology and Anthropology*.

THE ARTICULATIONS OR JOINTS.

SYNDESMOLOGY.

By David Hepburn.

Syndesmology is that branch of human anatomy which treats of the articulations or joints.

A junctura ossium (articulation or joint) constitutes a mode of union or connexion subsisting between any two separate segments or parts of the skeleton, whether osseous or cartilaginous. It has for its primary object either the preservation of a more or less rigid continuity of the parts joined together, or else the permission of a variable degree of mobility, subject to the restraints of the uniting media.

Classification of Joints.—In attempting to frame a classification of the numerous joints in the body, several considerations must be taken into account, viz., the manner and sequence of their appearance in the embryo; the nature of the uniting media in the adult, and also the degree and kind of movement permitted in those joints where movement is possible.

In this way we obtain two main subdivisions of joints:—

(1) Those in which the uniting medium is co-extensive with the opposed surfaces of the bones entering into the articulation, and in which a direct union of these surfaces is thereby effected.

(2) Those in which the uniting medium has undergone more or less of interruption in its structural continuity, and in which a cavity of greater or less extent is thus formed in the interior of the joint.

To the first group belong all the immovable joints, many of which are only of temporary duration; to the second group belong all joints which possess, as their outstanding features, mobility and permanence.

SYNARTHROSES.

The general characteristics of this group are partly positive and partly negative. Thus, there is uninterrupted union between the opposed surfaces of the bones joined together at the plane of the articulation, *i.e.* there is no trace of a joint cavity, and further, there is an entire absence of movement. Developmentally, these joints result from the approximation of ossific processes which have commenced from separate centres of ossification, and therefore the nature of the uniting medium varies according as the bones thus joined together have originally ossified in membrane or in cartilage. In the former case union is effected by an interposed fibrous membrane continuous with, and corresponding to, the periosteum. To such articulations the term **sutura** (Fig. 259) is applied. In the latter case the uniting medium is a plate of hyaline cartilage. Such articulations are called **synchondroses** (Fig. 260). In all the synchondroses, and in many of the sutures, the uniting medium tends to disappear in the progress of

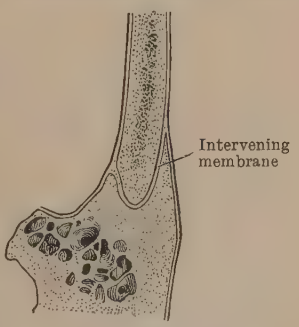

Fig. 259.—Vertical Section through a Suture.

ossification, and thus the plane of articulation becomes obliterated, so that direct structural continuity between the osseous segments takes place. The primary features common to all synarthroses are—(*a*) continuous and direct union of the opposing surfaces; (*b*) no joint cavity; (*c*) no movement.

FIG. 260.—SECTION THROUGH THE OCCIPITO-SPHENOID SYNCHONDROSIS.

Sutura.—This form of synarthrosis is found only in connexion with the bones of the skull. In a large number of cases the bones which articulate by suture present irregular interlocking margins, between which there is the interposed fibrous membrane to which reference has already been made. When these interlocking margins present well-defined projections they are said to form a **sutura vera (true suture)**; on the other hand, when the opposed surfaces present ill-defined projections, or even flat areas, they are described as **sutura notha (false suture)**. In each of these subdivisions the particular characters of the articulating margins are utilised in framing additional descriptive terms. Thus true sutures may possess interlocking margins whose projections are tooth-like **(sutura dentata)**, *e.g.* in the interparietal suture; saw-like **(sutura serrata)** (Fig. 261), *e.g.* in the interfrontal suture; ridge-like, or comparable to the parallel ridges on the welt of a boot **(sutura limbosa)**. Similarly false sutures may articulate by margins which are scale-like **(sutura squamosa)**, *e.g.* in the squamoso-parietal suture; or by rough opposed surfaces, **sutura harmonia**, *e.g.* in the suture between the palatine processes of the maxillary bones. There is one variety of synarthrosis which, in the adult, can scarcely be called a suture, although the differences are of minor importance, viz., **schindylesis**, which is an articulation between the edge of a plate-like bone, such as the rostrum of the sphenoid, and the cleft in another, such as the vomer.

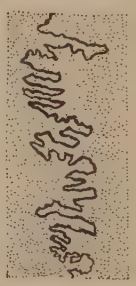

FIG. 261.—SUTURA SERRATA.

Synchondrosis.—Illustrations of this group can be found only in the young growing individual, because as age advances and growth ceases, the process of ossification affects the hyaline cartilage which constitutes the uniting medium, and the plane of articulation disappears. Under this heading we may include the planes of junction between all epiphyses and the diaphyses to which they severally belong. The occipito-sphenoid (Fig. 260) and the petro-jugular articulations in the base of the skull provide other well-marked examples.

AMPHIARTHROSES—DIARTHROSES (MOVABLE JOINTS).

The leading features of this group are capability of **movement** and **permanence**. In very few instances do such joints ever become obliterated under normal conditions. Determining their permanence, and regulating the amount of possible movement, there is always more or less of interruption in the continuity of the structures which bind the osseous elements together. That is, there is always some evidence of a **cavum articulare** (joint cavity), although as a matter of course such interruption can never be so extensive as entirely to disassociate the articulating elements. Therefore in all movable joints a new class of structures is found, viz., **ligamenta** (the ligaments), by means of which continuity is maintained even when all the other uniting media have given place to an articular cavity. The further subdivision of this group is founded upon the amount of movement permissible, and the extent to which the articular cavity takes the place of the original continuous uniting medium. Thus we obtain the **amphiarthroses**, or partly movable, and the **diarthroses**, or freely movable.

An **amphiarthrosis** (Fig. 264) presents the following characteristics: (*a*) partial movement; (*b*) union by ligaments and by an interposed plate or disc of fibro-cartilage, in the interior of which there is (*c*) an incomplete or partial joint cavity, which may be lined by a rudimentary **stratum synoviale** (synovial membrane)

whose function it is to provide a lubricating fluid, the **synovia** or joint-oil; (*d*) a plate of hyaline cartilage coating each of the opposing surfaces of the bones concerned. All the joints belonging to this group occur in the median plane of the body. It includes the symphysis pubis, the joints between the bodies of the vertebræ, and the joint between the manubrium sterni and the body of the sternum.

A **diarthrosis** (Fig. 262) is the most elaborate as well as the most complete form of articulation. It is characterised by (*a*) capability of movement which is more or less free in its range; (*b*) a reduction of the uniting structures to a series of retaining ligaments; (*c*) an articular cavity which is limited only by the surrounding ligaments; (*d*) the constant presence of **synovial membrane**; (*e*) cartilago articularis (hyaline encrusting cartilage) which clothes the opposed surfaces of the articulating bones. The majority of the joints in the adult belongs to this group. This series of joints has been subdivided into a number of minor sections, in order to emphasise the occurrence of certain well-marked structural features, or because of the particular nature of the movement by which they are characterised. Although in all diarthroses there is a certain amount of *gliding* movement between the opposed surfaces of the bones which enter into their formation, yet, when this gliding movement becomes their prominent feature, as in most of the joints of the carpus and tarsus, they are termed **arthrodia**. But bones may be articulated together so as to permit of movement in one, two, or more fixed axes of movement, or in modifications of these axes. Thus in **uniaxial joints** the axis of movement may lie in the longitudinal axis of the joint, in which case the **trochoid rotatory form** of joint results, as in the proximal and distal radio-ulnar articulations; or it may correspond with the transverse axis of the articulation, as in the elbow-joint and knee-joint, when the **ginglymus** or **hinge variety** results. If movement takes place about two principal axes situated at right angles to each other, as in the radio-carpal joint, the terms **ellipsoid (biaxial** or **condyloid)** are applied. Movements occurring about three principal axes placed at right angles to each other, or in modifications of these positions, constitute **multiaxial joints**, in which the associated structural peculiarities suggest the alternative terms of **enarthroses** or **ball-and-socket joints.**

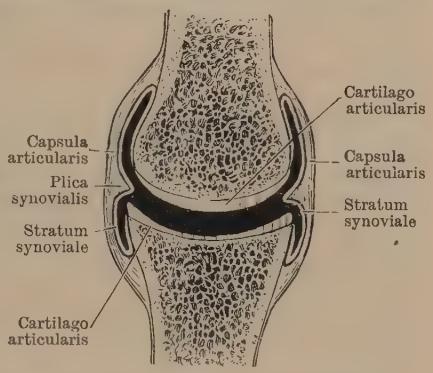

FIG. 262.—DIAGRAM OF A DIARTHRODIAL JOINT.

STRUCTURES WHICH ENTER INTO THE FORMATION OF JOINTS.

The structures which enter into the formation of joints vary with the nature of the articulation. In every instance there are two or more skeletal elements, whether bones or cartilages, and in addition there are the uniting media, which are either simple or elaborate according to the provision made for rendering the joint more or less rigid, or capable of movement. We have already seen that the uniting medium in **synarthrodial joints** is a remnant of the common matrix, whether fibro-vascular membrane or hyaline cartilage, in which ossification has extended from separate centres. Among the **amphiarthroses** there is still extensive union between the opposing surfaces of the articulating bones, but the character of the uniting medium has advanced from the primitive embryonic tissue to fibrous and fibro-cartilaginous material, as well as hyaline cartilage. These, with very few exceptions, are permanent non-ossifying substances, such as may be seen between the opposing osseous surfaces of two vertebral bodies. The joint cavity, more or less rudimentary, is confined to the centre of the fibro-cartilaginous plate, and may result from the softening or imperfect cleavage of the central tissue. It may also present rudiments of a synovial membrane.

In the **diarthrodial group** the extensive cavity has produced great interruption

in the continuity of the uniting structures which originally existed between the bones forming such a joint. Ligaments have therefore additional importance in this group, for not only do they constitute the uniting media which bind the articulating bones together, but, to a large extent, they form the peripheral boundary of the joint cavity, although not equally developed in all positions. Thus, every diarthrodial joint possesses a fibrous or ligamentous envelope constituting the *fibrous stratum* of the **articular capsule,** which is attached to the adjacent ends of the articulating bones. For special purposes, particular parts of the fibrous stratum may undergo enlargement and thickening, and so constitute strong ligamentous bands, although still forming continuous constituents of the envelope.

The fibrous stratum is lined by a **stratum synoviale** (O.T. **synovial membrane**), the two strata constituting the **capsula articularis**. The synovial stratum is continued from the inner surface of the fibrous stratum to the surface of the intracapsular portion of each articulating bone. The part of the bone included within the joint consists of a "non-articular" portion covered by the synovial layer and an "articular" portion covered by encrusting hyaline cartilage. The latter provides the surface which comes into apposition with the corresponding area of another bone. In its general disposition the synovial layer may be likened to a cylindrical tube open at each end. This layer is richly supplied by a close network of vessels and nerves.

Certain diarthroses present intracapsular structures which may be distinguished as interarticular ligaments and articular discs and menisci (O.T. interarticular fibro-cartilages).

Ligamenta Interarticularia.—**Interarticular ligaments** extend between, and are attached to, non-articular areas of the intracapsular portions of the articulating bones. They are usually situated in the long axis of the joint, and occasionally they widen sufficiently to form partitions which divide the joint-cavity into two compartments, *e.g.* the articulation of the heads of the ribs with the vertebral column, and certain of the costo-sternal joints.

Articular discs and menisci (O.T. **interarticular fibro-cartilages**) (Fig. 263) are more or less complete partitions situated between and separating opposing articular surfaces, and when complete they divide the joint cavity into two distinct compartments. By its periphery, a disc is rather to be associated with the articular capsule than with the articulating bones, although its attachments may extend to non-articular areas on the latter. Those found in the knee-joint are called **menisci**; those found in other joints are called **articular discs.**

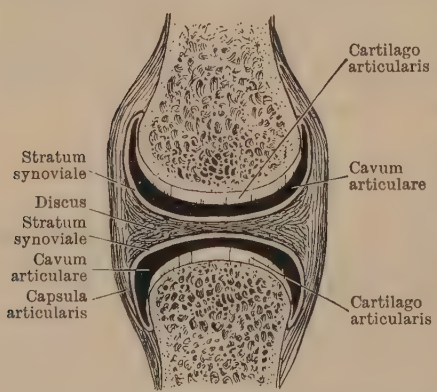

FIG. 263.—DIAGRAM OF A DIARTHRODIAL JOINT WITH ARTICULAR DISC DIVIDING THE JOINT-CAVITY INTO TWO COMPARTMENTS.

Both interarticular ligaments and articular discs and menisci have their free surfaces covered by the synovial stratum.

Adipose tissue, forming pads of varying size, is usually found in certain localities within the joint, between the synovial stratum and the surfaces which it covers. These pads are soft and pliable, and act as packing material, filling up gaps or intervals in the joint. During movement they adapt themselves to the changing conditions of the articulation.

In addition to merely binding together two or more articulating bones, ligaments perform very important functions in connexion with the different movements taking place at a joint. They do not appreciably lengthen under strains, and thus ligaments may act as inhibitory structures, and by becoming tense may restrain or check movement in certain directions.

Synovial strata, in the form of closed sacs termed **mucous** or **synovial bursæ**, are frequently found in other situations besides the interior of joints. Such bursæ are developed for the

purpose of reducing the friction, (*a*) between the integument and certain prominent subcutaneous bony projections, as, for instance, the point of the elbow, or the anterior surface of the patella **(subcutaneous mucous bursæ)**; (*b*) between a tendon and some surface, bony or cartilaginous, over which it plays **(subtendinous mucous bursæ)**; (*c*) between a tendon or a group of tendons and the walls of osteo-fascial tunnels, in which they play **(vaginæ mucosæ tendinum** or **mucous sheaths of tendons)**. Subtendinous mucous bursæ are often placed in the neighbourhood of joints, and in such cases it not infrequently happens that there is a direct continuity between the bursa and the synovial stratum which lines the cavity of the joint through an aperture in the articular capsule.

THE DIFFERENT KINDS OF MOVEMENT AT JOINTS.

Reference has already been made to the existence of fixed axes of movement as a basis for the classification of certain forms of diarthrodial joints. Hence it is evident that the movements which are possible at any particular joint depend to a large extent upon the shape of its articular surfaces as well as upon the nature of its various ligaments. Therefore the technical terms descriptive of movements either indicate the directions in which they occur, or else the character of the completed movement.

In the great majority of articulations between short bones, the amount of movement is so restricted, and the displacement of the opposing articular surfaces so slight, that the term **gliding** sufficiently expresses its character.

A **gliding** movement of an extensive kind, for example that of the patella upon the femur, in which the movement largely resembles that of the tyre of a wheel revolving in contact with the ground so that different parts are successively adapted to each other, is called **co-aptation**.

Articulations between long bones, on the other hand, are usually associated with a much freer range of movement, with a corresponding variety in its character. **Rotation** is a movement around an axis which is longitudinal. Sometimes it is the only form of movement which a joint possesses; at other times it is merely one of a series of movements capable of execution at the same joint. **Flexion** or bending is a movement in which the formation of an angle between two parts of the body is an essential feature. As it is possible to perform this movement in relation to two axes, viz., a transverse and an antero-posterior axis, it is necessary to introduce qualifying terms. Thus, when two anterior or ventral surfaces are approximated, as at the hip-, elbow-, or wrist-joints, the movement is called **ventral**, **anterior**, or **palmar flexion**; but if posterior or dorsal surfaces are approximated by the process of bending, then the flexion becomes **posterior** or **dorsi-flexion**, as at the knee- or wrist-joints. Further, at the wrist-joint, the formation of an angle between the ulnar border of the hand and the corresponding aspect of the forearm, produces **ulnar flexion**, and similarly the bending of the hand towards the radial border of the forearm is **radial flexion**.

Extension or straightening consists in obliterating the angle which resulted from flexion. In the case of certain joints, therefore, such as the elbow, wrist, and knee, the segments of the limb occupy a straight line as regards each other when extended.

At the ankle-joint the natural attitude of the foot to the leg is flexion at a right angle. The diminution of this angle by approximating the dorsum of the foot towards the anterior aspect of the leg constitutes *flexion*; while any effort at placing the foot and leg in a straight line, *i.e.* obliteration of the angle, as in pointing the toes towards the ground and raising the heel, constitutes *extension*.

Abduction is a term which either expresses movement of an entire limb in a direction away from the median plane of the body, or of a digit away from the plane of the middle finger in the hand, or the plane of the second toe in the case of the foot.

Adduction is the reverse of abduction, and signifies movement towards the median plane of the body, or towards the planes indicated for the digits of the hand and foot.

Circumduction is a movement peculiarly characteristic of multiaxial or ball-

and-socket joints. It consists in combining such angular movements as flexion, extension, abduction, and adduction, so as to continue the one into the other, whereby the joint forms the apex of a cone of movement, and the free end of the limb travels through a circle which describes the base of this cone.

THE DEVELOPMENT OF JOINTS.

Just as the question of structure determines to a large extent the presence or absence of movement in joints, so in tracing their development it will be found that the manner of their appearance forecasts their ultimate destination as immovable or movable articulations.

All joints arise in mesodermic tissue which has undergone more or less differentiation.

When this differentiation has produced a continuous membranous layer, in which ossific centres representing separate skeletal segments make their appearance, we get the primitive form of suture. The plane of the articulation merely indicates the limit of the ossific process extending from different directions. If, again, the differentiation of the mesoderm has resulted in the formation of a continuous cartilaginous layer, in which ossification commences at separate centres, the plane of the articulation is marked out by the unossified cartilage—in other words, the articulation is a synchondrosis. Ultimately this disappears through the extension of the process of ossification.

To some extent sutures also disappear, although their complete obliteration is not usual even in aged people. Developmentally, therefore, synarthroses or immovable joints do not present any special structural element, and, speaking generally, they have only a temporary existence.

The development of all movable joints is in marked contrast to that of synarthroses. Not only are they permanent arrangements so far as concerns normal conditions, but they never arise merely as planes which indicate the temporary phase of an ossific process. From the outset they present distinct skeletal units, from which the special structures of the joint are derived.

The primitive movable joint is first recognised as a mass of undifferentiated mesodermic cells situated between two masses, which have differentiated into primitive cartilage.

The cell-mass which constitutes the joint-unit presents the appearance of a thick cellular disc, the proximal and distal surfaces of which are in accurate apposition with the primitive cartilages, while its circumference is defined from the surrounding mesoderm by a somewhat closer aggregation of the cells of which the disc is composed. From this cellular disc or joint-unit all the structures characteristic of amphiarthrodial and diarthrodial joints are ultimately developed.

Thus, by the transformation of the circumferential cells into fibrous tissue the investing ligaments are produced. Within the substance of the disc itself a transverse cleft, more or less well-defined and complete, makes its appearance. In this manner the disc is divided into proximal and distal segments, separated from each other by an interval which is the primitive articular cavity. This cleft, however, never extends so far as to interrupt the continuity of the circumferential part of the disc which develops into the fibrous tissue of the investing ligaments. From the proximal and distal segments of the articular disc the various structures distinctive of movable joints are developed.

Thus, in amphiarthrodial joints the cellular articular disc or primitive joint-unit gives origin to the following structures:—From its circumference, investing ligaments; from its interior, the fibro-cartilaginous plate in which an imperfect articular cavity with corresponding imperfect synovial stratum may be found.

In the case of a diarthrodial joint the changes take place on a more extended scale. The articular cavity becomes a prominent feature, in relation to which the surrounding fibrous structures form an investing capsule, lined with a synovial stratum.

When a single cleft arises, but does not extend completely across the longitudinal axis of the articular disc, the undivided portion develops into fibrous interarticular ligaments. On the other hand, when two transverse clefts are formed, that portion of the cellular disc which remains between them becomes transformed into a fibro-cartilaginous disc (or in the case of the knee-joint, menisci), which in its turn may either be complete or incomplete, and thus we may obtain two distinct synovial joint cavities belonging to one articulation.[1]

In considering the development of the synovial layer, and the surfaces on which it is found in the interior of a joint, it is necessary to keep clearly in mind that a synovial layer is a special structure, whose function it is to produce a lubricating fluid or synovia, and that, therefore, its position is determined by the essential necessity of proximity to a direct blood-supply. In other words, this condition is provided by all parts of the interior of an articular cavity except the articular encrusting cartilage. Consequently the synovial stratum is absent only from the free surface of articular cartilage, although it forms a thicker layer upon the inner surface of the articular capsule than upon the free surfaces of interarticular ligaments, discs, and menisci.

[1] From a series of observations upon the development of diarthrodial joints, the writer considers that there is evidence to show that the "cellular articular disc" is directly responsible for the production of the epiphyses which adjoin the completed articular cavity, and that, among such amphiarthroses as exist between the bodies of vertebræ, not only the intervertebral fibro-cartilage, but the proximal and distal epiphyses which ultimately unite with the vertebral bodies have a common origin in the joint-unit.

It is not necessary to suppose that the synovial stratum has disappeared from these articular cartilages as the result of friction, because, notwithstanding constant friction, such parts as the interior of articular capsules or the menisci of the knee-joint have not been denuded of their synovial covering.

As the epiphyses adjoining articular cavities are produced in the joint-units, the attachments of the capsule should be found upon, and restricted to, the non-articular surfaces of the articular epiphyses. While this is the case in their earliest stages, yet, as development advances, considerable variations arise, until, in the adult condition, the capsule of the larger articulations, more particularly of the extremities, is not always restricted to the epiphyses for its attachments. The student will readily perceive and appreciate these variations by comparing the accounts and illustrations of the epiphyses with those of the articulations, and he should note that in some cases the epiphyseal line is *extra-capsular*, *i.e.* the capsular attachment is restricted to the epiphysis; in some the line is *intra-capsular*; and in some the epiphyseal line is partly intra-capsular and partly extra-capsular.

MORPHOLOGY OF LIGAMENTS.

From what has been said in connexion with the development of joints, it will be evident that ligaments are essentially products derived from the cellular articular disc.

Nevertheless, in relation to the fully formed joint, many structures are described as ligaments which do not take origin in the manner just indicated. Some of these ligamentous structures remain fairly distinct from the articular capsules with which they are immediately associated; others become thoroughly incorporated with the articular capsules and cannot be separated therefrom, while yet others may be found situated within the capsule of a joint, and thus play the part of interarticular ligaments.

Instances of each of these forms of adventitious ligaments may be readily given. For example, we may instance the expansion of the tendon of the semimembranosus muscle to the oblique ligament of the knee-joint, and the offshoots from the tendon of the tibialis posterior muscle to the plantar aspects of various tarsal bones, as illustrations of structures which play an important part as ligaments, but are not indelibly incorporated with the joint capsule.

Of structures which have become indelibly incorporated with the primitive capsule, we may instance the broad tendinous expansions of the quadriceps extensor muscle around the knee-joint.

The tibial collateral ligament of the same joint is regarded as a detached portion of the tendon belonging to that part of the adductor magnus muscle which takes origin from the ischium, while the fibular collateral ligament of the knee is considered by some to be the primitive femoral origin of the peronæus longus muscle. Another illustration of the same condition is found in the coraco-humeral ligament, which is regarded by some as representing a detached portion of the pectoralis minor muscle.

Two illustrations may be given of structures playing the part of ligaments within the capsule of a joint, although in the first instance they are not developed as ligaments. It is questionable if the ligamentum teres of the hip-joint is an interarticular ligament in the true sense of the term; it has been regarded as the isolated and displaced tendon of the *ambiens* muscle found in birds. In the shoulder-joint, many observers look upon the superior gleno-humeral ligament as representative of the ligamentum teres.

Such structures as the stylo-hyoid ligament and the spheno-mandibular ligament, although described as ligaments, are in reality skeletal parts which have not attained their complete ossific development.

Again, certain portions of the deep or muscular fascia of the body which become specialised into restraining and supporting bands (*e.g.* the ilio-tibial tract of the fascia lata; the stylo-mandibular ligament; the transverse carpal and dorsal carpal ligaments of the wrist-joint; the transverse crural ligament, and lig. laciniatum of the ankle-joint), although called ligaments, have no direct developmental association with articular ligaments.

Lastly, the inguinal ligament of Poupart and the lacunar ligament of Gimbernat, being special developments in connexion with an expanded tendon or aponeurosis, are still further removed from association with an articulation.

LIGAMENTA COLUMNÆ VERTEBRALIS ET CRANII.

Ligaments of the Vertebral Column and Skull.—All vertebræ, with the exception of those which deviate from the common vertebral type, present two sets of articulations whose various parts are arranged upon a uniform pattern. Thus, every pair of typical vertebræ presents an articulation between the bodies, and a pair of articulations between the vertebral arches. With the latter there are associated various important accessory ligaments which bind together laminæ, spinous processes, and transverse processes.

Articulations between Bodies of Vertebræ.—These are amphiarthrodial joints. Singly, they present only a slight degree of mobility, but when this amount of movement is added to that of the whole series, the range of movement of the vertebral

column becomes considerable. The articular surfaces are the flattened surfaces of adjacent vertebral bodies. They are bound together by the following structures:—

Fibrocartilagines Intervertebrales (Fig. 264).—Each **intervertebral fibro-cartilage** accommodates itself to the space it occupies between the two vertebral

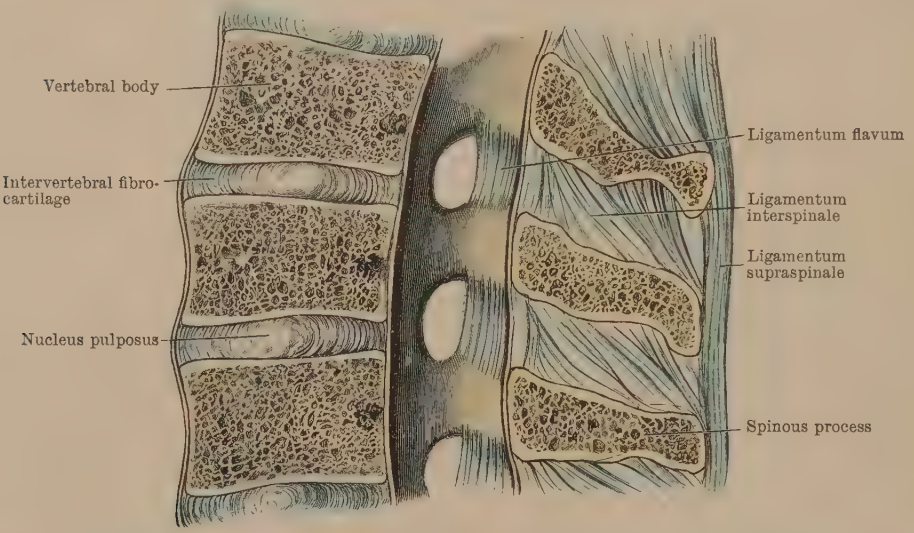

Fig. 264.—Median Section through a Portion of the Lumbar Part of the Vertebral Column.

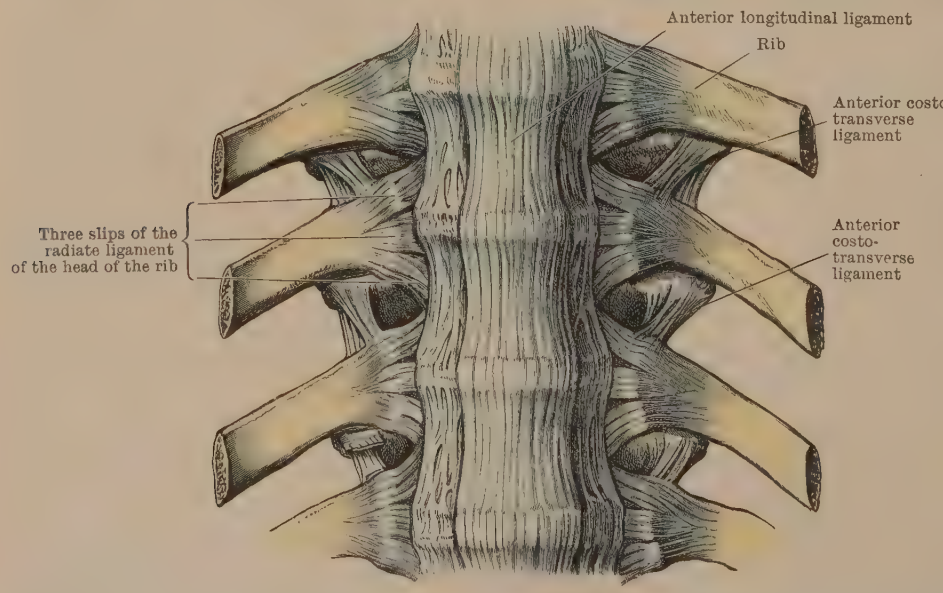
bodies, to both of which it is firmly adherent. The fibro-cartilages from different parts of the vertebral column vary in vertical thickness, being thinnest from the third to the seventh thoracic vertebra, and thickest in the lumbar region. In the cervical and lumbar regions each fibro-cartilage is thicker anteriorly than



Anterior longitudinal ligament
Rib

Three slips of the radiate ligament of the head of the rib
Anterior costo-transverse ligament

Fig. 265.—Anterior Longitudinal Ligament of the Vertebral Column, and the Costo-vertebral Joints as seen from the front.

posteriorly, thereby assisting in the production of the anterior convexity which characterises the vertebral column in these two regions. In the thoracic region the fibro-cartilages are thinnest on their anterior aspects in correspondence with the anterior concavity of this section of the vertebral column.

Each fibro-cartilage consists of a circumferential portion, **annulus fibrosus**, formed for the most part of oblique parallel fibres running from one vertebra to the other; horizontal fibres are also found. The axial or central part of the fibro-cartilage, the **nucleus pulposus**, is elastic, soft, and pulpy.

The superior and inferior surfaces of the fibro-cartilage are closely adherent to the adjoining epiphyseal plates of the vertebral bodies, and as ossification advances, the distinction between epiphyseal plates and vertebral body disappears.

As a rule the transverse diameter of the fibro-cartilage corresponds to that of the vertebral bodies which it joins together; but in the cervical region, where the inferior margin of the super-imposed vertebra is overlapped on each side by the one which bears it, the fibro-cartilage does not extend to the extreme lateral margin, and in this position a small diarthrosis may be seen at each lateral margin of the fibro-cartilage.

Lig. Longitudinale Anterius.—The **anterior longitudinal ligament** (Fig. 265) consists of a wide stratum of longitudinal fibres which extends from the front of the epistropheus vertebra to the front of the superior segment of the sacrum, and becomes gradually wider from above downwards. It lies on the anterior surfaces of the intervertebral fibro-cartilages, to which it is firmly attached as it passes from one vertebra to the other. Its fibres vary in length. Some are attached to contiguous margins of two adjoining vertebræ; others pass in front of one vertebra to be attached to the next below, and yet others find their lower attachment three or four vertebræ below the one from which they started. None of the fibres are attached to the transverse depression on the anterior surface of a vertebral body.

Lig. Longitudinale Posterius.—The **posterior longitudinal ligament** (Fig. 266) is found within the vertebral canal upon the posterior aspect of the vertebral bodies. It consists of longitudinal fibres, and it extends from the sacrum to the epistropheus vertebra, superior to which it is continued to the skull as the membrana tectoria. Opposite each intervertebral fibro-cartilage it is attached to the entire width of the adjacent margins of the two vertebral bodies, its fibres being continued over the posterior surface of the fibro-cartilage. In the lumbar and thoracic regions the width of the ligament is considerably reduced opposite the back of each vertebral body, and thus it forms a series of dentate projections along both of its margins; but in the cervical region the width of the ligament is more uniform. One or two large thin-walled veins escape from the body of each vertebra under cover of this ligament.

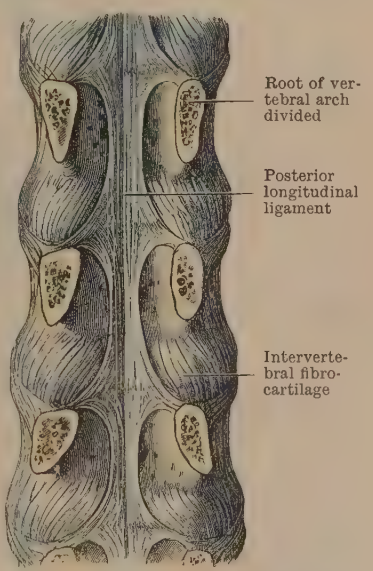

Fig. 266.—Posterior Longitudinal Ligament of the Vertebral Column.

Articulations between Vertebral Arches.—The vertebral arch of each typical vertebra carries two pairs of articular processes, by means of which it articulates with adjacent vertebral arches. The articulations between these processes are true diarthroses of the arthrodial variety.

The distinctive characters of these articular surfaces, as regards their shape and direction in the different groups of vertebræ, have been referred to in the section on osteology.

All these articulations are provided with complete but very thin-walled **capsulæ articulares**, which are thinnest and loosest in the cervical region, where also the movements are freest. Each capsule is lined with a **stratum synoviale**.

Associated with these joints between vertebral arches are certain ligaments which are accessory to the articulations, although they are quite distinct from the capsule.

The laminæ of adjoining vertebræ are bound together by the **ligamenta flava**

(Fig. 267), which consist of yellow elastic fibres. The ligamenta flava close the vertebral canal in the intervals between the laminæ. Each ligament is attached superiorly to the anterior aspect of the upper lamina at a short distance above its inferior border, and inferiorly it is attached to the posterior aspect of the lamina below.

In the thoracic region, where the imbrication of adjoining laminæ is a prominent feature, these ligaments are not so distinctly visible from behind as they are in the regions where imbrication of the laminæ is not so marked.

Laterally they extend as far as the articular capsules, while medially the margins of the ligaments of opposite sides meet under cover of the root of the spinous process.

Contiguous spinous processes are also attached to each other by **ligamenta interspinalia (interspinous ligaments)** (Fig. 264). These are strongest in the lumbar, and weakest in the thoracic region. Each consists of layers of obliquely interlacing fibres which spring from near the tips of the two adjacent spinous processes and radiate to their opposing margins. In the antero-posterior direction they extend from the base to the tip of the spinous process.

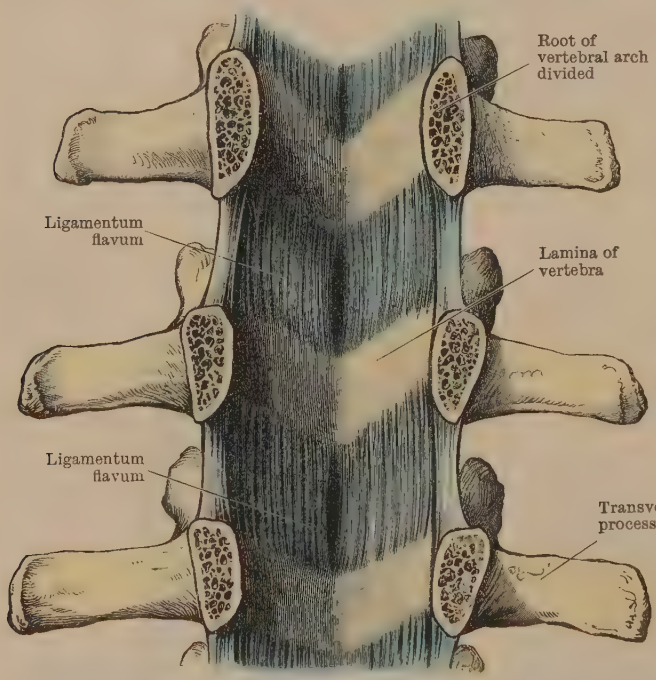

FIG. 267.—LIGAMENTA FLAVA AS SEEN FROM THE FRONT AFTER REMOVAL OF THE BODIES OF THE VERTEBRÆ BY SAWING THROUGH THE ROOTS OF THE VERTEBRAL ARCHES.

The **ligamenta supraspinalia (supra-spinous ligaments)** (Fig. 264) consist of longitudinal bands of fibres of varying lengths. They extend from spine to spine, being attached to their tips, and are situated superficial to, although in continuity with, the ligamenta interspinalia.

In the cervical region this series of ligaments is extensively developed, where they project backwards from the spinous processes between the muscles of the two sides of the neck in the form of an elastic partition called the **ligamentum nuchæ.**

The antero-posterior extent of the ligamentum nuchæ increases as it approaches the occiput, where it is attached to the external occipital crest from the external occipital protuberance to the posterior border of the foramen magnum. Its posterior margin is free, and extends from the external occipital protuberance to the spine of the vertebra prominens.

Between the transverse processes there are **ligamenta intertransversaria**, which consist of vertical fibres extending from the postero-inferior aspect of one transverse process to the superior margin of that next below. These ligaments are generally absent from the cervical and upper thoracic regions.

Sacro-coccygeal Symphysis.—The last piece of the sacrum is joined to the first piece of the coccyx by an intervertebral fibro-cartilage, and the junction is rendered more secure by the presence of certain strong ligaments. A **lig. sacrococcygeum anterius,** continuous with the lig. longitudinale anterius, is placed in front. A **lig. sacrococcygeum posterius,** which stretches downwards from the sharp border of the lower opening of the sacral canal, strengthens the joint behind. A **lig. sacrococcygeum laterale** supports the joint on each side, whilst strong

bands pass between the cornua of the two bones and constitute the **interarticular ligaments.**

Intercoccygeal Joints.—So long as they remain separate, the different pieces of the coccyx are joined by intervertebral fibro-cartilages and by anterior and posterior ligaments.

Movements of the Vertebral Column.—Although the amount of movement permissible between any two vertebræ is extremely limited, yet the total range of movement capable of being attained by the entire vertebral column is very considerable.

Flexion may occur both forwards and backwards at the articulations of vertebral bodies, but more freely in the lumbar and cervical regions than in the thoracic region, where the limited amount of intervertebral fibro-cartilage and the imbrication of the laminæ and spines restrict the movement. Backward flexion is most pronounced in the cervical region, and forward flexion in the lumbar region. Between the articular surfaces of the articulations between vertebral arches a variety of movements are permitted, dependent upon the directions of these surfaces. Thus **lateral flexion** is permitted in the lumbar, but not in the cervical or thoracic regions. Again, in the lumbar region **rotation** does not occur, owing to the shape of the articular processes, while it is possible in the thoracic region. In the cervical region the shape and position of the articular surfaces prevent the occurrence both of lateral flexion and of rotation as isolated movements, but a combination of these two movements may take place, whereby rotatory movement in an oblique median axis results. Finally, in the lumbar region, by combining the four forms of flexion, viz., forward, backward, and right and left lateral, a certain amount of **circumduction** is possible.

Articulatio Atlantoepistrophica.

Between the **atlas** and **epistropheus** vertebræ three diarthroses occur. Two of them are situated laterally, in relation to the articular processes, and are called

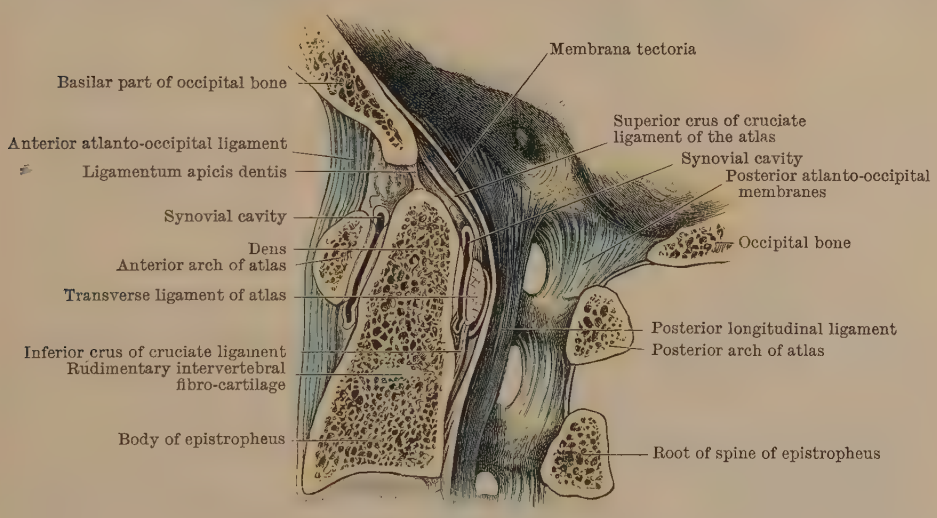

Fig. 268.—Median Section through the Atlanto-occipital and Atlanto-epistropheal Joints.

arthrodial diarthroses, because of the flattened nature of the articulating surfaces. The third articulation is median in position. It is found between the smooth anterior surface of the dens of the epistropheus and the articular facet on the posterior aspect of the anterior arch of the atlas. This joint is a rotatory diarthrosis.

Ligamenta.—Each of the joints is furnished with a **capsula articularis**, whereby the articular cavity is circumscribed. In the case of the lateral articulations, each articular capsule presents a distinct band, named the **accessory ligament**, which is situated within the vertebral canal (Fig. 269), and passes downwards and medially from the lateral mass of the atlas to the posterior aspect of the body of the epistropheus.

The following additional ligaments constitute the leading bonds of union :—

Lig. Obturatorium Atlantoepistrophicum Anterius.—The **anterior covering atlanto-epistropheal ligament** (O.T. **anterior atlo-axoid ligament**) (Fig. 268) is a membranous structure which is thin laterally, but strong in the median plane, where it is thickened by a prolongation of the lig. longitudinale anterius. It extends from the anterior arch of the atlas to the front of the body of the epistropheus.

Lig. Obturatorium Atlantoepistrophicum Posterius.—The **posterior covering atlanto-epistropheal ligament** (O.T. **posterior atlo-axoid ligament**) (Fig. 268) occupies the position which is elsewhere taken by the ligamenta flava. It extends from the posterior arch of the atlas to the upper border of the vertebral arch of the epistropheus.

Lig. Transversum Atlantis.—The **transverse ligament of the atlas** (Figs. 268 and 269) is a strong band, placed transversely, which arches backwards behind the neck of the dens of the epistropheus. By its extremities it is attached to the tubercle on the medial aspect of each lateral mass of the atlas. A thin plate of fibro-cartilage is developed in its central part.

A **stratum synoviale (synovial membrane)** lines each of the three articular capsules, and in addition a synovial sac is developed between the dens and the lig. transversum atlantis. This is more extensive than the synovial cavity between the dens and the atlas.

Articulatio Atlanto-occipitalis.

There are two articulations between the atlas and the occipital bone. Each is a diarthrosis in which movement takes place in relation to two axes, viz. the

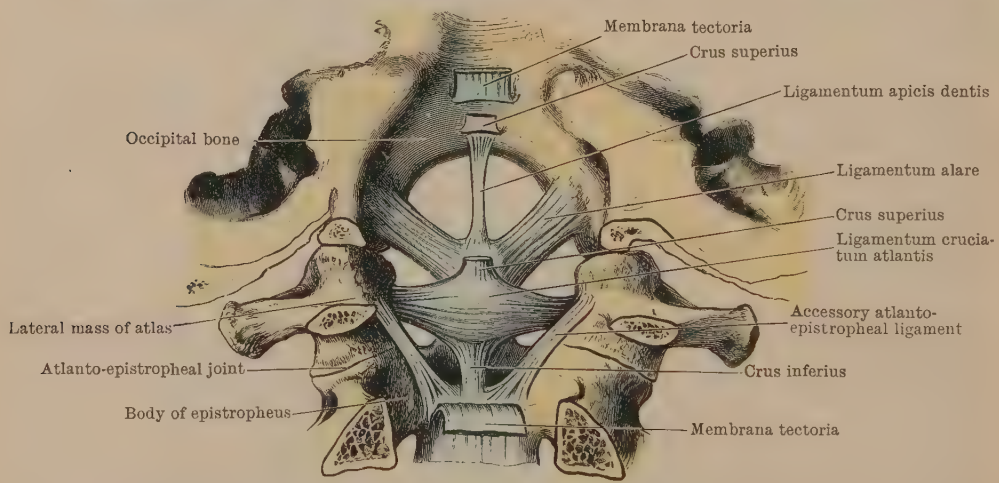

Fig. 269.—Dissection from behind of the Ligaments connecting the Occipital Bone, the Atlas, and the Epistropheus with each other.

transverse and the antero-posterior. The condyle of the occipital bone is bi-convex, and fits into the bi-concave superior articular surface of the atlas, while the long axes of the two joints are directed horizontally forwards and medially.

Ligamenta.—Each articulation is provided with a **capsula articularis** which is thin but complete. It is attached to the rough non-articular surfaces surrounding the articular areas on the atlas and occipital bone.

The following supplementary ligaments are the chief structures which bind the atlas to the occipital bone:—

The **membrana atlanto-occipitalis anterior (anterior occipito-atloid membrane)** (Fig. 268) is a strong although thin membrane, attached inferiorly to the anterior arch of the atlas, and superiorly to the anterior half of the circumference of the foramen magnum. Laterally it is in continuity with the articular capsules, while in the median plane, where it extends from the anterior tubercle of the atlas to the basilar part of the occipital bone, it presents a specially well-defined thickened band which might be regarded as a separate accessory ligament or as the beginning of the anterior longitudinal ligament of the vertebræ.

The **membrana atlanto-occipitalis posterior (posterior occipito-atloid membrane)** (Fig. 268) is another distinct but still thin membrane which is attached superiorly to the posterior half of the circumference of the foramen magnum, and inferiorly to the upper border of the posterior arch of the atlas. Laterally it is also continuous with the articular capsules. On each side of the median plane its inferior border

is arched in relation to the vertebral groove, and is therefore to some extent free, in order to permit the passage of the posterior ramus of the first cervical nerve and the vertebral artery. Not infrequently this arched border becomes ossified, thus converting the groove on the bone into a foramen.

A **synovial stratum** lines each of the articular capsules.

There is no direct articulation between the epistropheus and the occipital bone, but union between them is effected by means of the following accessory ligaments:—

The **membrana tectoria** (Fig. 269) is situated within the vertebral canal, and is usually regarded as the upward continuation of the posterior longitudinal ligament of the vertebral bodies. It extends from the posterior surface of the body of the epistropheus to the basilar groove on the superior surface of the basilar part of the occipital bone, spreading laterally on the circumference of the foramen magnum. Some of its deepest fibres are attached to the atlas immediately above the atlanto-epistropheal articulation.

Anterior to the membrana tectoria there is the **ligamentum cruciatum atlantis** (Fig. 269), a structure which is very closely associated with the lig. transversum atlantis. It consists of a *crus transversum*, formed by the superficial fibres of the transverse ligament of the atlas; a *crus inferius*, consisting of median longitudinal fibres which are attached below to the posterior surface of the body of the epistropheus, and above to the crus transversum; and a *crus superius*, also median and longitudinal, whose fibres extend from the crus transversum upwards to the posterior surface of the basilar part of the occipital bone, immediately anterior to the membrana tectoria.

Ligamenta Alaria.—The **alar ligaments** (O.T. **check ligaments**) (Fig. 269) are two very powerful, short, and somewhat rounded bands. They are attached medially to the sides of the summit of the dens, and laterally to the tubercle on the medial aspect of the condylar portions of the occipital bone.

Ligamentum Apicis Dentis.—The **ligament of the apex of the dens** (O.T. **middle odontoid**) (Fig. 269) consists of fibres running vertically upwards from the apex of the dens to the median part of the anterior margin of the foramen magnum. This ligament to some extent represents an intervertebral fibro-cartilage, in the centre of which remains of the notochord may be regarded as present.

Even in advanced life a small lenticular mass of cartilage, completely surrounded by bone, persists in the plane of fusion between the dens and the body of the epistropheus.

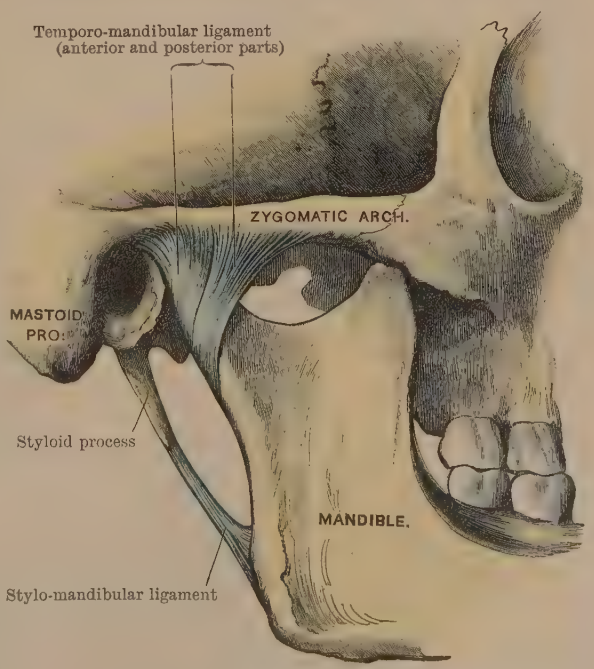

FIG. 270.—MANDIBULAR JOINT.

Movements at these Joints.—At the joints between occipital bone and atlas the movements are very simple, and consist essentially of movements whereby the head is elevated and depressed upon the vertebral column (nodding movements). In addition a certain amount of oblique movement is possible, during which great stability is attained by resting the anterior and posterior parts of opposite condyles upon corresponding parts of the atlas.

The head and the atlas rotate together upon the epistropheus, the pivot of rotation being the dens, and the amount of rotation is limited by the ligamenta alaria. No rotation can occur between the occiput and atlas, and stability between atlas and epistropheus is best attained after a slight amount of rotation, similar to the oblique movement between occipital bone and atlas.

ARTICULATIO MANDIBULARIS.

The **mandibular joint** (O.T. **temporo-mandibular**) is an arthrodial **diarthrosis.** It occurs between the mandibular fossa of the temporal bone and the condyle of the mandible. These two articular surfaces are markedly dissimilar both in size and shape. In its general outline the articular surface of the head of the mandible is cylindrical, having its long axis directed from the medial side laterally and forwards. On the other hand, the mandibular fossa is concavo-convex from behind forwards. Its articular surface includes the tuberculum articulare—the eminence at the base of the anterior root of the zygoma. The articular surfaces of the bones are clothed with hyaline encrusting cartilage, whilst the articular cavity is divided into a superior and inferior part by a disc of fibro-cartilage.

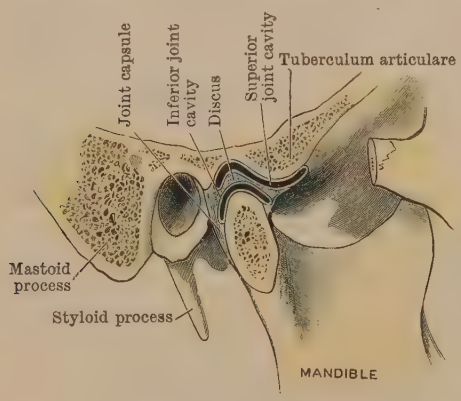

FIG. 271.—SECTION THROUGH THE MANDIBULAR JOINT.

Ligaments.—The joint is invested by an **articular capsule** which is quite complete, but is very thin on the medial side. The lateral part of the fibrous stratum of the capsule—the **temporo-mandibular ligament** (Fig. 271)—is divisible into anterior and posterior portions which are attached superiorly to the root tubercle and inferior border of the zygomatic process of the temporal bone, and inferiorly to the lateral side and posterior border of the neck of the mandible. The direction of its fibres is downwards and backwards.

Within the capsule there is a disc of fibro-cartilage, the **discus articularis** (Fig. 271), which is moulded upon the condyle of the mandible below, and on the articular surface of the temporal bone above. It thus compensates for the incongruity between the articular surfaces of the two bones. The disc is attached circumferentially to the capsule. It is widest in the transverse direction, thicker posteriorly than anteriorly, and thinnest towards the centre, where it may be perforated. Its anterior margin is intimately associated with the insertion of the external pterygoid muscle.

A **synovial stratum** lines each of the compartments into which the joint cavity is divided by the disc. As a rule these membranes are separate from each other, but they become continuous when the disc is perforated. The superior synovial stratum is larger and more loosely disposed than the lower.

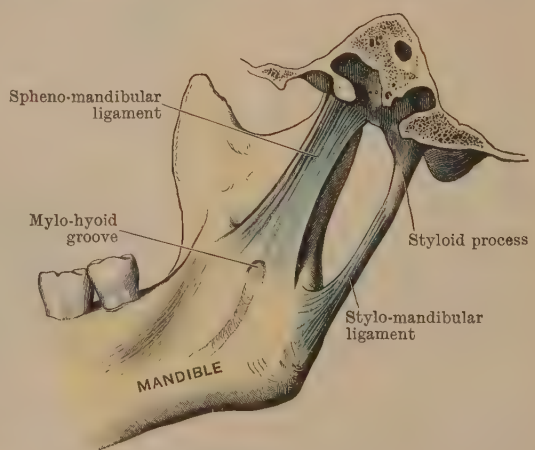

FIG. 272.—SPHENO-MANDIBULAR LIGAMENT OF THE MANDIBULAR JOINT.

Situated on the medial aspect of the joint, but at a short distance from it, and quite distinct from the capsule, there is an accessory band called the **lig. spheno-mandibulare** (Fig. 272). Superiorly the **spheno-mandibular ligament** is attached to the angular spine of the sphenoid bone, and inferiorly to the inferior as well as the anterior border or lingula of the inferior alveolar foramen. It is not an articular ligament in the true sense; for, instead of being connected with the joint, it is developed in the tissue surrounding part of Meckel's cartilage.

Portions of the following structures are found in the interval between the spheno-mandibular ligament and the ramus of the mandible—viz., the external pterygoid muscle; internal maxillary vessels; inferior alveolar vessels and nerve; middle meningeal vessels; auriculo-temporal nerve; and sometimes a deep portion of the parotid gland.

Movements of the Mandible.—The nature of the movements which the mandible can perform is determined partly by the character of the articular surfaces of the mandibular joint, and partly by the fact that, while the two joints always act simultaneously, they may also, to some extent, perform the same movement alternately.

When movement takes place through the long or transverse horizontal axis of each joint, the mandible may be elevated, as in clenching the teeth, or it may be depressed, as in gaping. In the latter movement the condyle leaves the mandibular fossa, and, along with the disc, it moves forwards until they rest upon the tuberculum articulare. Meantime the chin describes the arc of a circle, of which the centre or point of least movement corresponds to the position of the inferior alveolar foramen, and thus the structures which enter at that foramen are protected against stretching. Coincidently with the forward movement of the condyle, it glides in a revolving manner upon the inferior aspect of the disc.

At any stage in the movement of depressing the chin the mandible may be protruded, so that the inferior incisor teeth are projected in front of the upper set, a movement which results from the condyles of the mandible being drawn forwards upon the articular tubercles. A similar relation of the condyle to the articular tubercle occurs during the exaggerated depression of the mandible which results from yawning, in which position the articulation is liable to be dislocated. When the two joints perform the same movement alternately, a certain amount of lateral motion results, from the fact that the long axis of each joint presents a slight obliquity to the transverse axis of the skull, and consequently a grinding or oblique movement in the horizontal plane is produced. Excessive depression, with the risk of dislocation, is resisted by the fibres of the temporo-mandibular ligament, which becomes tense.

In all movements of the mandible the disc conforms closely to the position of the condyle, and they move forwards and backwards together, but at the same time the disc does not restrict the movements of the condyle. Thus while the disc, along with the condyle, is gliding upon the temporal aspect of the joint, the condyle itself revolves upon the inferior surface of the disc.

Cranial Ligaments not directly associated with Articulations.

Lig. Stylomandibulare.—The **stylo-mandibular ligament** (Figs. 270 and 272) is a specialised portion of the deep cervical fascia which extends from the anterior aspect of the tip of the styloid process of the temporal bone to the posterior border of the angle of the mandible, between the insertions of the masseter and internal pterygoid muscles.

Lig. Pterygospinosum.—The **pterygo-spinous ligament** is a membrane extending from the upper part of the posterior free margin of the lateral pterygoid lamina, posteriorly and slightly laterally, to the angular spine of the sphenoid. An interval is left between its upper border and the floor of the skull for the outward passage of those branches of the inferior maxillary nerve which supply the external pterygoid, temporal, and masseter muscles. This ligament has a tendency to ossify either wholly or partially.

Lig. Stylohyoideum.—The **stylo-hyoid ligament** may be regarded as the downward continuation of the styloid process of the temporal bone. Inferiorly it is attached to the lesser cornu of the hyoid bone. It is not infrequently ossified, in which case it constitutes the epihyal bone found in many animals.

THE JOINTS OF THE THORAX.

Articulationes Costovertebrales (Costo-vertebral Articulations). — The typical rib articulates with the vertebral column both by its head and by its tubercle. Thus, two sets of articulations, with their associated ligaments, exist between the ribs and the vertebræ, but each set is constructed upon a common plan, with the exception of certain joints situated at the upper and lower ends of the series, where the ribs themselves deviate from the typical form.

Articulationes Capitulorum.

The **articulations of the heads of the ribs** with the bodies of the vertebræ (Fig. 265) are all diarthroses, which, from their somewhat hinge-like action, may be classed as ginglymoid.

The head of every typical rib is wedge-shaped, and presents two articular facets, an upper and a lower, separated from each other by an antero-posterior ridge which abuts against an intervertebral fibro-cartilage, while the articular facets articulate with similar surfaces on the contiguous margins of the two vertebræ adjoining the fibro-cartilage. These surfaces form a wedge-shaped depression or cup, the bottom of which is more elastic than the sides, and thus an arrangement is provided which tends to reduce the shock of blows upon the walls of the chest.

Each of these articulations is provided with an **articular capsule** which surrounds and encloses the joint, and is attached to contiguous non-articular margins on the head of the rib and the two vertebral bodies. On its anterior or ventral aspect the capsule presents three radiating fasciculi which collectively form the **lig. capituli costæ radiatum** (**radiate ligament of the head of the rib**) (Fig. 265). These fasciculi radiate from a centre on the anterior surface of the head of the rib, so that the middle fasciculus becomes attached to the intervertebral fibro-cartilage while the upper and lower fasciculi proceed to the adjacent margins of the two vertebræ between which the fibro-cartilage is situated, and with which the rib articulates. To a slight extent these radiating fasciculi pass under cover of the lateral margin of the anterior longitudinal ligament of the vertebral bodies. In those joints in which the head of the rib does not articulate with an intervertebral fibro-cartilage the central fasciculus of the radiate ligament is wanting, but the other two retain the same general arrangement.

Lig. Capituli Costæ Interarticulare.—The **interarticular ligament of the head of the rib** consists of short horizontal fibres within the capsule. These are attached, on the one hand, to the ridge which intervenes between the two facets on the head of the rib, and on the other to the lateral aspect of the intervertebral fibro-cartilage. This ligament is not a disc or meniscus, but merely an interarticular ligament, of width sufficient to divide the joint cavity into an upper and a lower compartment. It is absent from those joints which do not articulate with an intervertebral fibro-cartilage, *i.e.* from those ribs which articulate with the body of only one vertebra.

The interarticular ligament is supposed to represent the lateral end of a ligament which, under the name of the **lig. conjugale costarum**, connects the heads of the ribs of certain mammals across the posterior aspect of the intervertebral fibro-cartilage, and, in the human subject, until the seventh month of fœtal life, connects the posterior aspects of the necks of a pair of ribs with each other across the median plane.

A **stratum synoviale** lines each joint cavity, and therefore, in all cases where the joint is divided into two compartments, each one has its own synovial lining.

Articulationes Costotransversariæ.

In the **costo-transverse joints** the tubercle of each *typical* rib articulates with the transverse process of the lower of the two thoracic vertebræ with which the head of the rib is associated. Near the tip of the transverse process there is an articular facet, on its anterior aspect, for articulation with the corresponding facet on the medial articular part of the rib tubercle. The joint so formed is an arthrodial diarthrosis.

The joint cavity is surrounded by a comparatively feeble **capsula articularis**, which is attached immediately beyond the margins of the articular facets, and in which no special bands can be distinguished.

A simple **stratum synoviale** lines the capsule in all cases where the latter is present.

The following accessory ligaments, in connexion with this joint, strengthen and support the articulation :—

Ligamentum Costotransversarium Anterius.—The **anterior costo-transverse ligament** (Fig. 265) consists of strong bands of fibres which are attached to the superior border of the neck of the rib, extending from the head laterally to the non-articular part of the tubercle. All these fibres may be traced upwards. Those situated nearest to the head of the rib proceed obliquely upwards and laterally, to be attached to the transverse process immediately above, but with

extensions to the adjoining rib and its costo-transverse articular capsule. Others proceed almost vertically upwards to the adjoining transverse process, while those which ascend from the upper surface of the tubercle pass obliquely upwards and medially to reach the postero-inferior aspect of the adjoining transverse process. Some posterior fibres connected with the transverse process at its junction with the lamina are called the **posterior costo-transverse ligament.**

Lig. Tuberculi Costæ.—The **ligament of the tubercle of the rib** is a band of transverse fibres applied to the postero-lateral aspect of the capsule. By one end these fibres are attached to the tip of the transverse process behind its articular facet, and by the other to the rough surface of the tubercle of the rib.

Lig. Colli Costæ.—The **ligament of the neck of the rib** consists of short fibres which stretch from the posterior aspect of the neck of the rib, backwards and medially, to the anterior aspect of the transverse process, but, in addition, a proportion of the fibres passes to the posterior aspect of the inferior articular process of the upper of the two vertebræ with which the head of the rib articulates.

The following exceptions to the general plan of rib-articulation indicated above must be noted:—

1. There is no articulation between the eleventh and twelfth ribs and the transverse processes of the corresponding vertebræ.
2. The anterior costo-transverse ligament is wanting from the first rib, and is either rudimentary or wanting in the case of the twelfth rib.
3. The lig. colli costæ is rudimentary in the eleventh and twelfth ribs.

The **ligamentum lumbocostale** extends from the superior surface of the base of the transverse process of the first lumbar vertebra to the inferior surface of the neck of the twelfth rib, as well as to the inferior surface of the transverse process of the twelfth thoracic vertebra.

Articulationes Costochondrales.

Each rib possesses an unossified portion, termed its costal cartilage. As age advances, this cartilage may undergo a certain amount of superficial ossification, but it never becomes entirely transformed. The line of demarcation between bone and cartilage is clear and abrupt, and usually the bone forms an oval cup, in which the end of the cartilage is retained by means of the continuity which exists between the periosteum and the perichondrium. There is no articulation in the proper sense between the rib and its cartilage, although a synovial cavity has occasionally been found between the first rib and its cartilage.

Articulationes Interchondrales.

Interchondral joints are arthrodial diarthroses, and they are found between adjoining margins of certain of the costal cartilages, viz., from the fifth to the eighth or ninth. The cartilages which thus articulate develop flattened, somewhat conical, prolongations of their substance, and thereby the intercostal spaces are interrupted where these flat articular facets abut against each other. Each joint is closed by a surrounding **articular capsule**, the superficial and thoracic aspects of which are specially strengthened by **external** and **internal interchondral ligaments.** These bands extend obliquely between adjacent cartilages.

A **stratum synoviale** lines each joint capsule.

Articulationes Sternocostales.

The upper seven pairs of costal cartilages, as a rule, extend to the lateral margins of the sternum to form **sterno-costal joints.** Of these, the *first pair* is implanted directly upon the manubrium sterni. The ossific process ends abruptly in connexion with the rib, and also ceases as suddenly in connexion with the sternum, and hence the cartilage does not normally present an articulation at either end. From the *second to the seventh* pairs of ribs inclusive, the sterno-costal joints are constructed upon the type of arthrodial diarthroses, although, in the case

of the sixth and seventh cartilages, the joint cavity is always small, and is frequently obliterated.

The sternal end of each of these costal cartilages presents a slight antero-posterior ridge which fits into a shallow V-shaped depression upon the lateral margin of the sternum. With the exception of the sixth cartilage, they articulate opposite the lines of union between the primary segments of the sternum; the sixth articulates upon the side of the lowest segment of the body of the sternum.

Each joint is enclosed by a **capsula articularis**, the fibrous stratum of which is attached to the adjacent borders of the articulating elements. Specially strong fibres distinguish the superficial and deep aspects of the capsule.

The **lig. sternocostale radiatum** (O.T. **anterior costo-sternal ligament**) (Fig. 273) is composed of strong fibres which radiate from the anterior surface of the costal cartilage, near its sternal end, to the front of the sternum. The ligaments of opposite sides interlace with each other, and so cover the front of the sternum with a felted membrane—the **membrana sterni**.

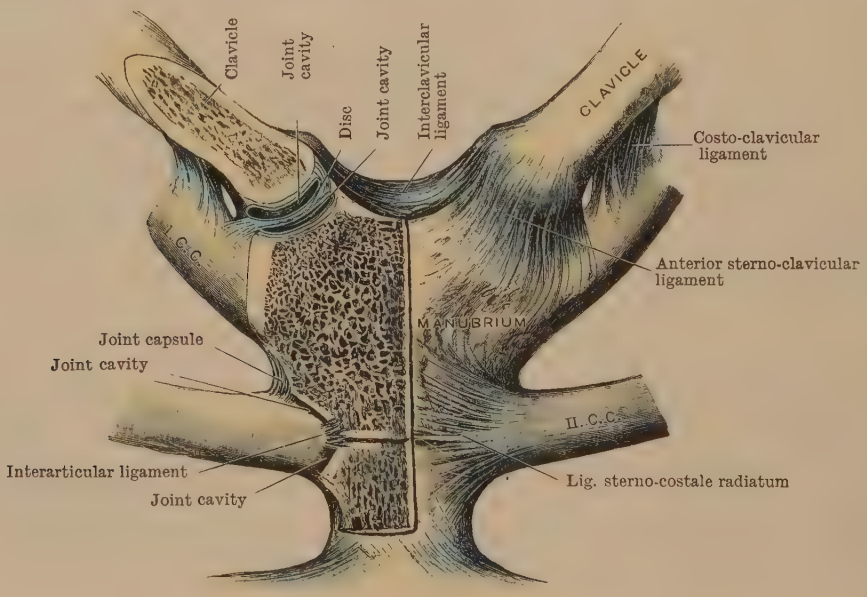

FIG. 273.—STERNO-CLAVICULAR AND STERNO-COSTAL JOINTS.

The **lig. sternocostale posterius (posterior costo-sternal ligament)**—also a part of the capsule—has attachments similar to the foregoing, but the arrangement of its fibres is not so powerful.

The **ligamentum costoxiphoideum** passes from the front of the upper part of the xiphoid process, obliquely upwards and laterally to the front of the seventh, and sometimes to the front of the sixth costal cartilage.

Within the capsules of these joints **ligamenta sternocostalia interarticularia (interarticular ligaments)** (Fig. 273) may be found. Their disposition is somewhat uncertain, for whereas, in the case of the second pair of cartilages, they invariably divide the joint cavity into two distinct compartments—an upper and a lower—such an arrangement is very uncertain in the other joints, and they occasionally, especially in the cases of the sixth and seventh cartilages, entirely obliterate the joint cavity. These ligaments extend horizontally between the ends of the costal cartilages and the side of the sternum.

The **stratum synoviale** is found wherever a joint cavity is developed, and therefore there may be one or two synovial strata, according to the presence or absence of a proper interarticular ligament. When the joint cavity is obliterated by the fibrous structure which represents the interarticular ligament, a synovial stratum is also absent.

Articulationes Sterni.

Primarily the sternum consists of an elongated plate of hyaline cartilage, which becomes subdivided into segments by the process of ossification.

The four segments of which the body of the sternum is originally composed unite with each other after the manner of typical synchondroses.

Similarly the xiphoid process and the body ultimately become united. It is not usual to find the joint between the manubrium and the body obliterated by the ossification of the two bony segments. Even in advanced life it remains open, and the joint, which is named the **synchondrosis sternalis**, partakes of the nature of an amphiarthrosis (Fig. 273), although a joint cavity is not found under any circumstances in the plate of fibro-cartilage which intervenes between the manubrium and the body of the sternum.

The **membrana sterni**, to which reference has already been made, assists in strengthening the union between the different segments of the sternum.

Movements of the Ribs and Sternum.—These movements may be considered either independently of, or as associated with, respiration.

In the former case the ribs move in connexion with flexion and extension of the vertebral column, being more or less depressed and approximated in flexion, and elevated or pulled apart in extension. Considered in connexion with respiration, it is necessary to observe that, to all intents and purposes, the vertebral column and the sternum are rigid structures. Next, we must remember that the heads of all the ribs occupy fixed positions, and similarly the anterior ends of seven pairs of cartilages are fixed to the lateral margins of the sternum. The ribs thus form arches, presenting a large amount of obliquity from behind forwards. Therefore, during inspiration, when the rib is elevated, the arch becomes more horizontal, and the transverse diameter of the chest is increased. At the same time, the anterior ends of the sternal ribs tend to thrust the sternum forwards and upwards; but the nature of the attachment of the first pair of ribs to the sternum, as well as the attachment of the diaphragm to the xiphoid process, prevents this movement from becoming excessive, and hence the sternum becomes a line of resistance to the forward thrust of the ribs. As a consequence, the ribs rotate upon themselves about an oblique axis which passes downwards, laterally, and posteriorly through the capitular joint and the neck of the rib anterior to the costo-transverse joint.

In this way increase, both of the antero-posterior and transverse diameters of the thorax, is provided for, although the amount of increase is not equally pronounced in all planes. Thus at the level of the first rib very little eversion is possible, because the axis of rotation is nearly transverse, and therefore any increase in the transverse or antero-posterior thoracic diameters at this level may be disregarded, although a certain amount of elevation of the manubrium sterni and anterior end of the first rib is evident.

Below the level of the sixth rib elevation and rotation of the rib during inspiration are usually said to be complicated by a certain amount of backward movement, due to the character of the costo-transverse joint, until, in the case of the last two ribs, which are destitute of costo-transverse joints, a movement backwards is almost entirely substituted for elevation. It is probable, however, that the movements of the asternal ribs exactly correspond to those of the sternal series, and that by the contraction of the costal digitations of the diaphragm the anterior ends of the false ribs are provided with fixed positions comparable to those supplied by the sternum to the ribs of the sternal series.

We may therefore say that during inspiration the ribs move upwards and laterally between their fixed ends, while as a whole the rib rotates, and its anterior end is thrust slightly forwards.

During expiration these movements are simply reversed.

THE ARTICULATIONS OF THE SUPERIOR EXTREMITY.

The bony arch formed by the clavicle and scapula articulates directly with the axial skeleton only at one point, viz., the sterno-clavicular joint.

ARTICULATIONS OF THE CLAVICLE.

Articulatio Sternoclavicularis.

The **sterno-clavicular joint** is an example of an arthrodial diarthrosis. The articular surfaces concerned in its formation present the following appearances:—

1. The sternal end of the clavicle is somewhat triangular in outline, having its most prominent angle directed downwards and backwards. The anterior and

posterior sides of the triangle are slightly roughened for the attachment of ligaments, while the base or inferior side is smooth and rounded, owing to the prolongation of the articular surface to the inferior aspect of the bone. In the antero-posterior direction the articular surface tends to be concave, while vertically it is slightly convex.

2. An articular facet, situated on the superior lateral angle of the manubrium sterni, but in a plane slightly behind the supra-sternal notch, articulates with the clavicle. This facet is considerably smaller than the clavicular facet with which it articulates.

3. The superior surface of the first costal cartilage close to the sternum also participates to a small extent in the articulation.

It should be noted that the articular surfaces of the clavicle and sternum are covered mainly by **fibro-cartilage.**

A **capsula articularis** is well marked on all sides except inferiorly, where it is very thin. The epiphyseal line of the clavicle is intra-capsular.

Lig. Sternoclaviculare Anterius. — The **anterior sterno-clavicular ligament** (Fig. 273) forms part of the fibrous stratum of the articular capsule, and consists of short fibres which extend obliquely downwards and medially from the anterior aspect of the sternal end of the clavicle to the adjoining anterior surface of the sternum and the anterior border of the first costal cartilage.

Lig. Sternoclaviculare Posterius. — The **posterior sterno-clavicular ligament** also forms part of the fibrous stratum of the capsule. Its fibres are not so strong as those of the anterior ligament, but they are similarly disposed on the posterior aspect of the articulation.

Discus Articularis.—A fibro-cartilaginous **articular disc** (Fig. 273) divides the joint cavity into two compartments. It is nearly circular in shape, and adapts itself to the articular surfaces between which it lies. It is thickest at the circumference and thinnest at the centre, where it occasionally presents a perforation, thereby permitting the two synovial cavities to inter-communicate. By its circumference it is in contact with, and adherent to, the surrounding capsule, but its superior margin is attached to the apex of the articular surface of the clavicle, while by its inferior margin it is fixed to the sternal end of the first costal cartilage.

Two **accessory ligaments** are associated with this joint, viz., the interclavicular and the costo-clavicular.

Lig. Interclaviculare.—The **interclavicular ligament** (Fig. 273) is a structure of considerable strength, forming a broad band of fibrous tissue which is attached to the superior rounded angle or apex of the sternal end of the clavicle as well as to the adjacent margins of the articular surface. Its fibres pass across the interclavicular notch to become attached to corresponding parts of the opposite clavicle, but in their course they dip down into the supra-sternal notch, in which many of them are fixed to the sternum. In this way their presence neither bridges nor obliterates the notch between the two clavicles, and the ligament really becomes a superior sterno-clavicular ligament for each joint.

Lig. Costoclaviculare.—The **costo-clavicular ligament** (Fig. 273) consists of short, strong fibres which are attached inferiorly to the superior surface of the first costal cartilage. They pass obliquely upwards, laterally and backwards, to a rough impression situated on the inferior aspect of the sternal end of the clavicle, and are distinct from the articular capsule. Occasionally a bursa is found in the interior of this ligament.

As a rule there is a **synovial stratum** lining each of the two joint cavities (Fig. 273), separated from each other by the articular disc. Sometimes, however, the two membranes establish continuity through a perforation in the disc.

Articulatio Acromioclavicularis.

The **acromio-clavicular joint** is another instance of an arthrodial diarthrosis. It is situated between the acromial end of the clavicle and the medial aspect of the acromion. Each articular surface is an oval flattened facet, covered with **fibro-cartilage.**

The **ligaments** which surround this small joint form a complete articular capsule, of which the superior and inferior parts are specially strong, and are therefore named the **superior** and **inferior acromio-clavicular ligaments** (Fig. 275). These consist of short fibres passing between the adjacent rough margins of the two bones in the positions indicated by their names.

An **articular disc**, which is nearly always incomplete, and may occasionally be wanting, is usually found within the joint cavity, where it lies obliquely, with its superior margin farther from the median plane than its inferior margin, and having its borders attached to the surrounding capsule. Frequently the disc is wedge-shaped, with its base directed upwards and its apex free.

A **synovial stratum** is found forming either a single or a double sac, according to the condition of the disc. Complete division of the joint cavity, however, is rare.

Ligamentum Coracoclaviculare.—Accessory to this articulation there is the strong **coraco-clavicular ligament** which binds the acromial end of the clavicle to the coracoid process of the scapula. It is readily divisible into two parts, viz., lig. conoideum and the lig. trapezoideum.

The **conoid ligament** (Fig. 275) is situated medial to and slightly posterior to the trapezoid. It is narrow and pointed at its inferior end, by which it is attached to the superior aspect of the coracoid process, in close proximity to the scapular notch. Its superior end widens out in the manner expressed by its name, and is attached to the coracoid tuberosity of the clavicle.

The **trapezoid ligament** (Fig. 275) is attached inferiorly to the superior surface of the posterior half of the coracoid process, lateral and anterior to the attachment of the conoid ligament. Superiorly it is attached to the ridge on the inferior surface of the acromial end of the clavicle. Its lateral and medial borders are free. Its anterior surface is principally directed upwards, and its posterior surface, to a similar extent, looks downwards.

A **mucous** or **synovial bursa** usually occupies the re-entrant angle between these two ligaments.

Movements at the Clavicular Joints.—The movements of the medial end of the clavicle at the **sterno-clavicular joint** are limited in their range, owing to the tension of the ligaments. When the shoulder is raised or depressed the acromial end of the clavicle moves upwards and downwards, whilst its sternal end glides upon the surface of the articular disc; when, on the other hand, the shoulder is carried forwards or backwards, the sternal end of the clavicle along with the articular disc moves upon the sternal facet. In addition to these movements of elevation, depression, forward movement and backward movement of the clavicle, there is also allowed at the sterno-clavicular joint a certain amount of circumduction of the clavicle.

The part which is played by certain of the ligaments in restraining movement requires careful consideration. The **costo-clavicular ligament** checks excessive elevation of the clavicle, and restrains within certain limits both backward and forward movement of the clavicle. When the clavicle is depressed, as in cases where a heavy weight, such as a bucket of water, is carried in the hand, it receives support by resting upon the first rib, and the tendency for the medial end of the bone to start up out of its sternal socket is obviated by the tension of the **articular disc**, the **interclavicular ligament**, and the **anterior** and **posterior sterno-clavicular ligaments.**

The **articular disc** not only acts as a cushion which lessens the shock of blows received upon the shoulder, but it also acts as a most important bond of union, and prevents the medial end of the clavicle from being driven upwards upon the top of the sternum when force is applied to its lateral end.

The movements at the **acromio-clavicular joint** are of such a kind as to allow the inferior angle, and to some extent the vertebral border of the scapula, to remain more or less closely applied to the chest-wall during the various movements of the shoulder. The strong connexion between the coracoid process and the acromial end of the clavicle, by means of the conoid and trapezoid ligaments, renders it necessary that the scapula should follow the clavicle in its various excursions. The presence of the acromio-clavicular joint, however, enables the scapula to change its position somewhat with reference to the clavicle as the shoulder is moved. Thus, when the shoulder is raised and depressed, a marked difference takes place in the angle between the two bones; again, when the shoulder is thrown forwards or backwards, these movements can be performed without altering in a material degree the direction of the glenoid cavity of the scapula, or in other words, the socket of the shoulder-joint.

The **conoid** and **trapezoid ligaments** set a limit upon the movements of the scapula at the acromio-clavicular joint. They both, but more particularly the trapezoid ligament, prevent the acromion from being carried medially below the lateral end of the clavicle when blows fall upon the lateral aspect of the shoulder.

Ligaments of the Scapula.

These ligaments are not directly connected with any articulation.

Lig. Coracoacromiale.—The **coraco-acromial ligament** (Fig. 274) completes the arch between the coracoid process and the acromion, and thus provides a secondary socket for the greater protection and security of the shoulder-joint. It is a flat triangular structure stretched tightly between its attachments. By its base it is fixed to a varying amount of the postero-lateral border of the coracoid process, and by its narrower apical end to the tip of the acromion, immediately lateral to the acromio-clavicular joint. Its surfaces look upwards and downwards, and its free borders laterally and medially. It is thinnest in the centre, where it is sometimes perforated by a prolongation of the tendon of the pectoralis minor muscle.

Lig. Transversum Scapulæ Superius.—The **superior transverse scapular ligament** is a distinct but short band which bridges the scapular notch. It may be continuous with the conoid ligament, and it is frequently ossified. As a rule the foramen completed by this ligament transmits the suprascapular nerve, while the transverse scapular vessels pass superior to the ligament to reach the supraspinous fossa.

A small duplicate of this ligament may often be found bridging the foramen on its costal aspect, subjacent to which small branches of the transverse scapular artery return from the supraspinous to the subscapular fossa.

Lig. Transversum Scapulæ Inferius.—The **inferior transverse scapular ligament** consists of another set of bridging fibres which are situated on the posterior aspect of the neck of the scapula. By one end they are attached to the lateral border of the scapular spine, and by the other to the adjacent part of the posterior aspect of the head of the scapula. The suprascapular nerve and the transverse scapular vessels pass subjacent to this ligament.

ARTICULATIO HUMERI.

The **shoulder-joint** is one of the largest as well as the most important of the joints of the upper limb. It is an example of the enarthrodial, *i.e.* ball-and-socket, variety of a diarthrosis, and, at the cost of a certain amount of security, it has obtained an extended range of movement.

The bones which enter into its formation are the glenoid cavity of the scapula and the head of the humerus.

The glenoid cavity is a shallow piriform articular surface, having its narrow end directed upwards and slightly forwards. The superior half of the anterior margin of the fossa is characterised by a shallow notch which accommodates the narrow part of the subscapularis muscle as it runs laterally to its insertion. At the apex of the cavity there is a flat area for the attachment of the long tendon of the biceps brachii muscle. The head of the humerus is hemispherical and articular, while, lateral to its articular margin, there is a slight constriction (the anatomical neck of the humerus), which is most strongly marked in relation to the greater and lesser tubercles of the humerus.

Under ordinary conditions the two articular surfaces are maintained in apposition by muscular action, aided by atmospheric pressure, and thus, when the muscles are removed, the bones fall asunder to the full extent of the restraining ligaments. Only a small part of the head of the humerus is in contact with the glenoid cavity at any particular moment, because the humeral head is much larger than the cavity, but, by reason of the shallow character of the cavity, all parts of the two articular surfaces may successively be brought into contact with each other.

In the position of rest, as the limb hangs parallel to the vertical axis of the trunk, the inferior aspect of the neck of the humerus is brought into close relation with the inferior part of the glenoid cavity.

Labrum Glenoidale.—The **labrum glenoidale** (Fig. 275) deepens the glenoid cavity, and thus extends the articular surface. It is situated within the fibrous stratum of the articular capsule, and to some slight extent increases the security of the articulation. It consists of a strong ring of dense fibrous tissue attached to the

margin of the glenoid cavity. Many of its fibres are short, and pass obliquely from the inner to the outer aspect of the ridge, so that its attached base is broader than its free edge, and therefore in cross section it appears somewhat triangular. The long tendon of the biceps, which arises from the apex of the glenoid cavity, becomes to a considerable extent incorporated with the labrum glenoidale.

Capsula Articularis.—The **fibrous stratum** (Fig. 274) of the **articular capsule** presents the general shape which is characteristic of the corresponding part in other ball-and-socket joints, viz., a hollow cylinder. By its proximal end the fibrous stratum is attached to the circumference of the glenoid cavity, external to the labrum glenoidale, and also, to a considerable extent, to the labrum glenoidale itself.

By its distal end it is attached to the neck of the humerus, and therefore beyond the articular area of the head. The fibrous stratum is strongest on its superior aspect, while inferiorly, where the neck of the bone is least defined, it

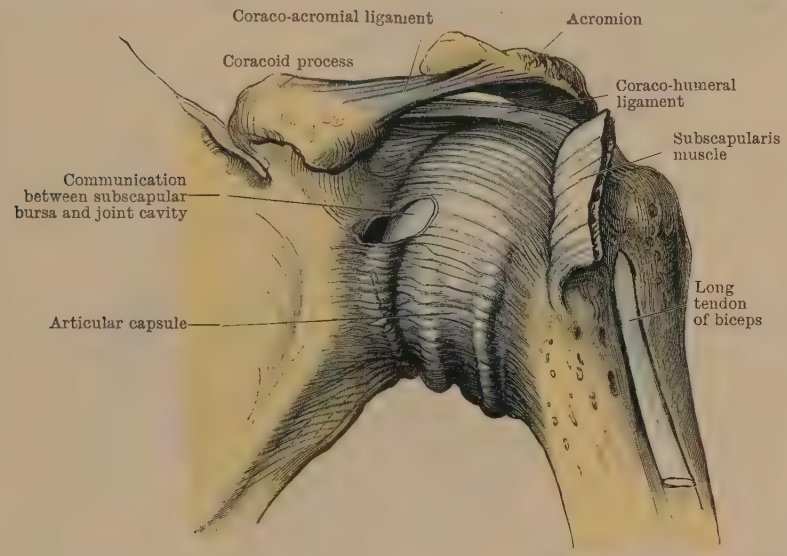

FIG. 274.—CAPSULE OF THE SHOULDER-JOINT AND CORACO-ACROMIAL LIGAMENT.

extends distally for a short distance upon the humeral shaft. Its fibres for the most part run longitudinally, but a certain number of them pursue a circular direction.

The greater part of the epiphyseal line of the proximal end of the humerus is extra-capsular, but it is intra-capsular on the medial side of the bone.

A prolongation of the fibrous stratum, the **transverse humeral ligament** presenting both longitudinal and transverse fibres, bridges that part of the intertubercular groove which is situated between the tubercles of the humerus. At this point an interruption in the fibrous stratum, beneath the transverse humeral ligament, permits the long tendon of the biceps to escape from its interior. In addition to the opening just referred to, there is another very constant deficiency in the superior and anterior part of the fibrous stratum, where the narrowing tendon of the subscapularis muscle is brought into contact with a bursa formed by a protrusion of the synovial stratum. This defect in the fibrous stratum has its long axis in the direction of the longitudinal fibres. Occasionally there is a similar but smaller opening under cover of the tendon of the infraspinatus muscle. Through the two latter openings the joint cavity communicates with bursæ situated between the capsule and the muscles referred to.

The tendons of the subscapularis, supraspinatus, and infraspinatus muscles fuse with, and so strengthen, the articular capsule as they approach their respective insertions.

On the superior aspect of the articulation the capsule is augmented by an

accessory structure, the **ligamentum coracohumerale** (Fig. 274). By its proximal end, which is situated immediately above the glenoid cavity, but subjacent to the coraco-acromial ligament, it is attached to the lateral border of the root of the coracoid process, while its distal end is attached to the humeral neck close to the greater tubercle. This ligament forms a flattened band, having its posterior and inferior border fused with the articular capsule, but its anterior and superior margin presents a free edge, slightly raised above the level of the capsule. This structure is believed to represent that portion of the pectoralis minor to which reference has already been made in connexion with the coraco-acromial ligament (p. 322).

The **coraco-glenoid ligament** is another accessory structure, which is not always present. It springs from the coracoid process along with the former ligament, and extends to the superior and posterior margin of the head of the scapula.

Gleno-humeral Ligaments (Fig. 275).—If the articular capsule is opened from behind, and the head of the humerus removed, it will be seen that the longitudinal fibres of the anterior part of the fibrous stratum are specially developed in the form of thick flattened bands which extend from the anterior border of the glenoid cavity to the anterior aspect of the neck of the humerus. These gleno-humeral ligaments are three in number, and occupy the following positions: the

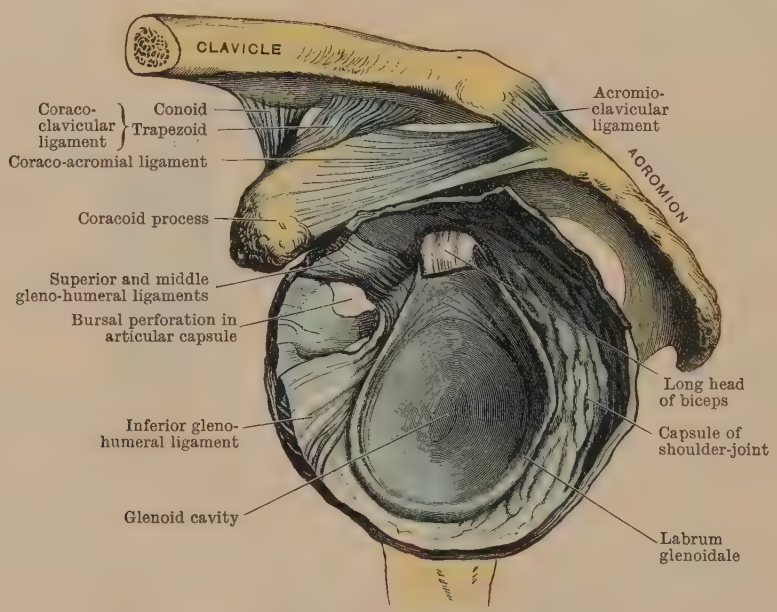

FIG. 275.—CAPSULAR LIGAMENT OF SHOULDER-JOINT CUT ACROSS AND HUMERUS REMOVED.

superior is placed *above* the aperture in the front of the capsule; the **middle** and **inferior** on the antero-inferior aspect of the capsule, and *below* the aperture mentioned.

The superior gleno-humeral ligament, which some believe to represent the ligamentum teres of the hip-joint, springs, along with the middle gleno-humeral band, from the superior part of the cavity. The inferior ligament is the strongest of the three, and springs from the inferior part of the anterior margin of the glenoid.

Intra-capsular Structures.—1. The labrum glenoidale, already described. 2. The long tendon of the biceps passes laterally from its attachment to the apex of the glenoid cavity and the adjoining part of the labrum glenoidale, above the head and neck of the humerus, to escape from the interior of the capsule by the opening between the tubercles of the humerus, subjacent to the transverse humeral ligament.

A **synovial stratum** (Fig. 276) lines the fibrous stratum of the capsule, and extends from the margin of the glenoid cavity to the humeral attachments of the fibrous stratum, where it is reflected towards the margin of the articular cartilage. It is therefore important to note that the inferior aspect of the humeral neck has the most extensive clothing of the synovial stratum. Further, the synovial stratum envelops the intra-capsular part of the tendon of the biceps, and although this tubular sheath is prolonged upon the tendon into the proximal part of the

intertubercular sulcus, yet the closed character of the synovial cavity is maintained. Thus, while the tendon is within the capsule, it is not within the synovial cavity. The synovial stratum is continuous with those bursæ which communicate with the joint cavity through openings in the fibrous stratum of the capsule.

Bursæ (*a*) *Communicating with the Joint Cavity.*—Practically there is only one bursa which is constant in its position, viz., the **subscapular**, between the capsule and the tendon of the subscapularis muscle. It varies considerably in its dimensions, but its lining membrane is always continuous with the synovial stratum of the capsule (Figs. 275 and 276), and therefore it may be regarded merely as a prolongation of the articular synovial stratum. Occasionally a similar but smaller bursa occurs between the capsule and the tendon of the infraspinatus muscle.

(*b*) *Not communicating with the Joint Cavity.*—The **subdeltoid** or **sub-acromial bursa** is situated between the muscles on the superior aspect of the shoulder-joint on the one hand and the deltoid muscle on the other. It is an extensive bursa, and is prolonged subjacent to the acromion and the coraco-acromial ligament. It does not communicate with the shoulder-joint, but it greatly facilitates the movements of the proximal end of the humerus against the inferior surface of the coraco-acromial arch.

FIG. 276.—VERTICAL SECTION THROUGH THE SHOULDER-JOINT.

Movements at the Shoulder-Joint.—A ball-and-socket joint permits of a great variety of movements, practically in all directions; but if these movements are analysed, it will be seen that they resolve themselves into movements around **three** primary axes at right angles to each other, or around axes which are the possible combinations of the primary ones.

Thus, around a transverse axis, the limb may move forwards **(flexion)** or backwards **(extension)**. Around an antero-posterior axis it may move laterally, *i.e.* away from the median plane of the trunk **(abduction)**, or medially, *i.e.* towards, and to some extent up to, the median plane **(adduction)**.

Around a vertical axis, the humerus may **rotate** upon its axis in a medial or lateral direction to the extent of a quarter of a circle.

Since these axes all pass through the shoulder-joint, and since each may present varying degrees of obliquity, it follows that very elaborate combinations are possible until the movement of **circumduction** is evolved. In this movement the head of the humerus acts as the apex of a **cone of movement** with the distal end of the humerus, describing the base of the cone.

The range of the shoulder-joint movements is still further increased owing to the mobility of the scapula as a whole, and owing to its association with the movements of the clavicle already described.

ARTICULATIO CUBITI.

The **elbow-joint**[1] provides an instance of a diarthrosis capable of performing the movements of flexion and extension around a single axis placed transversely, *i.e.*, a typical ginglymus diarthrosis or hinge-joint.

The bones which enter into its formation are the humerus, ulna, and radius. The trochlea of the humerus articulates with the semilunar notch of the ulna **(articulatio humeroulnaris)**; the capitulum of the humerus articulates with the shallow depression or cup on the proximal aspect of the head of the radius **(articulatio humeroradialis)**. The articular cartilage clothing the trochlea of the humerus terminates in a sinuous or concave margin both anteriorly and posteriorly, so that it does not line either the coronoid or the olecranon fossa. Medially, it merely rounds off the medial margin of the trochlea, but laterally it is continuous with the encrust-

[1] The articulatio cubiti or elbow-joint includes the humero-radial, humero-ulnar, and the proximal radio-ulnar joints; but, for convenience, the description given here is limited to the humero-radial and humero-ulnar joints.

ing cartilage covering the capitulum, to the margin of which the cartilage extends in all directions, and thus it presents a convex edge in relation to the radial fossa. The cartilage which lines the semilunar notch of the ulna presents a transverse interruption, considerably wider on its medial as compared with its lateral aspect. Thereby the coronoid and olecranon segments of the notch are separated from each other. The cartilage which clothes the coronoid segment is continuous with that which clothes the radial notch of the ulna. The shallow cup-shaped depression on the head of the radius is covered with cartilage which rounds off the margin, and is prolonged without interruption upon the vertical aspect of the head, extending to its most distal level on that part opposed to the radial notch of the ulna.

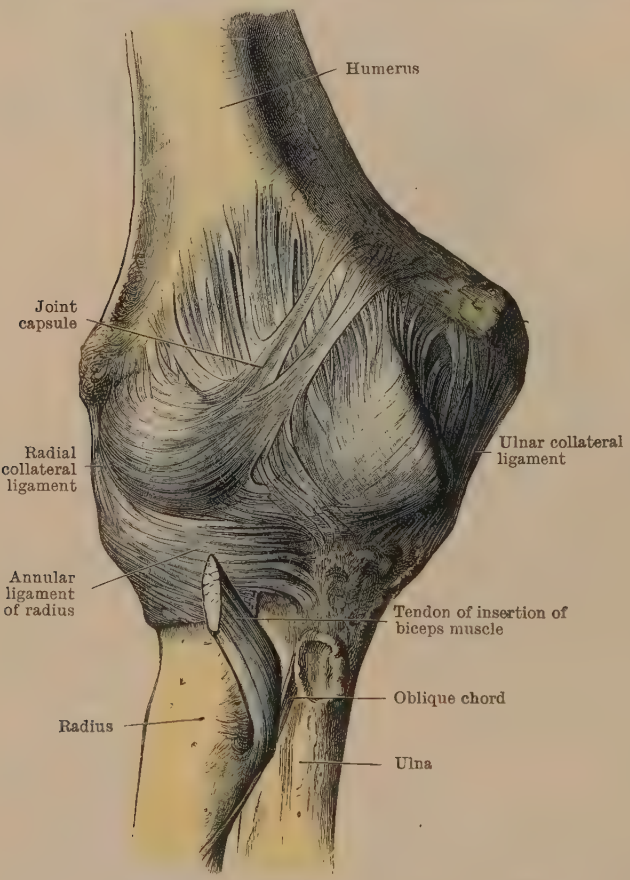

FIG. 277.—ANTERIOR VIEW OF ELBOW-JOINT.

Capsula Articularis.—Taken as a whole, the ligaments form a complete **fibrous stratum** of the **articular capsule**, which is not defective at any point, although it is not of equal thickness throughout, and certain bands of fibres stand out distinctly because of their greater strength.

The common epiphyseal line for the trochlea, capitulum, and the lateral epicondyle of the humerus, is partly intra-capsular and partly extra-capsular; that for the medial epicondyle is extra-capsular. The epiphyseal line of the olecranon may be intra-capsular anteriorly, or it may be altogether extra-capsular.

Lig. Anterius.—The **anterior ligament** (Fig. 277) consists of a layer whose fibres run in several directions—obliquely, transversely, and longitudinally—and of these the vertical fibres are of most importance. It is attached proximally to the proximal margins of the coronoid and radial fossæ; distally, to the margins of the coronoid process and to the annular ligament of the proximal radio-ulnar joint, but some loosely arranged fibres reach as far as the neck of the radius. The marginal portions of this ligament, which are situated in front of the capitulum and the medial margin of the trochlea respectively, are much thinner and weaker than the central part. Fibres of origin of the brachialis muscle are attached to the front of this ligament.

Lig. Posterius.—The **posterior ligament** is an extremely thin, almost redundant layer. Proximally it is attached, in relation to the margin of the olecranon fossa, at a varying distance from the trochlear articular surface, and distally to the summit and sides of the lip of the olecranon. Laterally some of its fibres pass from the posterior aspect of the capitulum to the posterior border of the radial notch of the ulna. This ligament derives material support from, and participates in the movements of, the triceps brachii muscle, since they are closely adherent to each other in the region of the olecranon.

Lig. Collaterale Ulnare.—The **ulnar collateral ligament** (Figs. 277 and 278)

is a fan-shaped structure of unequal thickness, but its margins, which are its strongest bands, are continuous with the adjoining parts of the anterior and posterior ligaments. By its proximal end it is attached to the anterior, distal, and posterior aspects of the medial epicondyle of the humerus. By its broad distal end it is attached to the medial margin of the semilunar notch, so that the *anterior band* is associated principally with the medial margin of the coronoid process, and the *posterior band* with the medial margin of the olecranon, while the intermediate weaker portion sends its fibres downwards to join a *transverse band*, sometimes very strong, which bridges the notch between the adjoining medial margins of the coronoid process and the olecranon.

Lig. Collaterale Radiale.—The **radial collateral ligament** (Fig. 277) is a strong flattened band attached proximally to the distal and posterior aspects of the lateral

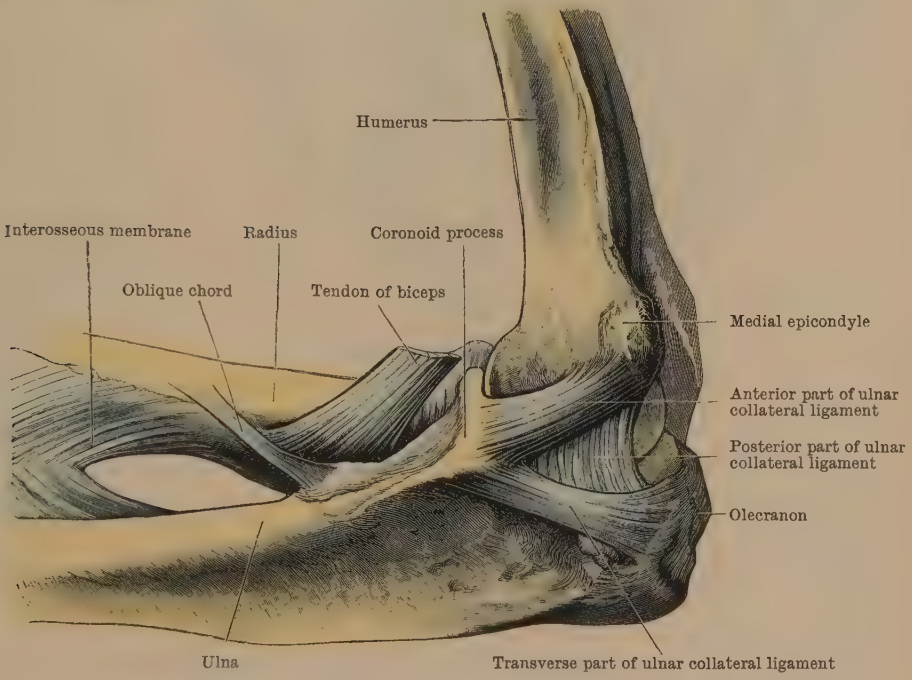

FIG. 278.—ELBOW-JOINT (Medial Aspect).

epicondyle of the humerus. It completes the continuity of the articular capsule on the lateral side, and blends distally with the lig. annulare radii, on the surface of which its fibres may be traced both to the anterior and posterior ends of the radial notch of the ulna. Both of the collateral ligaments are intimately associated with the muscles which take origin from the corresponding medial and lateral epicondyles of the humerus.

Synovial Pads of Fat (Fig. 279).—Internal to the fibrous stratum of the articular capsule, there are several pads of fat situated between it and the synovial stratum. Small pads are so placed as to lie immediately in front of the coronoid and radial fossæ, but a larger one projects towards the olecranon fossa.

A **stratum synoviale** (Fig. 279) lines the entire fibrous stratum and clothes the pads of fat referred to above, as well as those portions of bone enclosed within the capsule which are not covered by articular cartilage. By its disposition the elbow and the proximal radio-ulnar joints possess a common joint cavity. It should be specially noted that the proximal part of the neck of the radius is surrounded by this synovial layer.

Movements at the Elbow-Joint.—The movements of the radius and ulna upon the humerus have already been referred to as those characterising a uniaxial joint constructed on the plan of a hinge. In this case the axis of the joint is obliquely transverse, so that in the extended position the humerus and ulna form an obtuse angle open towards the radius, whereas in the

flexed position the hand is carried medially in the direction of the mouth. Extreme flexion is checked by the soft parts in front of the arm and of the forearm coming into contact, and extreme extension by the restraining effect of the ligaments and muscles. In each case the movement is checked before either the coronoid process or the olecranon comes into contact with the humerus. The anterior and posterior bands of the ulnar collateral ligament are important factors in these results. Lateral movement of the ulna is not a characteristic movement, although it may occur to a slight extent, owing to a want of complete adaptation between the trochlear surface of the humerus and the semilunar notch of the ulna. This incongruence is noteworthy since the medial lip of the trochlea is prominent in front, and the lateral lip is prominent behind. Consequently, this latter part is associated with a surface on the lateral side of the olecranon which is only utilised in complete extension.

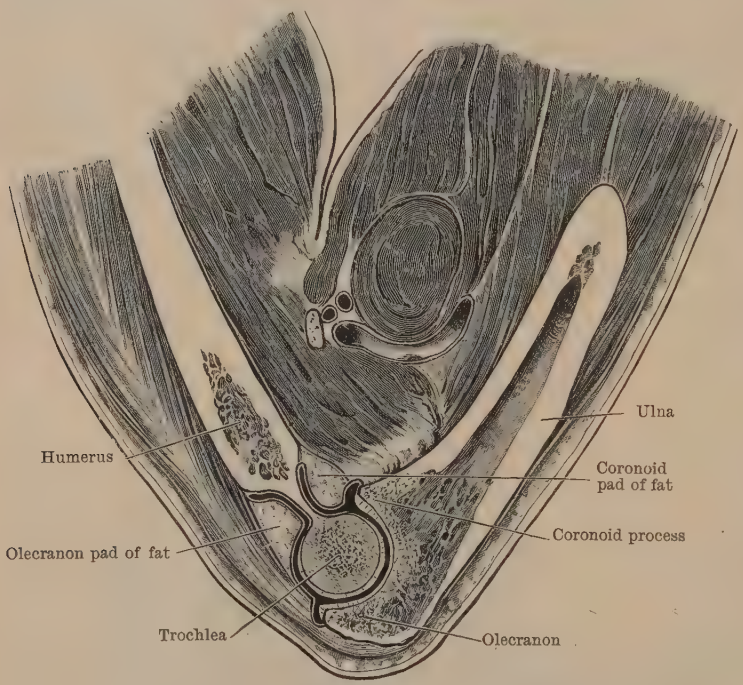

FIG. 279.—VERTICAL SECTION THROUGH THE HUMERO-ULNAR PART OF THE ELBOW-JOINT.

The capitulum and the opposing surface upon the head of the radius are always in varying degrees of contact. The head of the radius participates in the movements of flexion and extension, and is most closely and completely in contact with the humerus during the position of semi-flexion and semi-pronation. In complete extension a very considerable part of the capitulum is uncovered by the radius.

THE RADIO-ULNAR JOINTS.

These articulations, which are two in number, are situated at the proximal and distal ends of the radius and ulna. They provide an adaptation whereby the radius rotates around a longitudinal axis in the movements of pronation and supination, and hence this form of uniaxial diarthrosis is termed **lateral ginglymus.**

Articulatio Radioulnaris Proximalis.—The **proximal radio-ulnar joint** forms a part of the elbow-joint. The articular surfaces which enter into its formation are the radial notch of the ulna and the articular margin of the head of the radius. In each case the articular cartilage is continuous with an articular surface entering into the formation of the humero-radial and humero-ulnar joints, consequently the joint cavity is continuous with the cavities of those joints, and therefore, in a sense, it lies within the cover of the articular capsule of the elbow-joint; but its special feature is the annular ligament of the radius.

Lig. Annulare Radii.—The **annular ligament of the radius** (Figs. 277 and 280) has been mentioned above as the distal line of attachment of the radial collateral ligament and parts of the anterior and posterior ligaments of the elbow-joint.

It is a strong, well-defined structure, attached by its extremities to the volar and dorsal margins of the radial notch of the ulna, and thus it forms nearly four-fifths of an osseo-tendinous circle or ring. The circle is somewhat wider at the proximal than at the distal margin of the annular ligament of the radius, which, by encircling the proximal part of the neck of the radius, tends to prevent

displacement of the head of that bone in a distal direction. The distal margin of this ligament is not directly attached to the radius.

The **synovial stratum** is continuous with that which lines the elbow-joint. It closes the joint cavity at the distal unattached margin of the annular ligament, where it is somewhat loosely arranged in its reflexion from the ligament to the neck of the radius. The epiphyseal line at the proximal end of the radius is intra-capsular.

Articulatio Radioulnaris Distalis. — The **distal radio-ulnar joint** is situated between the lateral aspect of the head of the ulna and the ulnar notch on the medial side of the distal end of the radius. In addition, it includes the distal surface of the head of the ulna, which articulates with the proximal surface of a triangular articular disc by means of which the joint is excluded from the radio-carpal articulation.

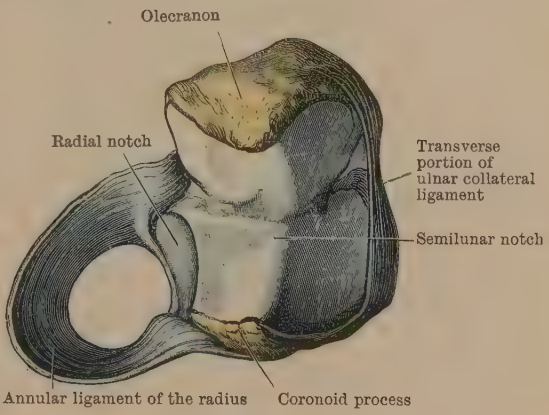

FIG. 280.—ANNULAR LIGAMENT OF THE RADIUS.

Discus Articularis.—The **triangular articular disc** (Figs. 281 and 282), besides presenting articular surfaces to two separate joints, is an important ligament concerned in binding together the distal ends of the radius and ulna. It is attached by its apex to the depression at the lateral side of the root of the styloid process of the ulna, and by its base to the sharp line of demarcation between the ulnar notch and the carpal articular surface of the radius.

Capsula Articularis.—The **fibrous stratum** is very imperfect, and consists of scattered fibres, termed the **anterior** and **posterior radio-ulnar ligaments** (Fig. 282). These ligaments pass transversely between adjoining non-articular surfaces on the radius and ulna, and are of sufficient length to permit of the movements of the radius in pronation and supination.

The **synovial stratum** completes the closure of the joint cavity. It forms a loose bulging projection (**recessus sacciformis**), passing proximally between the distal ends of the shafts of the radius and ulna, and it also clothes the proximal surface of the articular disc (Fig. 281). The cavity of this joint is quite distinct from that of the radio-carpal articulation, except when the articular disc presents a perforation.

Between the proximal and distal radio-ulnar articulations there are two **accessory ligaments**, viz., the chorda obliqua and the interosseous membrane, which connect together the shafts of the radius and ulna.

Chorda Obliqua.—The **oblique chord** (Fig. 277) is a slender fibrous band of very varying strength which springs from the tuberosity of the ulna, and stretches obliquely, distally, and laterally, to the radius where it is attached immediately distal to the tuberosity of the radius.

Membrana Interossea Antibrachii.—The **interosseous membrane of the forearm** (Fig. 278) is a strong fibrous membrane which stretches across the interval between the radius and ulna, and is firmly attached to the interosseous crest of each. Distally it extends to the distal limit of the space between the bones, whilst proximally it only reaches a point about one inch distal to the tuberosity of the radius. A gap, called the *hiatus interosseus*, is thus left between its proximal margin and the chorda obliqua, and through this the dorsal interosseous artery passes back-

FIG. 281.—CARPAL ARTICULAR SURFACE OF THE RADIUS, AND ARTICULAR DISC OF THE WRIST.

wards between the bones to reach the dorsal aspect of the forearm. The fibres which compose the interosseous membrane run for the most part distally and medially from the radius to the ulna, although on its dorsal aspect several bands may be observed stretching in an opposite direction. The interosseous membrane augments the surface available for the origin of the muscles of the forearm; it braces the radius and ulna together; and when shocks are communicated from the hand to the radius, owing to the direction of its fibres, the interosseous membrane transmits them, to a large extent, to the ulna.

Movements of the Radius on the Ulna.—The axis around which the radius moves is a longitudinal one, having one end passing through the centre of the head of the radius and the other through the styloid process of the ulna and the line of the ring-finger. In this axis the head of the radius is so secured that it can only rotate upon the radial notch of the ulna within the annular ligament of the radius, and consequently the radial head remains upon the same plane as the ulna; but the distal end of the radius being merely restrained by the articular disc, is able to describe nearly a half-circle, of which the apex of this ligament is the centre. In this movement the radius carries the hand from a position in which the palm is directed forwards, and in which the radius and ulna lie parallel to each other **(supination)**, to one in which the palm is directed backwards, and the radius lies diagonally across the front of the ulna **(pronation)**.

The ulna is unable to rotate upon a long axis, but while the radius is travelling through the arc of a circle from lateral to medial side in front of the ulna, it will usually be seen that the ulna appears to move through the arc of a smaller circle in the reverse direction, viz., from medial to lateral side. If the humerus is prevented from moving at the shoulder-joint, a very large proportion, if not the entire amount, of this apparent movement of the ulna will disappear. At the same time some observers maintain that it really occurs at the elbow-joint, associated with lateral movement during slight degrees of flexion and extension at that joint.

ARTICULATIO RADIOCARPEA.

The **radio-carpal joint** is a bi-axial diarthrosis, frequently called a condyloid joint.

The articular elements which enter into its formation are: on its *proximal side*, the carpal surface of the distal end of the radius, together with the distal surface of the discus articularis; on its *distal side*, the proximal articular surfaces of the navicular, lunate, and triquetral bones, and the interosseous ligaments between them. The articular surface of the radius is concave both in its antero-posterior and transverse diameters, in order to adapt itself to the opposing surfaces of the navicular and lunate, which are convex in the two axes named. In the ordinary straight position of the hand the articular disc is in contact with the lunate bone, and the proximal articular surface of the triquetral bone is in contact with the capsule of the joint. When, however, the hand is bent towards the ulna the triquetral bone is carried laterally as well as the lunate and navicular and the articular disc comes into contact with the triquetral. The articular surface of the radius is subdivided by an antero-posterior, slightly elevated ridge, into a lateral triangular facet which usually articulates with the navicular, and a medial quadrilateral facet for articulation with a portion of the lunate bone.

In the intervals between the navicular, lunate, and triquetral bones, the continuity of the distal articular surface is maintained by the presence of interosseous ligaments which are situated upon the same level as the articular cartilage.

Capsula Articularis.—An articular capsule completely surrounds the joint. It is somewhat loosely arranged, and its fibrous stratum permits of subdivision into the following four portions:—

Lig. Radiocarpeum Laterale.—The **lateral radio-carpal ligament** (Fig. 282) is a well-defined band which is attached by one end to the tip of the styloid process of the radius, and by the other to a rough area at the base of the tuberosity of the navicular bone, *i.e.* lateral to its radial articular surface.

Lig. Ulnocarpeum Mediale.—The **medial ulno-carpal ligament** (Fig. 282) is also a distinct rounded structure, having one end attached to the tip of the styloid process of the ulna, and the other to the rough non-articular border of the triquetral bone, some of its fibres being prolonged to the pisiform bone.

Lig. Radiocarpeum Volare.—The **volar radio-carpal ligament** (Fig. 282) is attached proximally to the volar margin of the distal end of the radius, as well

as slightly to the base of the styloid process of the ulna. Some transverse fibres may be seen, but the greater number pass obliquely, distally, and medially, to the volar non-articular surfaces of the navicular, lunate, and triquetral bones, while some of them may even be continued as far as the capitate bone. Those fibres from the ulna run obliquely laterally. On its deeper aspect this ligament is closely adherent to the volar border of the articular disc of the distal radio-ulnar articulation.

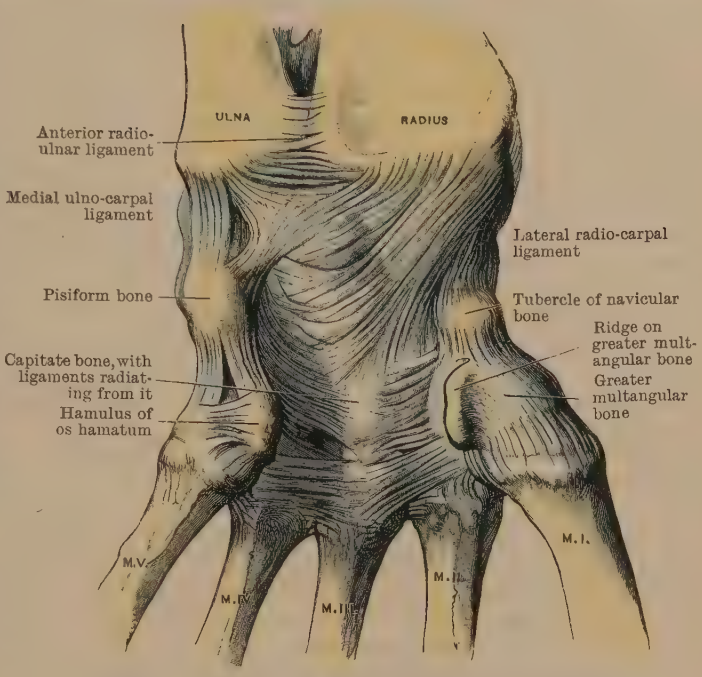

FIG. 282.—LIGAMENTS ON VOLAR ASPECT OF RADIO-CARPAL, CARPAL, AND CARPO-METACARPAL JOINTS.

Lig. Radiocarpeum Dorsale.—The **dorsal radio-carpal ligament** extends from the dorsal margin of the distal end of the radius, in an oblique direction distally and medially, to the dorsal non-articular areas on the proximal row of the carpal bones. The medial portion assists in forming the fibrous sheath through which the tendon of the extensor carpi ulnaris muscle travels to its insertion. The principal bundle of fibres is connected with the triquetral bone.

The **stratum synoviale** (Fig. 283) is simple, and is confined to the articulation, except in those cases in which the articular disc is perforated, or in which one of the interosseous ligaments between the carpal bones of the first row is absent. The epiphyseal lines at the distal ends of radius and ulna are extra-capsular.

Movements at the Radio-carpal Joint.—The radio-carpal joint affords an excellent example of a bi-axial articulation, in which a long transverse axis of movement is situated more or less at right angles to a short axis placed in the antero-posterior direction. The nature of the movements which are possible around these two axes is essentially the same in both cases, viz., **flexion** and **extension**. The movements around the longer transverse axis are anterior or volar flexion, extension, and its continuation into dorsi-flexion. Around the shorter antero-posterior axis we get movements which result from combined action by certain flexor and extensor muscles, whereby the radial or ulnar borders of the hand may be approximated towards the corresponding borders of the forearm. Lateral movement also may be possible to a slight extent. The range of movement in connexion with either of the principal axes is largely a matter of individual peculiarity, for, with the exception of the lateral ligaments, there is no serious obstacle to the cultivation of greater mobility at the radio-carpal joint.

ARTICULATIONES INTERCARPEÆ.

Carpal Joints.—The articulations subsisting between the individual carpal bones are all diarthroses, and although the total amount of movement throughout the series is considerable, yet the extent of movement which is possible between the two rows or between any two carpal bones is extremely limited. For this reason, as well as because of the nature of the movement, these articulations are called gliding joints (arthrodia).

It is advisable to consider, *first*, the articulations between individual bones of the proximal row; *second*, the articulations between the separate bones of the distal row; *third*, the articulation of the proximal and distal rows with each other; *fourth*, the pisiform articulation.

The **proximal row of carpal articulations** (Fig. 283) comprises the joints between the navicular, lunate, and triquetral bones. On their adjacent aspects these bones are partly articular and partly non-articular.

Three sets of simple but strong, although short, ligamentous bands bind these three carpal bones together, and form an investment for three sides of their intercarpal joints. These are—(1) the **ligamenta intercarpea volaria** (**anterior** or **volar ligaments**), two in number, which consist of transverse fibres passing between the adjacent rough volar surfaces of the bones; (2) the **ligamenta intercarpea dorsalia** (**posterior** or **dorsal ligaments**), also two in number, and composed of similar short transverse fibres passing between the adjacent dorsal surfaces; (3) the **ligamenta intercarpea interossea** (**interosseous ligaments**) (Fig. 283), again two in number, and transverse in direction, situated on a level with the proximal articular surfaces, and extending from the volar to the dorsal aspect of the bones while attached to non-articular areas of the opposing surfaces. The radio-carpal joint is entirely shut off from the intercarpal joints, and also from the joint between the two rows of carpal bones, except in rare cases, when an interosseous ligament is wanting.

The **distal row of carpal articulations** (Fig. 283) includes the joints between the greater multangular, lesser multangular, capitate, and hamate bones. Articular facets occur on the opposing faces of the individual bones.

Associated with this row there are again simple bands of considerable strength, and presenting an arrangement similar to that seen in the proximal row. As in the former case, they invest the intercarpal articulations, except on the proximal and distal aspects, where the distal intercarpal joints communicate respectively with the transverse carpal and carpo-metacarpal joint cavities.

The **ligamenta intercarpea volaria** (**anterior** or **volar ligaments**) are three in number. They extend in a transverse direction between contiguous portions of the rough volar surfaces of the bones. The **ligamenta intercarpea dorsalia** (**posterior** or **dorsal ligaments**), also three in number, are similarly disposed on the dorsal aspect. The **ligamenta intercarpea interossea** (**interosseous ligaments**) (Fig. 283) are two or three in number. That which joins the capitate to the os hamatum is the strongest; that between the lesser multangular and the capitate bone is situated towards the dorsal parts of their opposing surfaces; the third, situated between contiguous non-articular surfaces of the greater and lesser multangular bones, is always the feeblest, and is frequently absent.

The **transverse carpal articulation** (Fig. 283) is situated between the proximal and distal rows of the carpus. The bones of the proximal row present the following characters on their distal aspect. The lateral part of the articular surface is strongly convex, both in the antero-posterior and in the transverse directions, but the medial part of the same surface is concavo-convex, more especially in the transverse direction.

Proximally, the articular surfaces of the distal row of carpal bones present an irregular outline. That part pertaining to the greater and lesser multangular bones is concave in the antero-posterior and transverse directions, and lies at a considerably more distal level than the portion belonging to the capitate and os hamatum, which is, moreover, markedly convex in the antero-posterior and transverse directions, with the exception of the most medial part of the os hamatum, where it is concavo-convex in both of these directions.

This articulation is invested by a complete short **articular capsule** (Fig. 283) which binds the two rows of the carpus together, and sends prolongations to the investing capsules of the proximal and distal articulations. The ligament, as a whole, is very strong, and individual bands are not readily defined, although certain special bands may be described. The **lig. carpi radiatum** (**radiate carpal ligament** (**volar ligament**)) radiates from the capitate bone to the navicular, triquetral, and pisiform bones. The interval between the capitate and lunate is occupied by oblique fibres, some of which pass from navicular to triquetral, while these are joined by others, prolonged obliquely, distally, and medially, from the radial end of the anterior radio-carpal ligament. By these different bands the volar aspect of the joint is completely closed.

The **ligamenta intercarpea dorsalia** (**dorsal ligaments**) are more feeble than the volar. They form a thin, loosely arranged stratum, in which the only noteworthy bands are one which joins the navicular to the capitate, and another which joins the triquetral to the os hamatum.

Lig. Collaterale Carpi Radiale.—The **radial collateral carpal ligament** (Fig. 283) extends between contiguous rough areas on the lateral aspects of the navicular and greater multangular bone. By its margins it is continuous both with the volar and dorsal ligaments.

Lig. Collaterale Carpi Ulnare.—The **ulnar collateral carpal ligament** (Fig. 283) is arranged like the former in regard to its margins, and by its ends it is attached to the contiguous rough ulnar surfaces of the triquetral and the os hamatum.

Both of these collateral ligaments are directly continuous with the corresponding collateral ligaments of the radio-carpal joint.

A **lig. interosseum** (**interosseous ligament**) (Fig. 283) is occasionally found within the capsule, extending across the joint cavity between the capitate and the navicular.

Articulatio Ossis Pisiformis.—The **piso-triquetral articulation** is an arthrodial diarthrosis. The mutual articular surfaces of the two bones are flattened and circular, and permit of only a small amount of gliding movement.

The joint is provided with a thin but complete **articular capsule**, the fibrous stratum of which is specially strengthened distally by two strong bands, viz., lig. piso-hamatum and lig. pisometacarpeum (Fig. 282). Both of these bands extend from the distal and medial aspect of the pisiform to adjoining parts of the hook of the os hamatum and base of the fifth metacarpal bone respectively. To a great extent these ligamentous bands may be regarded as extensions of the insertion of the tendon of the flexor carpi ulnaris muscle, which is attached to the proximal part of the pisiform bone. Looked at as ligaments, however, they are specially strong to prevent the displacement of the pisiform bone during contraction of the muscle inserted into it.

The **synovial strata** (**synovial membranes**) (Fig. 283) of the carpal joints are two in number. Of these, one is restricted to the piso-triquetral articulation, and is correspondingly simple, although occasionally the joint cavity may communicate with that of the radio-carpal joint.

The other synovial stratum is associated with the transverse carpal joint which extends transversely between the two rows of carpal bones, with prolongations into the intervals between the adjoining bones of each row, *i.e.* the intercarpal articulations. It is, therefore, an elaborate cavity, which may be still further extended, by the absence of interosseous ligaments, so as to reach the radio-carpal and carpo-metacarpal series of joints. The first condition is rare, but the second is not uncommon, and may result from the absence of the interosseous ligament between the greater and lesser multangular bones, or of that between the lesser multangular and the capitate bones, but it may occur when all the interosseous ligaments are present.

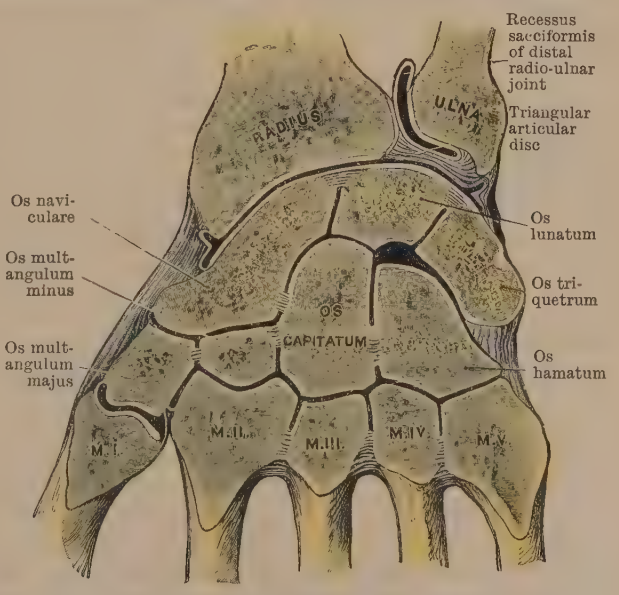

FIG. 283.—FRONTAL SECTION through the radio-carpal, carpal, carpo-metacarpal, and intermetacarpal joints, to show joint cavities and interosseous ligaments (diagrammatic).

ARTICULATIONES INTERMETACARPEÆ.

Intermetacarpal Joints.—The four medial metacarpal bones articulate with each other at their proximal ends or bases, between the opposing surfaces of which joint cavities are found—arthrodial diarthroses. These cavities are continuous with the carpo-metacarpal joint (not yet described), and hence the ligamentous arrangements only enclose three aspects of each joint.

Three strong **transverse ligaments** (Figs. 282 and 283) bind adjacent volar, dorsal, and interosseous areas of the bases of the metacarpal bones, and hence they are called **ligamenta basium** (oss. metacarp.) **volaria, dorsalia et interossea.** A synovial stratum is associated with each of these joints, but it may be regarded as a prolongation from the carpo-metacarpal articulation.

ARTICULATIONES CARPOMETACARPEÆ.

Carpo-metacarpal Joints.—The articulation of the metacarpal bone of the thumb with the greater multangular differs in so many respects from the articulation between the other metacarpal bones and the carpus, that it must be considered separately.

(*A*) The **articulatio carpometacarpea pollicis** (Figs. 282 and 283) is the joint between the disto-lateral surface of the greater multangular and the proximal surface of the base of the first metacarpal bone. Both of these surfaces are saddle-shaped, and they articulate by mutual co-aptation.

The joint cavity is surrounded by an **articular capsule**, in the fibrous stratum of which we may recognise volar, dorsal, lateral, and medial bands, the last being the strongest and most important.

A **synovial stratum** lines the fibrous stratum, and the joint cavity is isolated and quite separate from the other carpal and carpo-metacarpal articulations.

At this joint movements occur around at least three axes. Thus, around a more or less transverse axis, **flexion** and **extension** take place; in an antero-posterior axis **abduction** and **adduction** (movements which have reference to the middle line of the hand) are found; while a certain amount of **rotation** is possible in the longitudinal axis of the digit. The very characteristic movement of **opposition**, in which the tip of the thumb may be applied to the tips of all the fingers, results from a combination of flexion, adduction, and rotation, and by combining all the movements possible at the various axes a considerable degree of **circumduction** may be produced.

(*B*) The **articulationes carpometacarpeæ digitorum** are the joints between the bases of the four medial metacarpal bones and the four bones of the distal row of the carpus. They are all arthrodial diarthroses, and the opposed articular surfaces present alternate elevations and depressions which form a series of interlocking joints. The joint cavities between the carpal bones of the distal row, and also the more extensive intermetacarpal joint cavities, open into this articulation.

This series of joints is invested by a common articular capsule which is weakest on its radial side, but is otherwise well defined. Its fibres arrange themselves in small slips, which pass obliquely in different directions, and vary in number for each metacarpal bone. Thus the **ligamenta carpometacarpea volaria** (**volar carpo-metacarpal ligaments**) (Fig. 282) usually consist of one slip for each metacarpal bone, but there may be two slips, and the third metacarpal bone frequently has three, of which one lies obliquely in front of the tendon of the flexor carpi radialis muscle.

The **ligamenta carpometacarpea dorsalia** (**dorsal carpo-metacarpal ligaments**) are similar short bands, of greater strength and clearer definition, by which the index metacarpal is bound to the greater and lesser multangular bones; the middle metacarpal to the capitate, and frequently to the lesser multangular; the ring metacarpal to the capitate and os hamatum, and the metacarpal of the little finger to the os hamatum.

Ligamenta interossea (interosseous ligaments), one or sometimes two in number, occur within the capsule. They are usually situated in relation to one or both of the contiguous margins of the bases of the third and fourth metacarpal bones, from which they extend proximally to adjacent margins of the capitate and os hamatum. Occasionally they are sufficiently developed to divide the joint cavity into radial and ulnar sections.

The **synovial stratum** (Fig. 283) is usually single and lines the fibrous stratum, but, as already explained, it has prolongations into the intermetacarpal and intercarpal series of joints. In connexion with the intercarpal series, the frequent absence of the interosseous ligament between the greater and lesser multangular bones permits the free communication of this joint cavity with that of the transverse carpal joint.

ARTICULATIONES METACARPOPHALANGEÆ.

Metacarpo-phalangeal Joints.—In the case of the pollex this joint is constructed on the plan of a ginglymus diarthrosis; the four corresponding joints of the fingers are also diarthroses of a slightly modified ball-and-socket variety. With the exception of the metacarpal bone of the pollex, each metacarpal bone has a somewhat spherical head articulating with a shallow oval cup upon the base of the first phalanx. It is important to note that the articular surface upon the head of each of these metacarpal bones is wider on the volar aspect and narrower on the dorsal aspect. The articulation in the thumb presents features similar to those of an interphalangeal joint.

Each joint possesses a capsula articularis (Fig. 284) which presents very different degrees of strength in different aspects of the articulation. Thus, on the dorsal aspect, it cannot be demonstrated as an independent structure, but the necessity for dorsal ligaments is to a large extent obviated by the presence of the strong flattened expansions of the extensor tendons.

The epiphyseal lines are extra-capsular.

Ligamenta Collateralia.—The **collateral ligaments** (Fig. 284) are strong cord-like bands which pass from the tubercles and adjacent depressions on the sides of the heads of the metacarpal bones to the contiguous non-articular areas on the bases of the proximal phalanges. They are intimately connected on their volar aspects with the volar ligaments.

Ligamenta Accessoria Volaria.—The **volar accessory ligaments** consist of thick plates of fibro-cartilage loosely connected to the metacarpal bones, but firmly adherent to the phalanges. They are placed between the collateral ligaments, to both of which they are in each case connected. Each plate is grooved on the volar surface for the long flexor tendons, whilst on its dorsal or joint surface it supports and glides upon the head of the metacarpal bone during flexion and extension of the joint. In the case of the thumb this plate of fibro-cartilage is usually replaced by sesamoid bones, and in the case of the index finger one such sesamoid nodule is frequently found at the radial side of the plate (Fig. 285).

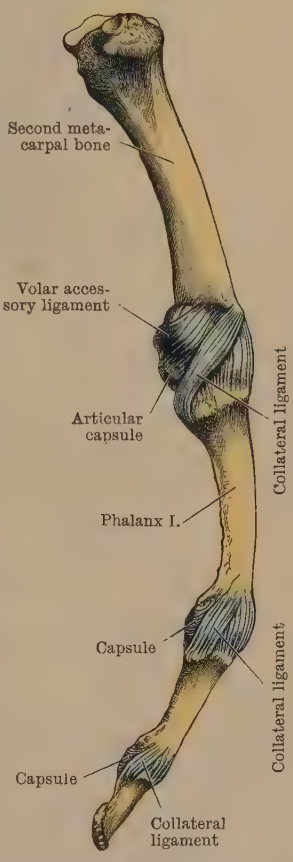

FIG. 284.—METACARPO-PHALANGEAL AND INTERPHALANGEAL JOINTS.

An important accessory ligament is found in connexion with the four medial metacarpo-phalangeal articulations, viz.:—

Ligamenta Capitulorum (Oss. Metacarpalium) Transversa.—The **transverse ligament of the heads of the metacarpal bones** (or **transverse metacarpal ligament**) binds together the distal extremities of the four medial metacarpal bones. The name is applied to three sets of transverse fibres of great strength which are situated in front of the three medial interosseous spaces. These fibres are continuous with the ligamenta accessoria volaria (volar metacarpo-phalangeal ligaments).

A **stratum synoviale** lines the capsula articularis of each joint.

ARTICULATIONES DIGITORUM MANUS.

Interphalangeal Joints.—Of these joints there are two for each finger and one for the thumb. They all correspond, in being ginglymus diarthroses in which the trochlear character of their articular surfaces is associated with one axis of movement directed transversely.

In their general arrangement they correspond with each other, and to a large extent with the metacarpo-phalangeal series already described. Each is provided with a definite **articular capsule** (Fig. 284), of which the volar, and the cord-like lateral portions are well marked, while on the dorsal aspect the extensor tendons act as the chief support. The volar portions contain fibrous plates of considerable thickness, and are attached to the two collateral ligaments and to the intervening rough surface on the distal phalanges, while their proximal margins are not attached to bone. Each ligament has its lateral margins prolonged proximally to the adjacent sharply defined lateral ridges on the phalangeal shafts.

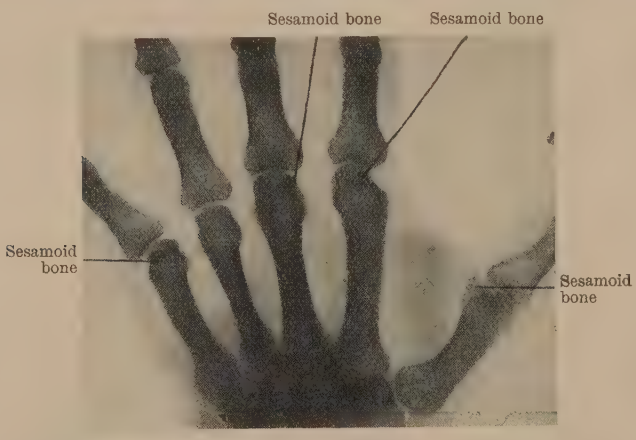

FIG. 285.—RADIOGRAPH OF HAND SHOWING SESAMOID BONES.

The **collateral ligaments** (Fig. 284) are strong, rounded, short bands, continuous with the preceding, and attached to the non-articular sides of adjacent heads and bases of the phalanges.

Each joint possesses a **synovial stratum** which lines its fibrous stratum, but its arrangement presents no special peculiarity. The epiphyseal lines of the bases of the phalanges are extra-capsular.

MOVEMENTS OF THE CARPAL, INTERMETACARPAL, METACARPO-PHALANGEAL AND INTERPHALANGEAL JOINTS.

The amount of movement which is possible at individual joints of the intercarpal, intermetacarpal, and carpo-metacarpal series is extremely limited, both on account of the interlocking nature of the articular surfaces and the restraining character of the ligamentous bands. Taken as a whole, however, the movements of the carpus and metacarpus enable the hand to perform many varied and important functions. This is largely due to the greater mobility of those joints on the radial and ulnar borders of the hand, as well as to the general elasticity of the arches formed by the carpus and metacarpus. These conditions particularly favour the movements of opposition and prehension. In the opposite direction, *i.e.* when pressure is applied from the volar aspect, the metacarpal and carpal arches tend to become flattened, but great elasticity is imparted by the tension of the various ligaments.

The four medial metacarpo-phalangeal joints are ball-and-socket joints, and movements of **volar-flexion** and **extension** are freely performed about a transverse axis. In exceptional cases a certain amount of **dorsi-flexion** is possible. About an antero-posterior axis movements occur which are usually referred to the middle line of the hand, and hence called **abduction** and **adduction**, but in consequence of the difference in the width of the articular surface on the dorsal and volar aspects of the heads of the four medial metacarpal bones it is only possible to obtain complete abduction when the joints are extended, while in the flexed position the joints become locked and abduction is almost impossible.

The movements of the index finger are less hampered than in the case of the others, but each of them can perform a modified kind of **circumduction**.

The metacarpo-phalangeal joint of the thumb and all the interphalangeal joints are uniaxial or hinge-joints acting about a transverse axis, which permits of **volar-flexion** and **extension** being freely performed, but **dorsi-flexion** is, as a rule, entirely prevented by the volar and lateral ligaments.

ARTICULATIONES ET LIGAMENTA CINGULI EXTREMITATIS INFERIORIS.

Articulations and Ligaments of the Pelvis.—Although we may consider the pelvis as a separate part of the skeleton, yet it is essential to remember that the bones which enter into its composition belong to the vertebral column (sacrum, coccyx) and the lower limb (hip bone). Accordingly, the articulations, with their corresponding ligaments, may be arranged as follows:—

(*a*) Those by which the segments of the coccyx are joined together (already described, *v.* p. 311);
(*b*) That by which the sacrum articulates with the coccyx (already described, *v.* p. 310);
(*c*) Those by which the sacrum articulates with the last lumbar vertebra (Lumbo-sacral joints);
(*d*) Those by which the hip bones are attached to the vertebral column (Sacro-iliac joints);
(*e*) That by which the hip bones are attached to each other (Symphysis pubis).

ARTICULATIONES SACROLUMBALES.

Lumbo-sacral Joints.—The articulation of the sacrum with the fifth lumbar vertebra is constructed precisely on the principle of the articulations between two typical vertebræ, and the usual ligaments associated with such joints are repeated. There is, however, an additional accessory ligament, termed the **lateral lumbo-sacral ligament.** This extends from the anterior aspect of the inferior border of the transverse process of the last lumbar vertebra, downwards and slightly laterally, to the ala of the sacrum, close to the sacro-iliac joint. Further, a variable membranous band extends between the lateral aspect of the inferior part of the body of the last lumbar vertebra and the front of the ala of the sacrum. This band lies in front of the anterior ramus of the fifth lumbar nerve.

ARTICULATIO SACROILIACA.

Each hip bone articulates with the sacral section of the vertebral column on each side through the intervention of a diarthrosis, termed the **sacro-iliac joint.**

This joint is formed between the contiguous auricular surfaces of the sacrum and ilium. Each of these surfaces is more or less completely clothed with hyaline articular cartilage. The joint cavity, which is little more than a capillary interval, may be crossed by fibrous bands.

The cavum articulare (joint cavity) is surrounded by ligaments of varying thickness and strength, which constitute the fibrous stratum of its **articular capsule.** Thus, its anterior part is thin, and consists of short but strong fibres which pass between adjoining surfaces on the ala of the sacrum and the iliac fossa of the hip bone; they form the **anterior sacro-iliac ligament.** On the posterior aspect there are three ligaments. The **interosseous sacro-iliac ligament** (Fig. 286) consists of numerous strong fasciculi, which pass from the rough area on the medial aspect of the ilium, above and behind its auricular surface, downwards and medially to the tubercles of the transverse processes and the depressions behind the first and second segments of the sacrum. This ligament is of great strength, and with its fellow it is responsible for suspending the sacrum and the weight of the superimposed trunk from the hip bones.

The **long posterior sacro-iliac ligament** (Fig. 287) is a superficial thickened portion of the interosseous ligament. It consists of a definite band of fibres passing from the posterior superior iliac spine to the tubercles of the transverse processes of the third and fourth segments of the sacrum.

The **short posterior sacro-iliac ligament** consists of superficial fibres of the interosseous ligament passing from the posterior superior iliac spine to the tubercles of the first and second transverse processes of the sacrum.

The **articular cavity** of this joint is very imperfect and rudimentary.

Several accessory ligaments are associated with the articulation of the hip bone to the sacral section of the vertebral column.

Lig. Iliolumbale.—The **ilio-lumbar ligament** (Fig. 287), which is merely the thickened anterior lamina of the lumbo-dorsal fascia, extends from the tip of the transverse process of the last lumbar vertebra, almost horizontally laterally, to the inner lip of the iliac crest at a point a short distance behind its highest level. A proportion of these fibres is attached to the medial rough surface of the ilium between the iliac crest and the auricular impression. To these the name of the **lig. iliolumbale inferius** is applied.

Lig. Sacrotuberosum.—The **sacro-tuberous ligament** (Fig. 286) is somewhat triangular in outline. It occupies the interval between the sacrum and the hip bone,

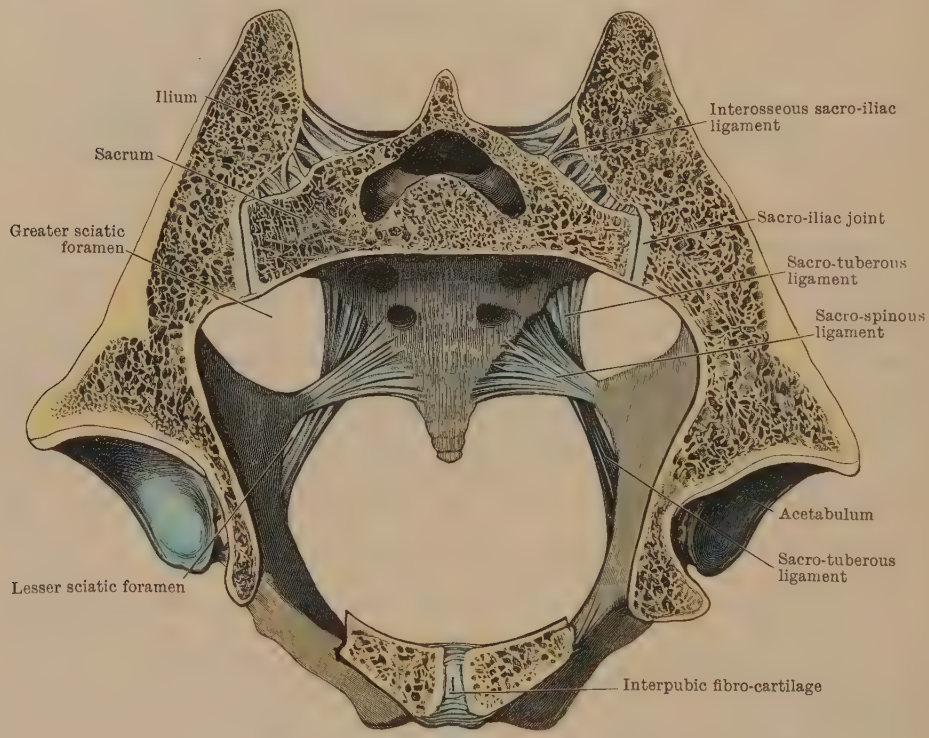

FIG. 286.—FRONTAL SECTION OF PELVIS.

and is attached medially to the posterior superior and the posterior inferior spines of the ilium; to the posterior aspects of the tubercles of the transverse processes and lateral margins of the third, fourth, and fifth segments of the sacrum, as well as to the side of the first segment of the coccyx. It passes downwards and laterally, becoming narrower as it approaches the ischium, near to which, however, it again expands, to be attached to the medial side of the tuber ischiadicum, immediately below the groove for the tendon of the obturator internus muscle, *i.e.* the lesser sciatic notch. A continuation of the medial border of the ligament—the **processus falciformis** (Fig. 287)—runs upwards and forwards on the medial aspect of the ramus of the ischium.

The ligamentum sacrotuberosum is believed by many to represent the original or proximal end of the long or ischial head of the biceps femoris muscle.

Ligamentum Sacrospinosum.—The **sacro-spinous ligament** (Figs. 286 and 287) is situated in front, and in a measure under cover of the sacro-tuberous ligament. Triangular in form, it is attached by its base to the last two segments of the sacrum and the first segment of the coccyx, and by its pointed apex to the tip and superior aspect of the spina ischiadica. This ligament is intimately associated

with the coccygeus muscle, and by some it is regarded as being derived from it by fibrous transformation of the muscle fasciculi.

By the sacro-tuberous and sacro-spinous ligaments the two sciatic notches of the hip bone are converted into foramina. Thus the sacro-spinous ligament completes the boundaries of the greater sciatic foramen (foramen ischiadicum

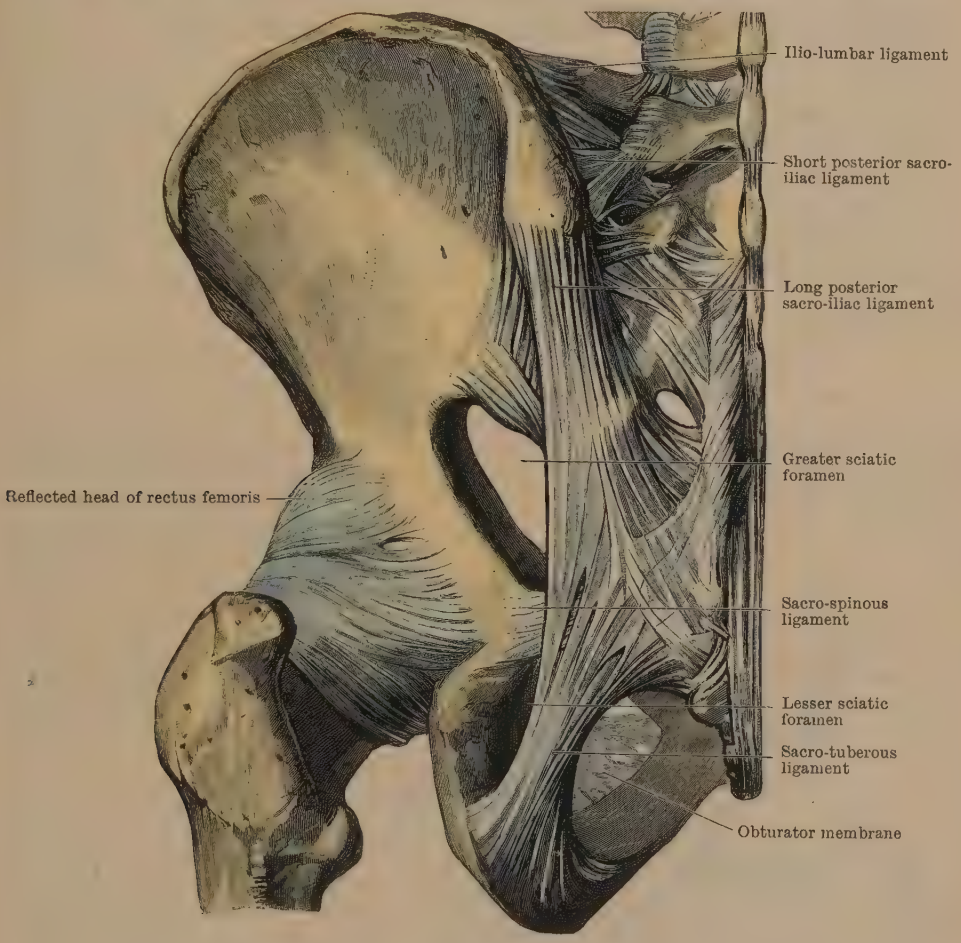

Fig. 287.—Posterior View of the Pelvic Ligaments and of the Hip-Joint.

majus); while the sacro-tuberous ligament, assisted by the sacro-spinous ligament, closes the lesser sciatic foramen.

SYMPHYSIS OSSIUM PUBIS.

The anterior wall of the osseous pelvis is completed by the articulation of the bodies of the two pubic bones, which constitutes the **symphysis pubis.** This joint conforms in its construction to the general plan of an amphiarthrosis. Thus it is median in position; each pubic bone is covered by a layer of hyaline cartilage, which closely adapts itself to the rough tuberculated surface of the pubic bone; while between these two hyaline plates there is an interposed fibro-cartilage called the *lamina fibrocartilaginea interpubica,* in the interior of which there is usually a vertical antero-posterior cleft. This cavity, which is placed nearer the posterior than the anterior aspect of the joint, does not appear until between the seventh and tenth years, and as it is not lined by a synovial stratum, it is supposed to result from the breaking down of the interpubic lamina.

Lig. Pubicum Anterius.—The **anterior pubic ligament** (Fig. 286) is a structure of considerable thickness and strength. Its superficial fibres, which are derived

very largely from the tendons and aponeuroses of adjoining muscles, are oblique, and form an interlaced decussation. The deeper fibres are short, and extend transversely from one pubic bone to the other.

Lig. Pubicum Posterius.—The **posterior pubic ligament** (Fig. 286) is very weak and consists of scattered fibres which extend transversely between contiguous pubic surfaces posterior to the articulation.

Lig. Pubicum Superius.—The **superior pubic ligament** also is weak; it consists of transverse fibres passing between the two pubic crests.

Lig. Arcuatum Pubis.—The **arcuate ligament of the pubis** (O.T. **inferior** or **subpubic ligament**) occupies the arch of the pubis, and is of considerable strength. It gives roundness to the pubic arch and forms part of the boundary of the inferior aperture of the pelvis. It has considerable vertical thickness immediately below the interpubic fibro-cartilage, to which it is attached. Laterally it is attached to adjacent sides of the inferior rami of the pubis. Its inferior border is free, and separated from the upper border of the fascia of the urogenital diaphragm by a transverse oval interval, through which the dorsal vein of the penis passes backwards to the interior of the pelvis.

Fascia Diaphragmatis Urogenitalis Inferior.

The **inferior fascia of the urogenital diaphragm** is a membranous structure which occupies the pubic arch below and distinct from the arcuate ligament of the pubis. It assists in completing the pelvic walls anteriorly in the same manner that the obturator membrane does laterally. Indeed, these two structures occupy the same morphological plane. The fascia presents two surfaces—one superficial or perineal, the other deep or pelvic—and both of these surfaces are associated with muscles. Its lateral borders are attached to the sides of the pubic arch, while its base is somewhat ill-defined, by reason of its fusion with the fascia of Colles in the urethral region of the perineum.

The apex of the fascia is truncated, free, and well defined, constituting the **transverse perineal ligament**, above which there is the interval for the dorsal vein of the penis. It is pierced by a number of vessels and nerves, but the principal opening is situated in the median plane one inch below the pubic arch, and transmits the urethra.

Membrana Obturatoria.

The **obturator membrane** (Fig. 287) occupies the obturator foramen. It is attached to the pelvic aspect of the circumference of this foramen. It consists of fibres irregularly arranged and of varying strength, so that sometimes it almost appears fenestrated. At the highest part of the foramen it is incomplete and forms a U-shaped border, between which and the bony circumference of the foramen the obturator canal is formed. In this position the membrane is continuous with the parietal pelvic fascia which clothes the medial side of the obturator internus muscle, above the superior free margin of the muscle. From the lateral or femoral aspect of the membrane some of its fibres are prolonged to the antero-inferior aspect of the capsule of the hip-joint.

Mechanism and Movements of the Pelvis.—The human pelvis presents a mechanism the principal requirement of which is stability and not movement, for, through the pelvis, the weight of the trunk, superimposed upon the sacrum, is transmitted to the lower limbs. Moreover, its stability is largely concerned in the maintenance of the erect attitude. The movements of its various parts are therefore merely such as are consistent with stability, without producing absolute rigidity.

The two hip bones, being bound together by powerful ligaments at the pubic articulation, constitute an inverted arch, of which the convexity is directed downwards and forwards, while its piers are turned upwards and backwards, and considerably expanded in relation to the posterior parts of the iliac bones. Between the piers of this inverted arch the sacrum is situated. This bone is in no sense a key-stone to an arch, because, as may readily be seen in antero-posterior transverse section, the sacrum is wider in front than behind, and the superposed weight naturally tends to make the sacrum fall towards the pelvic cavity, and so fit less closely between the hip bones. The sacrum is in reality an oblique platform, in contact with each hip bone through its articular auricular surfaces, and in this position it is suspended by the interosseous and posterior sacro-iliac ligaments, and kept securely in place by the "grip" due to the irregularity of the opposed surfaces of the two sacro-iliac articulations. Since the weight of the trunk is transmitted to the anterior and superior end of this sacral platform, there is a natural tendency

for the sacrum to revolve upon the transverse axis which passes through its sacro-iliac joints. If this were permitted, the promontory of the sacrum would rotate downwards and forwards towards the pelvic cavity, as really does occur in certain deformities. This revolution or tilting downwards of the anterior part of the sacrum is prevented by the action of the sacro-tuberous and sacro-spinous ligaments, extending from the ischial tuberosity to the posterior and inferior end of the suspended platform of the sacrum. Not only so, but these ligaments, acting on a rigid sacrum, tend to hold up the weight upon the sacral promontory.

The various ligaments passing between the last lumbar vertebra and the sacrum and ilium retain the weight of the trunk in position upon the anterior end of the sacrum, and resist its tendency to slip forwards and downwards towards the pelvic cavity. The entire weight of the trunk and pelvis is transmitted to the heads of the thigh bones in the most advantageous position, both for effectiveness and the strengthening of the inverted arch of the hip bones, for it will be evident that the heads of the femora thrust inwards upon the convex side of the arch, very much at the place where the arches are weakest, viz., at the springing of the arch from its piers. The forces which tend to cause movement of the pelvic bones during parturition act from within the pelvis, and have for their object the increase of the various pelvic diameters, in order that the fœtal head may more readily be transmitted. For this purpose the wedge-like dorsal surface of the sacrum is driven backwards, and a certain amount of extra space may thereby be obtained. An important factor, however, in the increase of the pelvic capacity at this period is found in the relaxation of its various ligaments.

ARTICULATIONES EXTREMITATIS INFERIORIS.

ARTICULATIO COXÆ.

The Hip-Joint.—The human body provides no more perfect example of an enarthrodial diarthrosis than the hip-joint. Combined with all that variety of movement which characterises a multi-axial joint, it nevertheless presents great stability, which has been obtained by simple arrangements, for restricting the range of its natural movements. This stability is of paramount importance for the maintenance of the erect attitude, and the mechanical adaptations whereby this result is obtained are such that the erect attitude may be preserved without any great degree of sustained muscular effort.

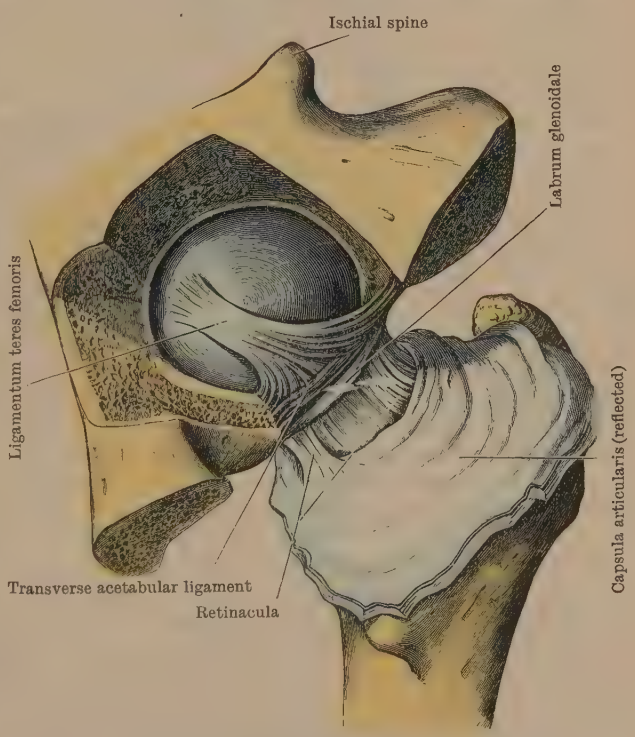

Fig. 288.—Dissection of the Hip-Joint.
Bottom of the acetabulum removed, and capsule of the joint thrown laterally towards the trochanters.

Articular Surfaces.—The head of the femur is globular in shape, and considerably exceeds a hemisphere. It is clothed with hyaline articular cartilage on those parts which come into direct contact with the acetabulum. There is frequently more or less of extension of the articular cartilage from the head to the adjoining anterior part of the neck, an extension which is accounted for by the close and constant apposition of this portion of the neck with the posterior aspect of the ilio-femoral ligament. The limit of the articular cartilage covering the head is indicated by a sinuous border. Further, there is an absence of articular cartilage from the fovea or pit on the head of the femur.

The acetabulum is a deep cup-shaped cavity which presents a notch on its antero-inferior margin. The interior of the cup is lined with a ribbon-like

band of articular cartilage which extends to the brim of the cavity, but does not cover its floor. This articular ribbon-shaped band is widest on its supero-posterior aspect, and narrowest at the anterior margin of the acetabular notch.

Lig. Transversum Acetabuli.—The **transverse ligament** (Fig. 288) bridges the acetabular notch, and consists of strong transverse fibres which are attached to both of its margins, but more extensively to the postero-inferior. This ligament does not entirely fill the notch, but leaves an open interval between its inferior border and the bottom of the notch through which vessels and nerves enter the cup. The acetabular aspect of this ligament constitutes an articular surface.

The acetabulum is deepened by the **labrum glenoidale** (Figs. 288 and 289), which consists of a strong ring of fibro-cartilaginous tissue attached to the entire rim of the cup. The attached surface of the ring is broader than its free edge, and, moreover, the latter is somewhat contracted, so that the ligament grasps the head of the femur which it encircles. Its fibres are partly oblique and partly circular in their direction. By the former it is firmly implanted on the rim of the acetabulum and the lig. transversum acetabuli; by the latter the depth of the cup is increased through the elevation of its edge, and its mouth slightly narrowed. By one surface this ligament is also articular.

Capsula Articularis.—An **articular capsule** (Figs. 288 and 289) completely invests the joint cavity. Its fibrous stratum is of great strength, although it is not of equal thickness throughout, being considerably thicker on the supero-anterior aspect than at any other part. Unlike the corresponding structure of the shoulder-joint, it does not permit of the withdrawal of the head of the femur from contact with the acetabular articular surfaces, except to a very limited extent. Its fibres are arranged both in the circular and in the longitudinal direction, the former, known as the **zona orbicularis**, being best marked posteriorly, while the longitudinal fibres stand out more distinctly in front, where they constitute special ligaments. Looked at as a whole, the fibrous stratum of the capsule has the following attachments: *proximally* it surrounds the acetabulum, on the superior and posterior aspects of which it is attached directly to the hip bone, while on the anterior and inferior aspects it is attached to the non-articular surfaces of the labrum glenoidale and transverse ligaments of the acetabulum; *distally* it encircles the neck of the femur, where it is attached in front to the intertrochanteric line; above, to the medial aspect of the root of the greater trochanter; below, to the lower part of the neck of the femur, in close proximity to the lesser trochanter; behind, to the line of junction of the lateral and middle thirds of the neck of the femur. It is a matter of some importance to note that only part of the posterior surface of the neck of the femur is enclosed within the articular capsule. The femoral attachments of the fibrous stratum of the capsule vary considerably in their strength, being particularly firm above and in front, but much weaker below and posteriorly, where the orbicular fibres are well seen. Many fibres of the fibrous stratum are reflected from its deep aspect proximally upon the neck of the femur, where they form ridges, and to these the term **retinacula** (Fig. 288) is applied.

The epiphyseal line of the head of the femur is intra-capsular; the epiphyseal lines of the two trochanters are extra-capsular.

The longitudinal fibres of the fibrous stratum of the capsule are arranged so as to form certain definite bands, viz.:—

(1) **Lig. Iliofemorale.**—The **ilio-femoral ligament** (Fig. 289) consists of a triangular set of fibres attached proximally, by their apex, to the inferior part of the anterior inferior iliac spine and the immediately adjoining part of the rim of the acetabulum, and distally, by their base, to the intertrochanteric line of the femur. This ligament is the thickest part of the fibrous stratum, but its sides are more pronounced than its centre, especially towards its base. Consequently the ilio-femoral ligament presents some resemblance to an inverted Y (ʎ), and therefore was formerly named the Y-shaped ligament of Bigelow.

The lateral or upper limb of the ilio-femoral ligament may be somewhat extended by the inclusion of additional longitudinal fibres, and described as the **ilio-trochanteric** ligament. This band arises from the anterior part of the dorsum of the acetabulum, and extends to the femoral neck, close to the anterior end of the medial surface of the greater trochanter.

(2) **Lig. Pubocapsulare.**—The **pubo-capsular ligament** (Fig. 289) is composed of some bands of fibres of no great strength, which extend from the lateral end of the superior ramus of the pubis, the ilio-pectineal eminence, the obturator crest and the obturator membrane, to lose themselves, for the most part, in the capsule, although a certain proportion of them may be traced to the inferior aspect of the femoral neck, where they adjoin the distal attachment of the ilio-femoral ligament.

(3) **Lig. Ischiocapsulare.**—The **ischio-capsular ligament** consists of a broad band of short, fairly strong longitudinal fibres, which, by their proximal ends, are attached to the ischium between the lesser sciatic notch and the obturator foramen, while their distal ends become merged in the zona orbicularis of the general capsule.

Within the capsule, and quite distinct from it, there are the ligamentum teres and the Haversian gland.

Lig. Teres Femoris.—The **round ligament** (Fig. 288) is a strong, somewhat flattened band of fibrous tissue, attached by one end to the superior half of the pit or depression on the head of the femur. By its medial end it is attached to the lower edge of the articular surface of the transverse ligament, with extensions to the opposite borders of the acetabular notch, but chiefly to the posterior or ischial border. This ligament varies very greatly in its strength and development in different subjects, and in certain rare cases it is absent.

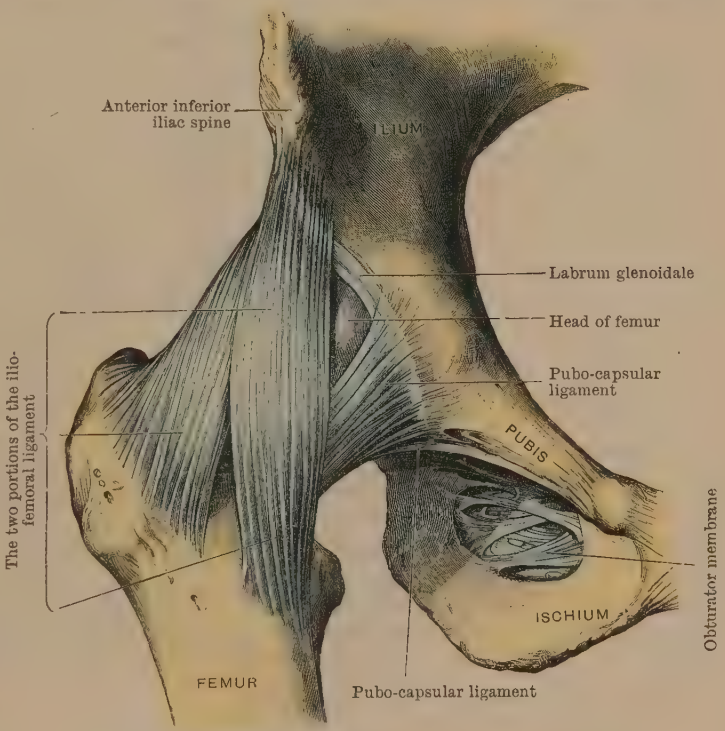

FIG. 289.—DISSECTION OF THE HIP-JOINT FROM THE FRONT.

The so-called **Haversian gland** occupies the bottom or non-articular area of the acetabulum. It consists of a mass of fat covered by the synovial stratum of the joint. This pad of fat is continuous with the extra-capsular fat through the passage subjacent to the transverse ligament of the acetabulum.

A **synovial stratum** lines the fibrous stratum of the capsule from which it is reflected to the neck of the femur along a line which corresponds to the femoral attachments of the fibrous stratum. Thus the synovial stratum clothes more of the femoral neck anteriorly than in any other position. Posteriorly, where the fibrous stratum is feebly attached to the neck of the femur, the synovial stratum may be seen from the outside of the capsule. The synovial stratum extends close up to the articular margin of the head of the femur, and on the superior and inferior aspects of the neck it is gathered into loose folds upon the retinacula. These folds or plicæ synoviales are best marked along the line of synovial reflexion, and do not reach as far as the femoral head. At its acetabular end the synovial stratum is prolonged from the inside of the capsule to the outer non-articular surface of the labrum glenoidale and transverse ligament, upon which it is continued as a lining for their acetabular or articular surfaces, and further, it

provides a covering for the fat at the bottom of the acetabular fossa, as well as a complete tubular investment for the ligamentum teres femoris.

Occasionally the **mucous** or **synovial bursa**, which is subjacent to the tendon of the ilio-psoas muscle, communicates with the interior of the hip-joint through an opening in the anterior wall of the capsule (Fig. 289), situated between the pubo-capsular ligament and the medial or lower limb of the ilio-femoral ligament.

Movements at the Hip-Joint.—The movements which occur at the hip-joint are those of a multiaxial joint. These are **flexion, extension, abduction, adduction, rotation,** and **circumduction.** The range of each of these movements is less extensive than in the case of the shoulder-joint, because, at the hip, the freedom of movement is subordinated to that stability which is essential alike for the maintenance of the erect attitude and for locomotion. When standing at rest in the erect attitude the hip-joint occupies the position of **extension,** and as the weight of the trunk is transmitted in a perpendicular which falls behind the centres of the hip-joints, both the erect attitude and the extended position are maintained to a large extent mechanically, by means of the tension of the ilio-femoral ligament, without sustained muscular action. Moreover, the tension of this ligament is sustained by the pressure of the front of the head and neck of the femur against its synovial surface. In this association of parts it is important to note that the articular cartilage of the femoral head may be, and in certain races is, prolonged to the front of the femoral neck; and further, that the constant friction does not destroy the synovial stratum of the capsule. Again, the same mechanism which preserves the erect attitude prevents an excessive degree of extension or dorsiflexion. In movement forwards, *i.e.* ventral **flexion,** the front of the thigh is approximated to the anterior abdominal wall. The amount of this movement depends upon the position of the knee-joint, because when the latter is flexed the thigh may be brought into contact with the abdominal wall, whereas when the knee-joint is straightened (*i.e.* extended) the tension of the hamstring muscles greatly restricts the amount of flexion at the hip-joint. **Abduction** and **adduction** are likewise much more restricted than at the shoulder-joint. **Abduction** is brought to a close by the tension of the pubo-capsular band and the lower part of the capsule, and, in addition, the upper aspect of the neck of the femur locks against the margin of the acetabulum. Excessive **adduction** is prevented by the tension of the upper band of the ilio-femoral ligament and the upper part of the capsule. **Rotation** or movement in a longitudinal axis may be either medially, *i.e.* towards the front, or laterally, *i.e.* towards the back. In the former the movement is brought to a close by the tension of the ischio-capsular ligament and posterior part of the capsule, aided by the muscles on the back of the joint; in the latter—rotation laterally—the chief restraining factor is the lateral or upper limb of the ilio-femoral ligament. The total amount of rotation is probably less than 60°.

Circumduction is only slightly less free than at the shoulder, but it is complicated by the preservation of the balance upon one foot.

The value and influence of the ligamentum teres femoris are not easily estimated, because it may be absent without causing any known interference with the usefulness of the joint. In the erect attitude this ligament lies lax between the lower part of the femoral head and the acetabular fat. In the act of walking it is rendered tense at the moment when the pelvis is balanced on the summit of the supporting femur. Analysis of this position shows the femur to be adducted, with probably, in addition, a small amount of flexion (*i.e.* bending forwards) and medial rotation. Again, this ligament is said to be tense when the thigh is rotated laterally. The equivalent of this movement is doubtless found in the rotation of the pelvis, which occurs in the act of walking at the moment of transition from the toe of the supporting foot to the heel of the advancing foot. The interest connected with this ligament is perhaps rather morphological than physiological. It is believed by some to represent the tendon of a muscle which in birds occupies a position external to the joint capsule.

ARTICULATIO GENU.

The **knee-joint** is the largest articulation in the body, and its structure is of a very elaborate nature. The part it plays in maintaining the erect attitude materially influences its construction, and special arrangements are provided for the mechanical retention of the joint in the extended position in view of the fact that the line of gravity falls in front of the centre of the articulation. Its principal axis of movement is in the transverse direction, consequently it belongs to the ginglymus or hinge variety of the diarthroses. At the same time a slight amount of rotation of the tibia in its long axis is permitted during flexion; but while this fact is of considerable importance in the study of certain accidents to which the joint is liable, as well as in the study of its comparative morphology, it is not sufficiently pronounced to interfere with its classification as a hinge-joint.

Articular surfaces pertaining to the femur, tibia, and patella enter into the formation of the knee-joint. The articular surface of the femur extends over a large part of both condyles, and may be divided into patellar and tibial portions by faintly-marked, almost transverse grooves, which pass across the articular

surface immediately in front of the intercondylar notch. As a rule marginal indentations of the articular surface render the positions of these transverse grooves more distinct.

The **patellar portion** (Fig. 290) is situated anteriorly, and is common to both condyles, although developed to a larger extent in association with the lateral condyle, on which it ascends to a more proximal level than on the medial condyle. This surface is trochlear, and forms a vertical groove bordered by prominent borders.

The **tibial portion** of the articular surface of the femur is divided into two articular areas, in relation to the distal aspects of the two condyles, by the wide non-articular intercondyloid notch. These two surfaces are for the most part parallel, but in front the medial tibial surface turns obliquely laterally as it passes into continuity with the patellar trochlea, while posteriorly, under certain circumstances, *e.g.* the squatting posture, the articular surface of the medial condyle may extend to the adjoining portion of the popliteal area of the bone.

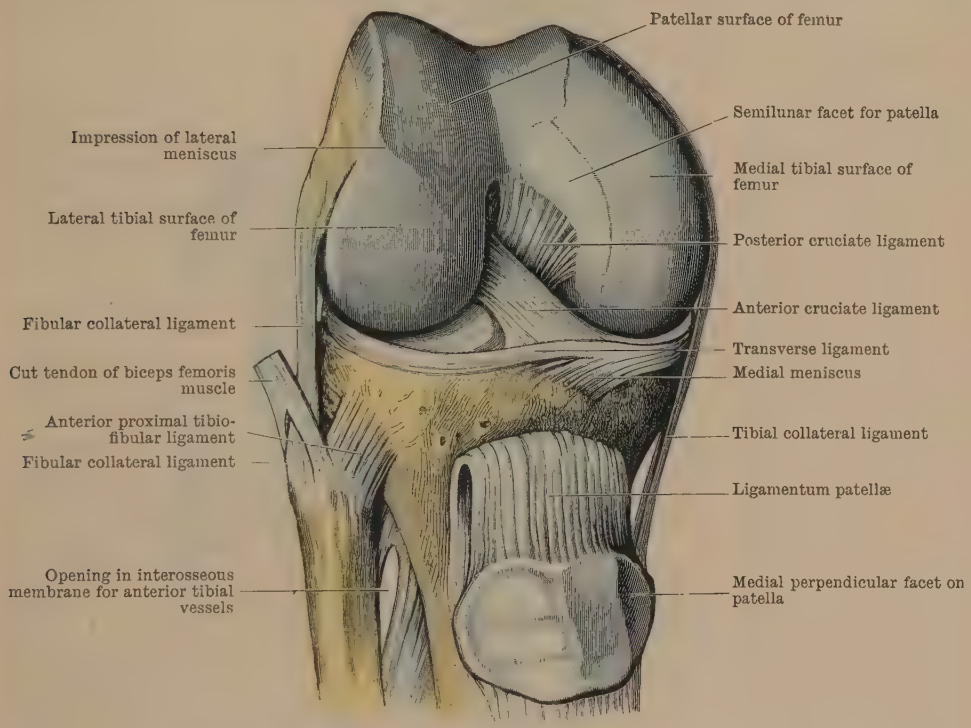

FIG. 290.—DISSECTION OF THE KNEE-JOINT FROM THE FRONT: PATELLA THROWN DISTALLY.

When the joint is in the position of extreme flexion, the patella is brought into direct contact with that part of the articular surface on the medial condyle which bounds the intercondyloid notch upon its medial and anterior aspects. This relationship is indicated by the presence of a distinct semilunar facet on the cartilage in that situation (Fig. 290). The articular surface of the femur may therefore be regarded as presenting **femoro-patellar** and **femoro-tibial areas.**

The **patella** presents on its posterior aspect a transversely elongated oval articular facet and a distal rough, triangular, non-articular area. The articular facet is divided into two principal portions by a prominent rounded vertical ridge. Of these the lateral is the wider. A less pronounced and nearly vertical ridge marks off an additional facet called the medial perpendicular facet, close to the medial margin of the articular surface. Two faint transverse ridges cut off narrow proximal and distal facets from the general articular surface without encroaching on the narrow, most medial vertical facet (Goodsir) (Fig. 290).

The head of the **tibia** presents on its superior aspect two condylar articular surfaces, separated from each other by a non-articular antero-posterior area, which

is wider anteriorly and posteriorly than in the middle, where it is elevated to form a bifid eminentia intercondyloidea.

The **lateral condylar facet** is slightly concavo-convex from before backwards and slightly concave transversely. This surface is almost circular, and extends to the free lateral border of the tibial condyle, where it is somewhat flattened. Posteriorly the articular surface is prolonged downwards on the condyle in relation to the position occupied by the tendon of the popliteus muscle. The **medial condylar facet** is oval in outline, and distinctly concave both in its antero-posterior and transverse diameters.

Ligaments.—Like all diarthroses, this joint is invested by an envelope or capsula articularis, which does not, however, entirely surround the articular cavity,

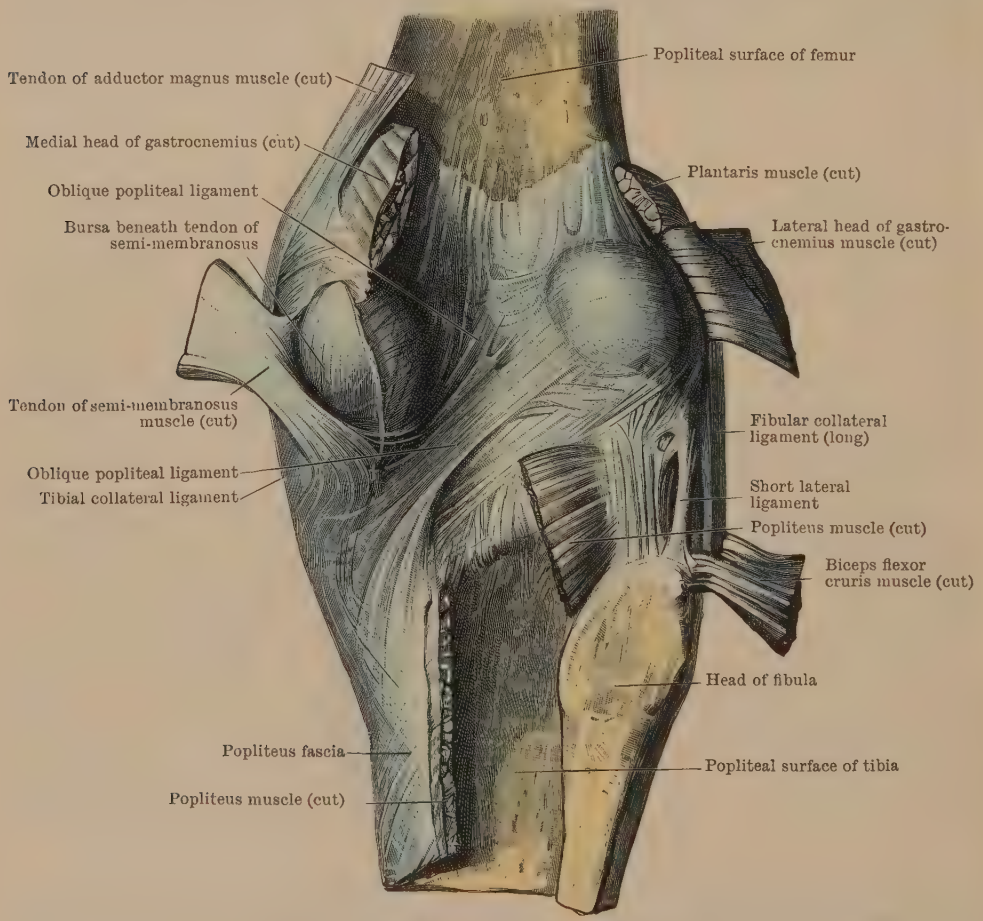

FIG. 291.—THE KNEE-JOINT. POSTERIOR VIEW.

for it is absent as a fibrous stratum proximal to the articular cavity, subjacent to the tendon of the quadriceps extensor muscle. Its specially named bands are not of themselves sufficient to form a complete investment, and the fibrous stratum, which largely consists of augmentations from the fascia lata and the tendons of surrounding muscles, supplies the defective areas. Thus, anteriorly, on each side of the patella and the ligamentum patellæ, expansions of the vasti tendons and fascia lata, constituting the **collateral patellar ligaments**, are evident. On the lateral side of the joint the fibular collateral ligament is hidden within a covering derived from the ilio-tibial tract of the fascia lata. On the medial side expansions from the tendons of the sartorius and semi-membranosus muscles augment the articular capsule, which here becomes continuous with the ligamentum collaterale tibiale. Posteriorly the articular capsule also receives augmentation from the tendon of the semi-membranosus muscle, but it is very thin subjacent to the origins of the

gastrocnemius muscle, where it covers the posterior parts of the condyles. Not unfrequently the articular capsule presents an opening of communication between the interior of the articular cavity and a bursa which lies under cover of the medial head of the gastrocnemius muscle.

The epiphyseal line of the distal end of the femur is partly intra-capsular and partly extra-capsular; that of the proximal end of the tibia is extra-capsular.

Ligamentum Patellæ.—The **ligamentum patellæ** or **anterior ligament** (Fig. 290) is a powerful flattened band, attached proximally to the apex and adjoining margins of the patella, and distally to the rough anterior tuberosity at the proximal end of the shaft of the tibia. This ligament also serves as a tendon of insertion for the quadriceps extensor muscle, and a certain number of the fibres of the tendon may be observed to run distally as a thin fibrous covering for the anterior surface of the patella. The deep surface of the tendon is separated from the front of the head of the tibia by a synovial bursa, and proximal to this it rests upon the infra-patellar pad of fat, which is placed between the tendon and the synovial stratum of the joint.

The **ligamentum posterius (posterior ligament)** (Fig. 291) is a compound structure of unequal strength, and those portions by which it establishes continuity with the lateral parts of the articular capsule are remarkably thin. It is attached proximally to the popliteal surface of the femur, close to the intercondyloid notch, with lateral extensions to the non-articular areas immediately proximal to the posterior articular margins of the two condyles, where it is closely associated with the origins of the gastrocnemius muscle.

Distally it is attached to the rough non-articular posterior border of the head of the tibia, where, to its fibular side, it presents an opening of exit for the tendon of the popliteus muscle (Fig. 291).

The tendon of insertion of the semi-membranosus muscle contributes an important expansion which augments the posterior ligament on its superficial aspect. This expansion—**lig. popliteum obliquum**—passes obliquely proximally and laterally to lose itself in the general ligament, but it is most distinct in the region between the femoral condyles, where it may present proximal and distal arcuate borders (lig. popliteum arcuatum). A number of vessels and nerves perforate this ligament, and hence it presents a number of apertures.

Lig. Collaterale Tibiale.—The **tibial collateral ligament** (Figs. 291 and 292) is a well-defined, strong, flat band which is applied to the medial side of the knee-joint, and is rather wider in the middle than at either end. It is frequently regarded as consisting of two portions—an anterior or long portion, and a posterior or short one. The two parts arise close together from the medial epicondyle, immediately distal to the adductor tubercle. The **short** or **posterior portion** passes distally and slightly backwards, to be attached to the postero-medial aspect of the medial part of the tibia proximal to the groove for the semi-membranosus tendon. The **long** or **anterior portion** inclines somewhat forwards, and extending distally superficial to the tendon of the semi-membranosus, it is attached to the proximal part of the medial surface of the shaft of the tibia distal to the level of the tuberosity.

On its superficial aspect the tibial collateral ligament is augmented by prolongations from the tendon of the semi-membranosus muscle, but is separated by a bursa from the tendons of the gracilis, semi-tendinosus, and sartorius. Its deep surface is adherent to the convex edge of the meniscus medialis, but more distally the distal and medial articular vessels intervene between the ligament and the body of the tibia.

Lig. Collaterale Fibulare.—The **fibular collateral ligament** (Figs. 291 and 292) is a distinct rounded band which is obscured by capsular fibres, and yet well separated from the articular cavity by intervening objects. It is attached proximally to the lateral epicondyle, immediately proximal to the groove occupied by the tendon of the popliteus muscle, superficial to which the ligament extends distally to be attached to the lateral side of the head of the fibula, in front of the styloid process. In its course it splits the tendon of insertion of the biceps femoris (Fig. 290), the portions of which are fixed to the head of the

fibula anterior and posterior to the ligament, and a bursa may intervene between the tendon and the ligament. The distal lateral articular vessels pass forwards medial to this ligament and proximal to the head of the fibula. Unlike the tibial collateral ligament, it is not attached to the corresponding meniscus.

The **ligamentum laterale externum breve seu posterius** (Fig. 291) is an inconstant structure which is attached by its proximal end immediately behind the preceding, and subjacent to the lateral head of the gastrocnemius muscle. It likewise passes superficial to the popliteal tendon, and is affixed distally to the apex capituli of the fibula.

The **intra-articular structures** of the knee-joint are more important and more numerous than in any other joint of the body.

FIG. 292.—THE KNEE-JOINT OPENED FROM BEHIND BY THE REMOVAL OF THE POSTERIOR LIGAMENT.

Ligamenta Cruciata Genu.—The **cruciate ligaments** are two strong, rounded, tendinous bands, which extend from the non-articular area on the proximal surface of the head of the tibia to the non-articular sides of the intercondyloid notch of the femur. These interarticular ligaments are distinguished from each other as the anterior or lateral and the posterior or medial. They cross each other like the limbs of an X, yet they remain distinct throughout, and each has its own partial synovial covering. They lie within the articular capsule, and extend between non-articular surfaces in relation to the longitudinal axis of the limb.

The **ligamentum cruciatum anterius** (Figs. 290, 292, and 293) is attached distally to the medial part of the rough, depressed area in front of and close to the intercondyloid eminence of the tibia. It passes obliquely proximally, laterally, and backwards to the medial non-articular surface of the lateral condyle, where it

finds attachment far back in the posterior part of the intercondyloid notch. This ligament is tense in the position of extension, and therefore it assists in maintaining the erect attitude.

The **ligamentum cruciatum posterius** (Figs. 291, 292, and 293) is somewhat shorter than the preceding. It is attached distally to the posterior part of the depressed surface behind the intercondyloid eminence of the tibia and close to the popliteal notch. Its fibres pass obliquely proximally, forwards, and medially, to be inserted into the lateral non-articular surface of the medial condyle, far forwards towards the anterior margin of the intercondyloid notch. It is rendered tense in the position of flexion.

The **semilunar menisci** are two in number—a medial and a lateral—placed horizontally between the articular surfaces of the femur and tibia. In general outline they correspond to the circumferential portions of the tibial facets upon which they rest. Each has a thick, convex, fixed border in relation to the periphery of the joint, and a thin, concave, free border directed towards the interior of the joint. Neither of them is sufficiently large to cover the whole of the tibial articular surface upon which it rests. The proximal and distal surfaces of each meniscus are smooth and free, and each terminates in an anterior and a posterior fibrous horn or cornu.

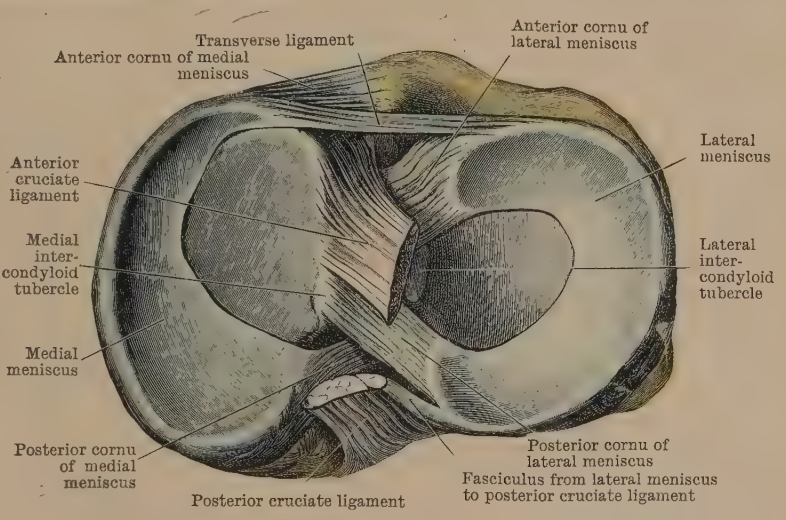

FIG. 293.—PROXIMAL END OF TIBIA WITH MENISCI AND ATTACHED PORTIONS OF CRUCIATE LIGAMENTS.

Meniscus Medialis.—The **medial meniscus** (Figs. 292 and 293) forms very nearly a semicircle. It is attached by its anterior horn to the non-articular surface on the head of the tibia, in front of the tibial attachment of the anterior cruciate ligament, and by its posterior horn to the non-articular surface immediately in front of the tibial attachment of the posterior cruciate ligament. The deep or posterior part of the tibial collateral ligament is attached to its periphery.

Meniscus Lateralis.—The **lateral meniscus** (Figs. 292 and 293) is attached by its anterior horn to the non-articular surface of the tibia in front of the intercondyloid eminence, where it is placed to the lateral side, and partly under cover of the tibial end of the anterior cruciate ligament. By its posterior horn it is attached to the interval between the two tubercles which surmount the intercondyloid eminence, *i.e.* in front of the attachment of the posterior horn of the meniscus medialis. This fibro-cartilage, with its two horns, therefore forms almost a complete circle. Posteriorly it is attached by its periphery to the posterior ligament, but on the lateral side it is separated from the fibular collateral ligament by the tendon of the popliteus muscle, and on this aspect its periphery is free.

The two horns of the lateral meniscus are embraced by the two horns of the medial meniscus, and, while the anterior cruciate ligament has its tibial attachment almost between the anterior horns of the two menisci, the tibial attachment of the posterior cruciate ligament is situated behind the posterior horns of the two menisci.

Both menisci possess certain accessory attachments. Thus the lateral meniscus sends a large bundle of fibres from its convex posterior border to augment the posterior aspect of the posterior cruciate ligament by which these fibres are

conducted to the femur. Again, the convex or peripheral margins of each meniscus possess certain attachments to the deep surface of the fibrous stratum of the capsule on its medial and posterior aspects, as has already been explained, but, in addition, they are attached to the non-articular circumference of the tibial head by short fibrous bands known as the **ligamenta coronaria.** Lastly, a rounded band which varies in strength, the **lig. transversum genu (transverse ligament)** (Figs. 290 and 293), stretches between the anterior convex margins of the two menisci, crossing the front part of the non-articular area on the tibial head in its course.

The **stratum synoviale** of the knee-joint is not only the largest, but the most elaborately arranged of its kind in the body. It not only lines the fibrous stratum of the capsule articularis, but it forms a more or less extensive covering for the intracapsular ligaments and the free surface of the **infra-patellar pad of fat.** This pad acts as a wedge which fits into the interval between the patella, tibia, and femoral condyles, and the synovial stratum upon its surface forms a band or fold which extends from the region distal to the level of the patellar articular surface to the anterior part of the intercondyloid notch. It is named the **plica synovialis patellaris.** At its femoral end it is narrow and attenuated, but at its patellar end it expands on each side to form wing-like fringes or membranes—the **plicæ alares**—medial and lateral. These folds are more or less loaded with fat.

Apart from these special foldings, the synovial stratum lines the deep surface of the common extensor tendon, and extends for a variable distance proximal to the patella. This extension of the articular cavity almost always communicates with a large bursa situated still more proximally on the front of the femur. Tracing the synovial stratum distally, it will be found to cover both surfaces of the two menisci. The peripheral or convex margins of these menisci are only covered by this membrane where they are unattached to the capsule. A prolongation invests the intracapsular portion of the tendon of the popliteus muscle, and separates this tendon from the posterior part of the tibial head, besides intervening between the lateral meniscus and the head of the tibia.

From the posterior part of the articular cavity the synovial stratum extends forwards, and provides a partial covering for the cruciate ligaments between which a bursa may be found.

This somewhat complicated arrangement of the synovial stratum may be readily comprehended if it is borne in mind that it really represents the fusion of three separate synovial cavities, which in some animals are permanently distinct. These are indicated in the two femoro-tibial and the single femoro-patellar parts of the articulation.

The articular cavity may communicate with **bursæ** situated in relation to the medial head of the gastrocnemius muscle and the tendon of the semi-membranosus muscle, besides the large supra-patellar bursa already described. Lastly, there may be intercommunication between this articular cavity and that of the proximal tibio-fibular articulation.

Movements at the Knee-Joint.—In studying the movements which may occur at the human knee-joint, it is necessary to bear in mind that the lower limb of man is primarily required for purposes of support and locomotion. The principal requirement of the former function is stability accompanied by rigidity, whereas in the latter function the special desideratum is regulated and controlled mobility. Thus, in the same joint, two entirely opposite conditions have to be provided. The stable conditions of support are chiefly concerned in the maintenance of the erect attitude, and the mechanism associated therewith does not call for the exertion of a large degree of sustained muscular effort.

In standing erect the attitude of the limb is that of extension, which mainly concerns the femoro-tibial parts of the joint. In this position the force of gravity acts along a vertical line which falls in front of the transverse axis of the joint, and therefore any tendency to flexion, *i.e.* bending backwards, is mechanically counteracted by the application of a force which tends to produce bending forwards (so-called over-extension). This, however, is absolutely prohibited in normal states of the joint, by the tension of the posterior and collateral ligaments aided by the anterior cruciate ligament. The value of this fact may be seen by observing the effect produced by giving the joint a sudden push from behind, which causes an immediate reversal of the positions of the transverse and vertical axes, whereby the body weight at once produces flexion of the joint.

The menisci and the infra-patellar pad of fat also assist in maintaining extension, by reason of their close adaptation to, and packing round the condyles as these rest upon the tibia.

The anterior margin of the intercondyloid fossa is also brought into contact with the front of the anterior cruciate ligament.

In the position of extension the patella is retained at such a proximal level in relation to the trochlear surface of the femur, that the distal articular facets of the patella are in contact with the trochlea.

During locomotion the movements of the knee-joint are somewhat intricate, for both the femoro-tibial and the femoro-patellar sections of the joint are brought into action. The principal movement which results is flexion, with which there is associated, both at its beginning and ending, a certain amount of screw movement or rotation. Flexion and rotation occur at the femoro-tibial sections of the joint, whereas the movement at the femoro-patellar portion produces a regulating and controlling influence upon flexion.

Taking these factors separately, we observe that each femoral condyle adapts itself to a shallow cup formed by the corresponding tibial condyle and meniscus, and as the two femoral condyles move simultaneously and parallel to each other, there is more than the characteristic hinge-joint action, for each femoral condyle glides and rolls in its cup "like a wheel restrained by a drag" (Goodsir) when the movement of bending occurs. Thus the different parts of the condyles are successively brought into relation with the transverse axis of the joint while it passes from extension to flexion and *vice versa*. From the fact that the medial femoral condyle is longer, antero-posteriorly, than the lateral, it is believed that extension is completed by a movement of rotation whereby the joint becomes locked, and the anterior cruciate, the posterior and the collateral ligaments, become tense. A similar rotation initiates the movement of flexion, and unlocks the joint by relaxing the ligaments just mentioned.

Since the tibia and foot are fixed in the act of walking, it is the femur which rotates upon the tibia in passing from extension to flexion and *vice versa*; and as relaxation of the ilio-femoral ligament is essential for this rotation, some observers are of opinion that the body weight falls behind the transverse axis of the knee-joint, as in the case of the hip-joint, and consequently that extension of the knee-joint is maintained by the ilio-femoral ligament, as it is not possible to bend the knee without first having bent the hip-joint.

During flexion and extension the menisci glide along with the condyles, so as to maintain their close adaptation and preserve their value as packing agents. When the movement of flexion is completed, the condyles are retained upon the tibia, and prevented from slipping off by the tension of the posterior cruciate ligament. In this position a small degree of rotation of the tibia, both medially and laterally, is also permissible.

The regulating and controlling influence of the femoro-patellar portion of the articulation is brought into play during the movements of flexion and extension. In the latter position the distal pair of patellar facets is in apposition with the proximal part of the femoral trochlea. As flexion advances, the middle pair of facets adapt themselves to a deeper area of the trochlea, into which the patellar keel fits. When flexion is still further advanced, the proximal pair of patellar facets will be found fitting into that part of the trochlea adjoining the intercondyloid notch; and finally, when flexion is complete, the patella lies opposite the intercondyloid notch, while the forward thrust of the longer medial femoral condyle brings its semilunar facet (Goodsir) into apposition with the somewhat vertical facet at the medial border of the patella. The wedge-like influence of the patella is most marked, for it is only in the position of extension that it can be moved from side to side. The movements of the patella may be described as gliding and co-aptation, as it slips or rocks from one pair of facets to another in its progress along the trough of the femoral trochlea.

ARTICULATIONES TIBIOFIBULARES.

The Tibio-Fibular Joints.—The proximal and distal ends of the fibula articulate with the tibia. Primarily, the fibula is required to form a strong lateral support for the ankle-joint, and therefore its articulations are so arranged as to provide a certain amount of elasticity without any sacrifice of the rigidity necessary for security. Hence the amount of movement is very small, but what there is enables these joints to be classified as arthrodial diarthroses.

Articulatio Tibiofibularis.—The **proximal tibio-fibular joint** is formed, on the one hand, by a flat oval or circular facet which is situated upon the postero-lateral aspect of the lateral condyle of the tibia, and is directed distally and posteriorly; on the other hand, by a similar facet on the proximal surface of the head of the fibula in front of the apex capituli.

An articular capsule (Fig. 292) invests the joint, and it may be regarded as holding the articular surfaces in apposition, although certain special bands receive separate designations. Occasionally there is an opening in the stratum fibrosum by which communication is established between the articular cavity and the knee-joint, through the intermediation of the synovial prolongation, subjacent to the tendon of the popliteus muscle.

The proximal epiphyseal line of the fibula is extra-capsular.

Lig. Capituli Fibulæ Anterius.—The **anterior ligament of the head of the fibula** (Fig. 290) is a strong flat band whose fibres extend from the anterior aspect of the fibular head, proximally and medially, to the adjoining part of the lateral condyle of the tibia.

Lig. Capituli Fibulæ Posterius.—The **posterior ligament of the head of the fibula** (Fig. 292) is a similar, but weaker band, passing, proximally and medially, from the posterior aspect of the fibular head to the posterior aspect of the lateral condyle of the tibia, where it is attached immediately distal to the opening in the capsule of the knee-joint, from which the tendon of the popliteus muscle escapes.

Equally strong but much shorter bands are found on the lateral and medial aspects of the joint. The former is intimately associated with the tendon of the

biceps flexor cruris muscle which strengthens the lateral aspect of the joint, and here also is found the occasional opening by which it communicates with the knee-joint.

The **synovial stratum** is in certain cases continuous with that of the knee-joint in the manner already described.

Membrana Interossea Cruris.—The **interosseous membrane** (Figs. 290 and 294) plays the part of an accessory ligament both for the proximal and the distal tibio-fibular joints. It is attached to the interosseous borders on the shafts of the tibia and fibula, and binds them together. The general direction of its fibres is from the tibia distally and laterally to the fibula, but many fibres pass in the opposite direction. The membrane may extend upwards until it comes into contact with the ligaments of the proximal tibio-fibular joint, but there is always a vertical

oval aperture in its proximal part for the passage of the anterior tibial vessels. This aperture (Fig. 290), which is about one inch long, adjoins the shaft of the fibula at a point rather less than one inch distal to its head. Towards the distal end of the leg the distance between the tibia and the fibula rapidly diminishes, and consequently the width of the interosseous membrane is correspondingly reduced, and it is tense throughout its entire length. In the distal part of the membrane there is a small opening for the passage of the perforating peroneal vessels. There is no sharply marked demarcation between the interosseous membrane and the interosseous ligament which connects the distal ends of the tibia and fibula—the one, indeed, may be said to run into the other.

Syndesmosis Tibiofibularis.—The **distal tibio-fibular joint** is not on all occasions provided with articular cartilage, so that it may either be a separate articulation, or it may merely present a series of ligaments which are accessory to the (ankle-joint), because it is clear that, under any circumstances, the object aimed at in this articulation is to obtain additional security for the ankle-joint. The articular surface on the tibia, when present, constitutes a narrow articular strip on the lateral side of the distal end of the bone, and the joint-cavity is practically an upward extension of the ankle-joint. The corresponding fibular facet is continuous with the extensive articular area, by means of which the fibula articulates with the talus. By far the greater part of the opposing surfaces of tibia and fibula are, however, non-articular and rough.

The supporting **ligaments** are of great strength.

Lig. Malleoli Lateralis Anterius.—The **anterior ligament of the lateral malleolus** (Fig. 297) consists of strong fibres which pass obliquely distally and laterally from the front of the distal end of the tibia to the front of the lateral malleolus.

Lig. Malleoli Lateralis Posterius.—The **posterior ligament of the lateral malleolus** (Figs. 294 and 297) is equally strong, and passes in a similar direction between corresponding posterior surfaces.

Lig. Malleoli Lateralis Distale.—The **distal ligament of the lateral malleolus** (Figs. 294 and 297) stretches between the posterior border of the distal end of the tibia and the proximal end of the pit on the medial and posterior aspect of the lateral malleolus.

Ligamentum Interosseum.—An **interosseous ligament**, powerful and somewhat extensive, connects the contiguous rough non-articular surfaces. Proximally, as already mentioned, it is continuous with the interosseous membrane. Anteriorly and posteriorly it comes into contact with the more superficial ligaments. Distally it descends until it comes into intimate association with the articular cavity.

A **synovial stratum** is found lining the small articular cavity, but it is always a direct prolongation from that which lines the ankle-joint.

ARTICULATIONES PEDIS.

ARTICULATIO TALOCRURALIS.

The **ankle-joint** is a ginglymus variety of a diarthrosis. The bones which enter into its formation are the distal ends of the tibia and fibula, with the articular areas on the superior, lateral, and medial surfaces of the talus. The tibia and fibula, aided by the distal ligament of the lateral malleolus, form a three-sided socket within which the talus is accommodated. The roof or most proximal part of the socket, which is wider in front than behind, is formed, chiefly, by the quadrilateral articular surface on the distal end of the tibia, but towards its postero-lateral margin the distal ligament of the lateral malleolus assists in its formation. There also the tibial articular surface is continuous with the narrow articular facet already described as forming part of the tibio-fibular syndesmosis. The medial wall of the socket is formed by the articular facet on the lateral side of the medial malleolus, and there is no interruption of the articular cartilage between the roof and medial wall. The lateral wall of the socket is quite separate from the foregoing parts, and consists of a large triangular facet upon the medial side

of the lateral malleolus. This facet is situated immediately in front of the deep pit which characterises the posterior part of this surface of the fibula.

A small lunated facet is frequently found upon the anterior surface of the distal end of the tibia, particularly among those races characterised by the adoption of the "squatting" posture. When this facet exists it is continuous with the anterior margin of the roof of the socket, and it articulates with a similar facet upon the superior surface of the neck of the talus in the extreme flexion of the ankle-joint which "squatting" entails.

The articular surface upon the body of the talus adapts itself to the tibio-fibular socket, and presents articular facets corresponding to the roof and sides of the socket. Thus the superior surface of the talus possesses a quadrilateral articular area, wider in front than behind, distinctly convex in the antero-posterior direction, and slightly concave transversely. In addition, towards its postero-lateral margin, there is also a narrow antero-posterior facet corresponding to the distal ligament of the lateral malleolus. The articular cartilage of this superior surface is continued without interruption to the tibial and fibular sides of the bone, although the margins of the superior area are sharply defined from the facets on the sides, the lateral of which is triangular in outline, while the medial is piriform, but in each case the surface is vertical.

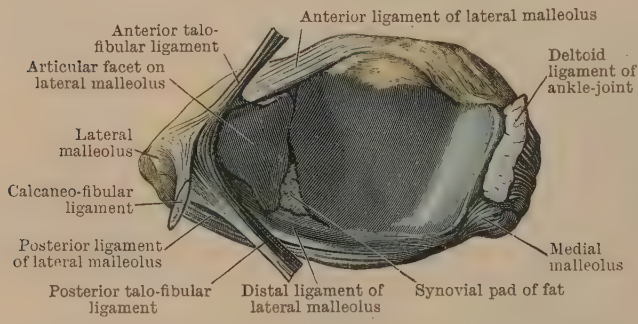

FIG. 295.—ARTICULAR SURFACES OF TIBIA AND FIBULA WHICH ARE OPPOSED TO THE TALUS.

Ligaments.—The ligaments form a complete investment for the joint, *i.e.* a *fibrous stratum* of an **articular capsule** in which the individual parts vary considerably in strength, and are described under separate names. Their proximal attachments are restricted to the epiphysis of the distal end of the tibia but lie proximal to the epiphyseal line of the fibula (Fig. 228). Therefore the epiphyseal line of the tibia is extra-capsular and that of the fibula partly intra-capsular.

The **anterior ligament** is an extremely thin membrane, containing very few longitudinal fibres. It extends from the distal border of the tibia to the dorsal border of the head of the talus, passing in front of a pad of fat which fills up the hollow above the neck of that bone.

The **posterior ligament** is attached to contiguous non-articular borders of the tibia and talus. Many of its fibres radiate medially from the lateral malleolus. This aspect of the joint is strengthened by the strong, well-defined, distal ligament of the lateral malleolus already described in connexion with the tibio-fibular syndesmosis.

The **lateral ligament** (Figs. 294, 295, and 297) is very powerful, and is divisible into three fasciculi, which are distinguished from each other by names, descriptive of their chief points of attachment.

Lig. Talofibulare Anterius.—The **anterior fasciculus** is the shortest. It extends from the anterior border of the lateral malleolus to the talus immediately in front of its lateral articular surface.

Lig. Calcaneofibulare.—The **middle fasciculus** is a strong and rounded cord. It is attached by one end to the front of the tip of the lateral malleolus, and by the other to the lateral side of the calcaneus immediately proximal and posterior to the groove for the peroneal tendons.

Lig. Talofibulare Posterius.—The **posterior fasciculus** is the strongest. It runs transversely between the distal part of the fossa on the medial aspect of the fibular malleolus and the posterior surface of the talus, where it is attached to the posterior process and the adjoining rough surface. Sometimes this process is detached from the talus, and represents a separate bone—the *os trigonum*.

Lig. Deltoideum.—The **deltoid ligament** is the **medial ligament** of the ankle-joint (Figs. 295 and 296). It has the general shape of a delta, and is even stronger

than the lateral ligament. It is attached proximally to a marked impression on the distal part of the medial malleolus, and below, in a continuous layer, to the navicular, talus and calcaneus. In it we may recognise the following special bands—(*a*) the *lig. talotibiale anterius*, which extends from the front of the medial malleolus to the neck of the talus; (*b*) the *lig. talotibiale posterius*, stretching between the back of the medial malleolus and the postero-medial rough surface of the talus; (*c*) the *lig. tibionaviculare*, which extends from the tip of the medial malleolus to the medial side of the navicular bone; (*d*) the *lig. calcaneotibiale*, which extends between the tip of the medial malleolus and the medial side of the sustentaculum tali; (*e*) *lig. talotibiale profundum*, which consists of deeper fibres extending from the tip of the medial malleolus to the medial side of the talus.

A **synovial stratum** lines the fibrous stratum of the articular capsule and, as

already described, the articular cavity extends into the interval between the tibia and fibula distal to the tibio-fibular interosseous ligament. Both at the front and back of the ankle-joint, as well as proximally in the angle formed by the three bones, the synovial membrane covers pads of fat.

Movements at the Ankle-Joint.—In the erect attitude the foot is placed at right angles to the leg; in other words, the normal position of the ankle-joint is **flexion**. Those movements which tend to diminish the angle so formed by the dorsum of the foot and the front of the leg are called **dorsiflexion**, while those which tend to increase the angle, *i.e.* to straighten the foot upon the leg, are called **extension**. As a matter of fact neither dorsiflexion nor extension is ever completely carried out, and the range of movement of which the foot is capable is limited to about 90°. These movements occur about an obliquely transverse axis, as is indicated by the natural lateral pointing of the toes. The weight of the body falls slightly anterior to the ankle-joint, so that a certain amount of muscular action is necessitated in order to maintain the foot at right angles to the leg; but additional stability is obtained from the obliquity above mentioned.

When the foot is raised from the ground, muscular action tends naturally to produce a certain amount of extension. When the foot is extended, as in standing on the toes, the posterior narrow part of the talus moves forwards into the wider part of the interval between the tibia and fibula, whereas in dorsiflexion, as in raising the anterior part of the foot from the ground, the widest part of the talus is forced back between the tibia and fibula; but notwithstanding the difference between these two movements, the fibula remains in close contact with the talus by reason of the action of the distal ligament of the lateral malleolus and the posterior talo-fibular ligament, so that lateral movement is prevented.

It is doubtful whether lateral movement at the ankle-joint can be obtained by any natural movement of the foot, although it is generally believed that in the position of partial extension a small amount of side-to-side movement may be produced by the application of external force. "This apparent play" of the ankle-joint during extension "is really due to oscillation of the small bones of the foot on each other, largely of the navicular on the talus, but also of the cuboid on the calcaneus. Excessive mobility of these latter is restrained by an important function of the posterior tubercle of the cuboid which locks into a notch in the calcaneus" (Blake).

ARTICULATIONES INTERTARSEÆ.

The **intertarsal joints** are all diarthroses in which the gliding movement is characteristic, as in the carpus. With the view of obtaining a proper conception of the many beautiful mechanical principles involved in the construction of the foot, it is necessary to study these articulations with considerable attention to detail.

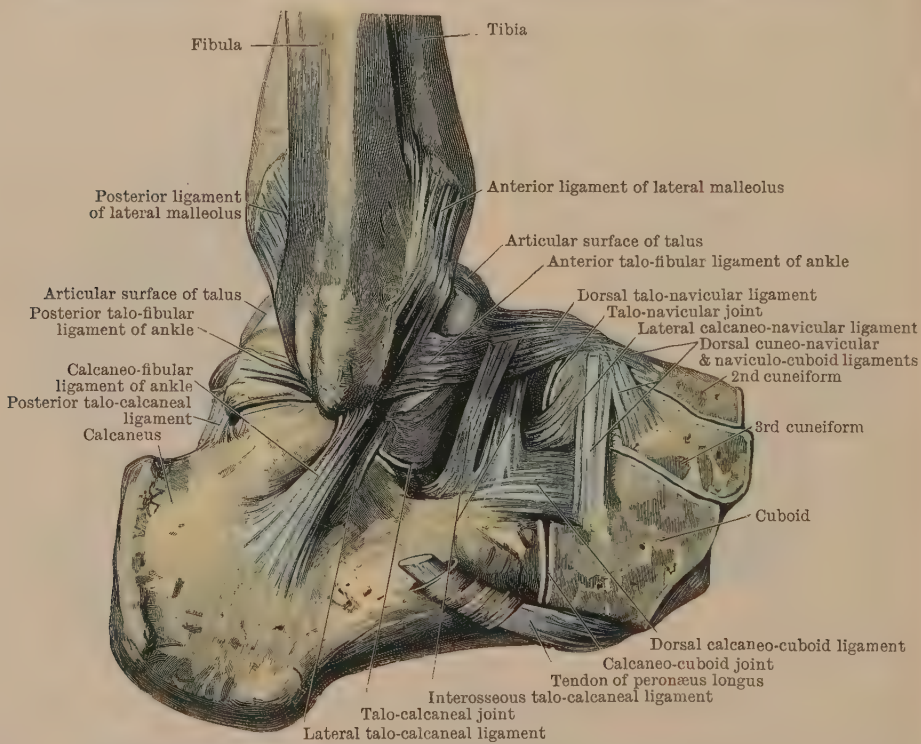

FIG. 297.—LIGAMENTS ON THE LATERAL ASPECT OF THE ANKLE-JOINT AND ON THE DORSUM OF THE TARSUS.

Articulatio Talocalcanea.—The talus and calcaneus articulate with each other in the **talo-calcaneal joint.**

This joint is situated between the inferior facet on the body of the talus and a corresponding facet on the middle of the superior aspect of the calcaneus. On each bone the articulation is limited in front by a wide, deep groove which runs obliquely across each bone from the medial to the lateral side and forwards.

The supporting and investing ligaments form the fibrous stratum of an **articular capsule**, consisting for the most part of short fibres, but the joint derives additional strength from the calcaneo-fibular ligaments of the ankle-joint. The fibrous stratum of the capsule is subdivided into the following talo-calcaneal bands:—

The **ligamentum talocalcaneum anterius** consists of a band of short fibres placed immediately in relation to the anterior end of the deep groove which bounds the articular facets. They are attached to the antero-lateral aspect of the neck of the talus, from which they extend downwards to the adjacent superior surface of the calcaneus.

The **ligamentum talocalcaneum laterale** (Fig. 297) is in continuity with the posterior border of the preceding ligament, and it is placed parallel to, but on

a deeper plane than, the calcaneo-fibular ligament of the ankle-joint. It consists of short fibres passing between the adjacent rough lateral margins of the two bones.

The **ligamentum talocalcaneum posterius** (Fig. 297) closes the joint-cavity on its posterior aspect. It consists of fibres which radiate from the posterior aspect of the posterior process of the talus to the superior surface of the calcaneus, immediately behind the articular facet.

The **ligamentum talocalcaneum mediale** lies obliquely on the medial side of the joint, and consists of fibres which extend from the medial posterior tubercle of the talus to the posterior roughened border of the sustentaculum tali. Some of its fibres become continuous with the plantar calcaneo-navicular ligament.

The **ligamentum talocalcaneum interosseum** (Fig. 298) closes the antero-medial aspect of the joint. It is the strongest of the series of ligaments entering into

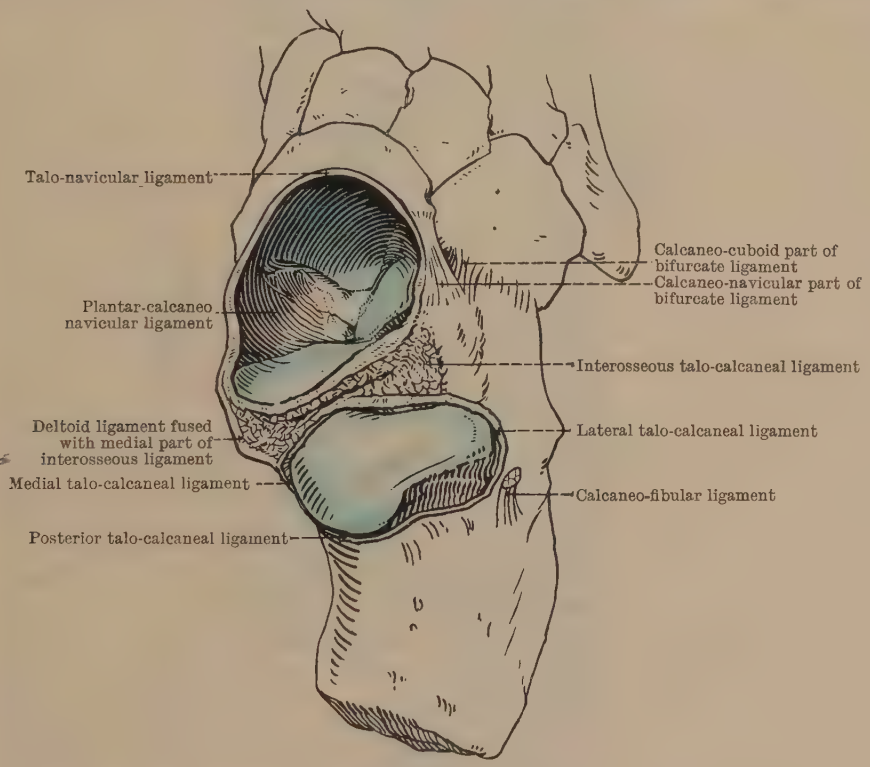

FIG. 298.—THE LIGAMENTS OF THE POSTERIOR CALCANEO-TALOID AND THE CALCANEO-TALO-NAVICULAR JOINTS (seen from above after removal of the Talus).

the capsule. Compared with it the other bands are, comparatively speaking, insignificant. Its attachments are to the bottom of each groove, so that it occupies the tarsal canal formed by these opposing grooves.

A **synovial stratum** lines the fibrous stratum, and it is distinct from other tarsal synovial membranes.

Articulatio Talocalcaneonavicularis.—This is one of the most important of the joints of the foot, not only because the talus is here situated in relation to the summit of the antero-posterior arch of the foot, but because the head of the talus is received into a composite socket made up of the sustentaculum tali, the navicular, and the plantar calcaneo-navicular ligament.

The articular surface on the head of the talus presents anteriorly a convex rounded facet for articulation with the navicular, inferiorly a convex facet which rests upon the sustentaculum tali, and intermediate between these two there is a triangular facet which articulates with the plantar calcaneo-navicular ligament. All these facets are in continuity with each other, and are in front of the

groove on the inferior surface of the talus. Occasionally a fourth narrow facet is found along the lateral and posterior part of the articular surface of the head of the talus, whereby it articulates with the calcaneo-navicular part of the bifurcate ligament.

The navicular bone presents a shallow, cup-shaped, articular cavity towards the head of the talus.

The articular surface of the sustentaculum tali is concave, and is usually marked off into two facets.

Two ligaments play an important part in binding together the calcaneus and

FIG. 299.—PLANTAR ASPECT OF TARSAL AND TARSO-METATARSAL JOINTS.

the navicular, although these bones do not directly articulate; and further, these ligaments provide additional articular surfaces for the head of the talus. These are the two following:—

(*a*) The **ligamentum calcaneonaviculare plantare** (Figs. 298 and 299) is an extremely powerful fibro-cartilaginous band. It extends between the anterior margin of the sustentaculum tali and the plantar surface of the navicular. Certain of its upper fibres radiate upwards on the medial surface of the navicular, and become continuous with the tibio-navicular portion of the deltoid ligament of the ankle-joint. The plantar aspect of this ligament is in contact with the tendon of the tibialis posterior muscle, through which the head of the talus receives great support. Superiorly it contributes an articular surface which forms a triangular portion of the floor of the composite socket in which the head of the talus is received.

(*b*) The **calcaneo-navicular part of the bifurcate ligament** (Fig. 298) lies deeply in the front part of the sinus tarsi, *i.e.* the interval between the talus and calcaneus. Its fibres are short, and extend from the dorsal surface of the front part of the calcaneus, immediately to the lateral side of the sustentacular facet, forwards to the lateral side of the navicular bone. Frequently the ligament presents a surface which articulates with the head of the talus, and in these cases it forms a part of the composite socket.

The cavity of the talo-calcaneo-navicular joint is closed posteriorly by the interosseous talo-calcaneal ligament already described. On its medial and lateral inferior aspects it is closed by the calcaneo-navicular ligaments.

The superior and lateral aspects are covered by the **ligamentum talonaviculare dorsale**. This ligament is thin, and extends from the proximal non-articular area on the head of the talus to the dorsal surface of the navicular bone. It may be subdivided into *dorsal*, *lateral*, and *medial* **talo-navicular bands** (Fig. 297), which, with the calcaneo-navicular and interosseous talo-calcaneal ligaments, complete the capsular investment of the joint.

A distinct **synovial stratum** lines all parts of the capsule of the joint.

Articulatio Calcaneocuboidea.—This is situated between the anterior concavo-convex surface of the calcaneus and the posterior similar surface of the cuboid.

The **ligaments** which invest this joint constitute a **calcaneo-cuboid capsule**, whose parts are arranged in relation to the four non-articular sides of the cuboid bone, and are especially strong upon the plantar aspect, in relation to their great importance in resisting strains.

The **medial calcaneo-cuboid ligament** occupies part of the interval between the talus and calcaneus—the sinus tarsi. It is the *calcaneo-cuboid part* of the **lig. bifurcatum**, and is a V-shaped structure, of which the single end is attached to the calcaneus, and the double ends separate to reach contiguous areas on the navicular and cuboid respectively.

The **dorsal calcaneo-cuboid ligament** (Fig. 297) is a broad portion of the fibrous stratum of the capsule extending from the dorsal and lateral surfaces of the calcaneus to the dorsal surface of the cuboid.

The **lateral calcaneo-cuboid ligament** is another but narrower part of the capsule which extends from the lateral aspect of the calcaneus to the lateral side of the cuboid, immediately behind the facet on the tuberosity.

The **inferior calcaneo-cuboid ligament** consists of two parts—a superficial and a deep. The superficial series of fibres, the **long plantar ligament** (Fig. 299), is attached to the plantar surface of the calcaneus in front of the processes of the tuber calcanei. It forms a long powerful structure which runs forwards to be fixed to the plantar surface of the cuboid ridge, but many of its fibres pass superficial to the tendon of the peronæus longus, and extend to the bases of the third, fourth, and fifth metatarsal bones.

The deep series of fibres, the **plantar calcaneo-cuboid ligament** (Fig. 299), is distinctly separated from the long plantar ligament by a layer of areolar tissue. It forms a broad but short band of great strength, which is attached to the plantar surface of the distal end of the calcaneus, and extends to the plantar surface of the cuboid just behind the ridge. Both of these ligaments are of great importance in maintaining the longitudinal arch of the foot, and in this respect are only second to the plantar calcaneo-navicular ligament.

A **synovial stratum** lines the capsule.

Articulatio Tarsi Transversa (Choparti).—This is a term sometimes applied to the talo-navicular and calcaneo-cuboid joints. These articulations do not communicate with each other; and although there is an occasional direct articulation between the navicular and cuboid, it does not constitute an extension of the transverse tarsal joint, but is a prolongation from the series of cuneo-navicular and cuneo-cuboid articulations.

Nevertheless there is always a set of **ligaments** which bind the navicular and cuboid bones together, and these may be regarded as accessory to the various transverse tarsal joints.

The **dorsal cuboideo-navicular ligament** (Fig. 297) consists of short oblique fibres which attach the contiguous dorsal surfaces of the cuboid and navicular bones.

The **plantar cuboideo-navicular ligament** is transverse in direction, and extends between adjacent plantar areas of the cuboid and navicular bones.

The **interosseous cuboideo-navicular ligament** intervenes between contiguous surfaces of the same bones. When there is an extension of the cuneo-navicular joint backwards between the navicular and cuboid, it is situated in front of the last-mentioned ligament, and is called the **articulatio cuboideonavicularis**. Around this joint the preceding ligaments are grouped. Since, however, the joint is inconstant while the ligaments are always present, it is preferable to consider them as above indicated.

Articulatio Cuneonavicularis.—The **cuneo-navicular articulation** is situated between the navicular and the three cuneiform bones. The anterior surface of the navicular presents a facet for each of the cuneiform bones, but its articular sufrace is not interrupted. These facets form a somewhat convex anterior surface which fits into the shallow articular concavity presented by the proximal ends of the three cuneiform bones. This joint may be extended by the occasional cuboideo-navicular articulation already referred to.

The **fibrous stratum** of the **articular capsule** is composed of short strong bands which are distinctly visible on all sides except towards the cuboid bone, where the joint may communicate with the cuneo-cuboid and cuboideo-navicular joints. Anteriorly the joint communicates with the intercuneiform articulations. The dorsal parts of the capsule are short longitudinal bands termed **dorsal cuneo-navicular ligaments** (Figs. 296 and 297). These extend without interruption to the medial aspect of the joint. Inferiorly there are similar bands, known as **plantar cuneo-navicular ligaments**, also longitudinal in direction, but intimately associated with offsets from the tendon of the tibialis posterior muscle.

The **synovial stratum** which lines the fibrous stratum sends prolongations forwards on each side of the second cuneiform bone, and in addition it often communicates with the cuneo-cuboid joint cavity (Fig. 300). It always communicates with the cuboideo-navicular cavity when that joint exists.

Articulationes Intercuneiformeæ.—These are two in number, and exist between adjacent contiguous surfaces of the three cuneiform bones. These surfaces are partly articular and partly non-articular. The small size of the second cuneiform bone allows the first cuneiform as well as the third cuneiform to project forwards beyond it, one on each side, and therefore the articular surfaces turned towards the second cuneiform are not entirely occupied by that bone. They form a recess facing the metatarsus, into which the base of the second metatarsal bone is thrust (Fig. 300).

Ligamenta intercuneiformea dorsalia constitute fairly strong transverse bands which extend between adjacent dorsal surfaces and invest the joint cavities in this direction.

The **ligamenta intercuneiformea plantaria** are two strong bands which pass from the rough non-articular areas on opposite sides of the second cuneiform to the opposing surfaces of the first and third cuneiform bones. These ligaments shut in the joint cavities inferiorly, and also anteriorly in the case of the lateral of the two joints.

The **ligamenta intercuneiformea interossea** are bands which bind together adjacent cuneiform bones.

The **synovial stratum** is continuous with that which lines the cuneo-navicular joint, and it is prolonged through the medial inter-cuneiform joint into the tarso-metatarsal series of joints.

Articulatio Cuneocuboidea.—This occurs between the rounded or oval facets on the opposing surfaces of the cuboid and third cuneiform.

The **ligamentum cuneocuboideum dorsale** is a flat, somewhat transverse band which closes the joint on its dorsal aspect, and extends between the dorsal surfaces of the two bones.

The **ligamentum cuneocuboideum plantare** is difficult to determine. It is

situated deep to the long plantar ligament, and extends between adjacent rough surfaces of the two bones.

The **ligamentum cuneocuboideum interosseum** is the strongest. It closes the joint cavity anteriorly, and is attached to the contiguous non-articular surfaces of the two bones.

The **synovial stratum** is frequently distinct, but at other times the joint cavity communicates with those of the cuneo-navicular and cuboideo-navicular articulations.

Synovial Strata of the Intertarsal Joints.—Four and sometimes five distinct and separate synovial strata may thus be enumerated in connexion with the tarsal articulations, viz.: (1) talo-calcaneal; (2) talo-calcaneo-navicular; (3) calcaneo-cuboid; (4) cuneo-navicular and its extensions (Fig. 300); (5) occasionally cuneo-cuboid.

ARTICULATIONES TARSOMETATARSEÆ.

The **tarso-metatarsal joints** are found between certain articular facets on the cuboid and three cuneiform bones on the one hand, and others on the bases of the five metatarsal bones. These articulations are associated with three distinct synovial cavities—namely, a medial, lateral, and intermediate.

(1) The **medial tarso-metatarsal articulation** occurs between the anterior convex reniform surface of the first cuneiform bone and the concavo-reniform surface on the posterior aspect of the base of the first metatarsal bone.

Ligaments which form the fibrous stratum of the **articular capsule** surround the articulation. In the capsule the **ligamenta tarsometatarsea dorsalia et plantaria** are its strongest parts, but it is not deficient either on the medial or on the lateral aspects.

A separate **synovial stratum** lines the fibrous stratum.

(2) The **intermediate tarso-metatarsal articulation** is an elaborate joint. It involves the three cuneiform bones and the bases of the second, third, and part of the fourth metatarsal bones.

The articulation presents the outline of an indented parapet both on its tarsal and its metatarsal aspects. Thus, on its tarsal side, the first and the third cuneiform bones project in front of the second cuneiform, so that the latter only presents a distal surface to the articulation; while the first cuneiform presents a portion of its lateral surface, and the third cuneiform presents both its distal and portions of its lateral and medial surfaces, since it projects in front of the cuboid bone. On its metatarsal side the base of the second metatarsal bone fits into the indentation between the third and first cuneiforms, to which it presents lateral and medial articular facets, but its posterior facet rests upon the anterior facet of the second cuneiform. The base of the third metatarsal bone rests its posterior facet upon the third cuneiform. The fourth metatarsal base presents part of its medial facet to the lateral side of the third cuneiform. In this way the indentations alternate on the two sides of the articulation, and an extremely powerful interlocking of parts is provided, which places any marked independent movement of these metatarsal bones entirely out of the question.

The **ligamenta tarsometatarsea dorsalia** are broad, flat bands which represent the most distinct part of the fibrous stratum of an investing **articular capsule.** They pass from behind forwards, and while the second metatarsal bone receives three, *i.e.* one from each cuneiform, the third metatarsal only receives one—from the third cuneiform.

The **ligamenta tarsometatarsea plantaria** correspond with the foregoing in their general arrangement, but they are weaker. That for the second metatarsal is the strongest. Oblique bands extend from the first cuneiform bone to the second and third metatarsals.

The **ligamenta cuneometatarsea interossea** are three in number. The *medial* connects the lateral side of the first cuneiform with the medial side of the base of the second metatarsal bone. The *middle* connects the medial side of the third cuneiform with the lateral side of the base of the second metatarsal. The *lateral* connects the adjacent lateral sides of the third cuneiform and fourth metatarsal.

The **stratum synoviale**, which lines this articulation, sends a prolongation backwards between the first and second cuneiform bones, where it opens into the cuneo-navicular joint. It is likewise prolonged forwards upon both sides of each of the bases of the second and third metatarsal bones.

(3) The **lateral tarso-metatarsal articulation** is found between the proximal

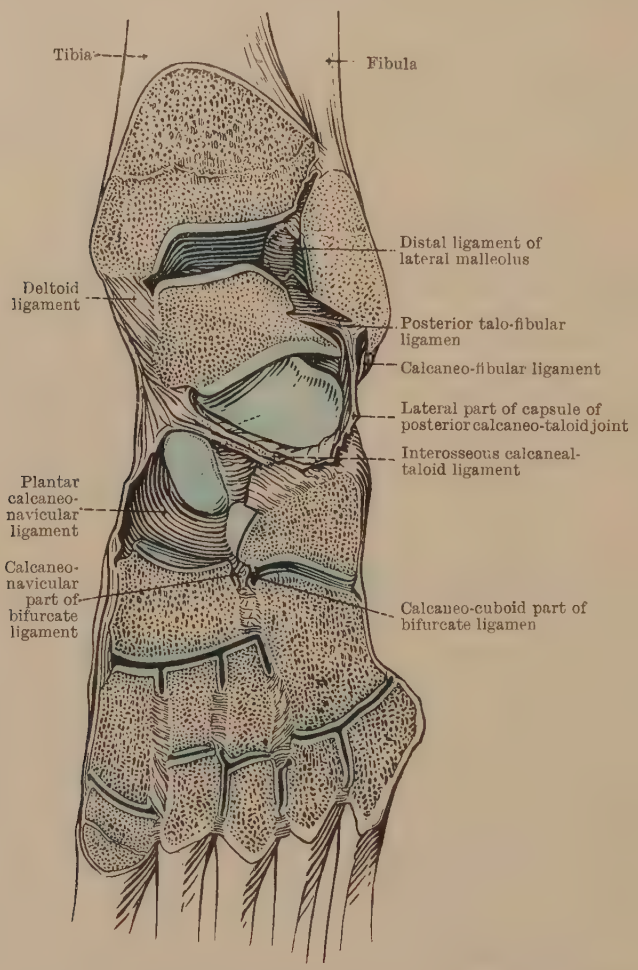

FIG. 300.—SECTION SHOWING THE JOINT CAVITIES OF THE ANKLE AND THE REGION OF THE TARSUS.

The communication between the medial inter-cuneiform joint and the tarso-metatarsal joint is not shown.

surfaces of the bases of the fourth and fifth metatarsal bones and the distal surface of the cuboid (Fig. 300).

The fibrous stratum of the investing **articular capsule** may be resolved into the following ligaments :—

The **ligamenta tarsometatarsea dorsalia** resemble those already described. The base of the fourth metatarsal receives one from the third cuneiform and one from the cuboid. The base of the fifth metatarsal receives one from the cuboid.

The **ligamenta tarsometatarsea plantaria** are the weakest bands of the series, and consist of scattered fibres passing from the cuboid to the bases of the two metatarsals. Some fibres, which are almost transverse, extend from the third cuneiform to the fifth metatarsal, and additional fibres reach the fifth metatarsals from the long plantar ligament.

Occasionally the tarsal end of the ligamentum cuneometatarseum interosseum laterale is attached to the medial margin of the cuboid.

The **synovial stratum** is restricted to this articulation, and merely sends a prolongation forwards between the opposing articular surfaces of the fourth and fifth metatarsal bases.

ARTICULATIONES INTERMETATARSEÆ.

The **intermetatarsal articulations** are found between adjacent lateral aspects of the bases of the four lateral metatarsal bones. The articular facets are small, oval, or rounded surfaces which occupy only a limited portion of the flattened contiguous surfaces of the bones. Each joint is provided with an **articular capsule**, which, however, is not a complete investment, because the three joint cavities are in free communication on their proximal aspects with the tarso-metatarsal joint cavities —one with the lateral and two with the intermediate. The definite fibres of each fibrous stratum are situated chiefly in the transverse direction.

The **ligamenta basium dorsalia** are short bands which extend from one base to the other.

The **ligamenta basium plantaria** and the **ligamenta basium interossea** are similarly arranged, but the interosseous ligaments are the strongest and most important members of this series.

The **synovial stratum** of each capsule is an extension from the lateral and intermediate tarso-metatarsal joints (Fig. 300).

Frequently a bursa is found between the bases of the first and second metatarsal bones. It produces an appearance of indistinct facetting upon these bones, and it may communicate with the first cuneo-metatarsal joint.

The **ligamentum metatarsale transversum (transverse metatarsal ligament)** lies upon, and is attached to, the non-articular plantar aspects of the heads of all the metatarsal bones. It differs from the corresponding ligament in the palm in the fact that it binds all the metatarsal bones together, whereas in the palm the thumb is left free. It is closely associated with the plantar fibrous plates of the metatarso-phalangeal joints, to the plantar surfaces of which it contributes prolongations.

ARTICULATIONES METATARSOPHALANGEÆ.

Metatarso-phalangeal Joints.—Each of these joints is a modified ball-and-socket in which a shallow cup upon the bases of the first phalanges receives the somewhat globular head of a metatarsal bone.

Each joint retains a modified **articular capsule** which invests the joint. Its only distinct bands of the fibrous stratum are the **ligamenta collateralia**. These are strong cord-like bands which are situated on the medial and lateral sides of each joint, where they extend between adjacent rough surfaces.

On the dorsal aspect, ligaments distinct from the dorsal expansion of the extensor tendons can hardly be said to exist. The plantar aspect of the capsule consists of a thick **fibrous plate** strengthened by transverse fibres to form the **plantar accessory ligament**, which in the case of the great toe presents developed within it two large sesamoid bones. In the other toes this plate remains fibrous throughout, and is grooved on its plantar aspect for the accommodation of the long flexor tendons. It will thus be seen that the metatarso-phalangeal joints are constructed upon a plan very similar to that of the corresponding joints in the hand.

A **synovial stratum** lines the capsule of each articulation; and the epiphyseal lines of the metatarsals and phalanges are extra-capsular.

ARTICULATIONES DIGITORUM PEDIS.

Interphalangeal Joints.—Each toe possesses two interphalangeal joints except the great toe, which has only one. Not infrequently in the little toe the distal joint is obliterated through ankylosis. All the joints of this series are uniaxial or hinge joints. The nature of the articular surfaces closely resembles the corresponding joints in the fingers.

Each joint possesses an **articular capsule** which is either very thin or limited to

the synovial stratum on the dorsal aspect. The plantar surface of the capsule is strengthened by a **fibrous plate**. The **ligamenta collateralia** are well-defined bands similar to those already described in connexion with the metatarso-phalangeal joints.

A **synovial stratum** lines each capsule in the series. The epiphyseal lines are extra-capsular.

Mechanism of the Foot.—The bones of the foot are arranged in the form of a longitudinal and a transverse arch. The longitudinal arch is built on a very remarkable plan. Posteriorly the mass of the calcaneus constitutes a rigid and stable pier of support, while anteriorly, by increasing the number of component parts, the anterior pier acquires great flexibility and elasticity without sacrificing strength or stability. The summit of the arch is formed by the talus, which receives the weight of the body from the tibia, and the resilience of the arch is assured by the calcaneo-navicular, calcaneo-cuboid, and long plantar ligaments, together with the plantar aponeurosis, which act as powerful braces or tie-bands, preventing undue separation of the piers of the arch, and consequent flattening of the foot. The weight of the body is distributed over all the five digits, owing to the arrangement of the bones of the foot in two parallel columns, a **medial** and a **lateral**. The former, consisting of the talus, navicular, and the three cuneiforms, with the three medial metatarsal bones, distributes weight through the talo-navicular joint, while the latter (*i.e.* the lateral column), comprising the calcaneus, cuboid, and the two lateral metatarsal bones, acts in a similar manner through the talo-calcaneal joint. The main line of immobility of this arch passes from the heel forwards through the middle toe, but its anterior section, which is slender, is supported on either side by two metatarsal bones, with their proximal tarsal associations, in all of which greater freedom of movement is found. The transverse arch is most marked at the level of the tarso-metatarsal articulations. The intersection of these two arches at right angles to each other introduces an architectural feature of great importance in connexion with the support of heavy weights. These longitudinal and transverse arches of the foot are in effect "vaults" intersecting each other at right angles, and in relation to the area which is common to both "vaults" the body weight is superposed exactly as the dome of a cathedral is carried upon two intersecting vaults.

Movements at the Joints of the Tarsus, Metatarsus, and Phalanges.—Considered in detail, the amount of movement which takes place between any two of these bones is extremely small, and, so far as the tarsus and metatarsus are concerned, it is mostly of the nature of a gliding motion.

At the metatarso-phalangeal and interphalangeal joints movement is much more free, and is of the nature of **flexion** (bending of the toes towards the sole of the foot, *i.e.* plantar flexion) and **extension**. The latter movement when continued so as to raise the toes from the ground, and bend or approximate them towards the front of the leg, is termed **dorsiflexion**. Coincident with dorsiflexion there is always associated a certain amount of spreading of the toes, which is called **abduction**, and similarly with prolonged flexion there follows a diminution or narrowing of the transverse diameter of the anterior part of the foot by drawing the toes together—a movement termed **adduction**. In the foot the movements of abduction and adduction take place in regard to a plane which bisects the foot antero-posteriorly through the second toe, for this toe carries the first and second dorsal interosseous muscles.

Notwithstanding the small amount of possible movement in connexion with individual tarsal and metatarsal joints, yet the sum total of these movements is considerable as regards the entire foot. In this way the movements of **inversion** and **eversion** of the foot result. By inversion we mean the raising of the medial border of the foot so that the sole looks medially, while the toes are depressed towards the ground, and the lateral border of the foot remains downwards. This takes place chiefly at the talo-calcanean joint, but the transverse tarsal joints also participate.

Eversion is chiefly the opposite of inversion, and the return of the foot to the normal position of the erect attitude; but under certain conditions it may be carried further, so that the lateral border of the foot is raised from the ground, while the medial border is depressed. In both of these movements there is **rotation** between the talus and calcaneus about an oblique axis which passes from the medial side of the neck of the talus to the lateral and inferior part of the calcaneus.

Of course, all the movements of the foot are subordinated to its primary functions as an organ of support and progression. For these purposes its longitudinal and transverse arches are of extreme importance. The longitudinal arch resting on the calcaneus behind and the heads of the metatarsal bones in front receives the weight of the body, as already explained, on the summit of the talus in the line of the third toe. Hence it is that the medial malleolus appears to be unduly prominent on the medial side of the ankle. The transverse arch buttresses the longitudinal one, and therefore, whether the body weight fall to the lateral or the medial side of the longitudinal arch, it is supported by a mechanism at once stable, flexible, and elastic, or resilient, and capable of reducing to a minimum all jars that may be received by the fore part of the foot. As the heel is raised in the act of walking, the weight is gradually transferred from the lateral to the medial side of the foot, until the foot finally leaves the ground with a propulsive movement, which results from flexion of the phalanges of the great toe. In this connexion it is worthy of note that the longitudinal line of greatest strength is on the medial side of the longitudinal arch, *i.e.* in relation to the great toe.

THE MUSCULAR SYSTEM.

MYOLOGY.

By A. M. Paterson.

Revised and partly rewritten by T. B. Johnston.

All muscle is derived from mesoderm, the cells of which become specialised to form muscle fibres and acquire the characteristic power of contractility. There are three varieties of muscle tissue, which can readily be distinguished from one another by their histological appearances, viz. :—(*a*) **striated** or **voluntary**; (*b*) **cardiac**; and (*c*) **unstriated, plain,** or **involuntary**. Group (*b*) is present only in the walls of the heart, and group (*c*) is found in the walls of viscera, blood-vessels, ducts of glands, etc. Both are entirely concerned with the internal economy of the body. Group (*a*), of which the skeletal muscles are formed, is concerned, for the most part, in the production of movements which result in some alteration of a part or parts of the body relative to the outside world.

It is with the skeletal muscles only that this section deals.

A **typical skeletal muscle** consists of a number of *fasciculi* or muscle bundles, enveloped in a connective tissue sheath termed *fascia*, and usually connected, at one or both extremities, with bundles of white fibrous tissue which constitute some variety of *tendon*.

Each fasciculus is surrounded and bound to its neighbours by a delicate connective tissue, the **perimysium externum**, and each consists of a number of elongated muscle fibres, held together in their turn by the **perimysium internum**. The perimysium internum is connected on the one hand to the **sarcolemma** (or cell-wall of the muscle fibre) and on the other to the perimysium externum, by which it is brought into connexion with some part of a tendon.

Attachments.—In order that a muscle may effectively exercise its power of contractility, it must possess (1) a relatively fixed point of attachment, which is termed the **origin**, and (2) a movable point of attachment, which is termed the **insertion**. These attachments are subject to a wide range of variation. Bones, cartilages, tendons, fibrous raphes, fasciæ, ligaments, and skin may serve this purpose, and the extent and character of the attachments show marked individual differences.

Muscular attachments may be (1) fleshy, (2) tendinous, or (3) a combination of the two. In the first case, *e.g.* vastus intermedius, the fleshy fibres appear to spring directly from the bone, although the actual union is perimysium to periosteum. In the second case, a varying extent of white fibrous tissue is interposed between the attachment and the fleshy belly. This intermediary is termed a **tendon**, and the shape and appearance of tendons show well-marked variations, the extremes being represented by the narrow ribbon-like tendon of the palmaris longus and the broad sheet-like tendon of the obliquus externus abdominis. The latter is usually referred to as an **aponeurosis**.

In some cases a muscle consists of two bellies connected by an *intermediate tendon*. Such muscles are termed digastric or biventral. The fleshy bellies may be set at an angle to one another (*e.g.* digastric and omohyoid), and in this event the intermediate tendon is anchored to some part of the skeletal system by

a fascial sling. On the other hand, the two bellies may be placed in the same straight line.

The tendon, whether of origin or insertion, usually sends prolongations into the substance of the muscle, an arrangement which obviates the necessity for long fibres.

Muscular Form.—The amount of shortening which any muscle undergoes during contraction is directly proportional (nearly 1 : 2) to the length of its constituent fibres. (The longest muscle fibres are found in the sartorius and they do not exceed 15 cm.) The power which a muscle can exert varies directly with the number of its fibres. These two facts serve to explain the form of many skeletal muscles.

In some muscles the fibres run parallel (or nearly parallel) to the long axis. They are termed **fusiform**. When the points of attachment of a fusiform muscle are widely separated, a long tendon of insertion is provided, an arrangement which is economical of muscle tissue and does not interfere with efficiency.

When power is a prime consideration, a different arrangement of the fibres is adopted and the various **penniform** types result. In **unipenniform** muscles, the fibres are placed parallel to one another but not to the long axis. This arrangement provides the necessary increase in the number of fibres by increasing the length of the muscular belly (*e.g.* vastus medialis). There is a very slight loss of efficiency, it is true, but this loss is partly compensated for by economy in tendon, since the long broad tendon, which would have been required had the fibres been arranged in a fusiform manner, is replaced by a tendon, broad distally but tapering as it is continued proximally along one border of the muscle. In **bipenniform** (*e.g.* rectus femoris) and **multipenniform** muscles (*e.g.* deltoid) still greater power is obtained by a slight modification of the same arrangement.

Muscular Action.—Certain muscles, *e.g.* the diaphragm, the constrictors of the pharynx, etc., although included amongst the skeletal muscles and controlled, for the most part, by the will, exert their actions on viscera, but the great majority of skeletal muscles exercise their functions by producing movements at the joint or joints over which they pass on their way from origin to insertion.

When a muscle contracts, its insertion is, as a general rule, approximated to its origin, but, in cases where both attachments are movable, it frequently happens that the insertion may, for the time being, become relatively more fixed than the origin. The contraction of the muscle then results in the approximation of the origin to the insertion. For example, under ordinary conditions the serratus anterior acts on the scapula, but, when that bone is fixed by the action of synergic muscles, it can act as an accessory muscle of inspiration by elevating the ribs from which it arises.

Most of the skeletal muscles utilise the bones as levers and the particular action of any muscle is a simple problem in mechanics. It depends on the position of the two attachments and the relation of the muscle to the axes of the movements which are possible at the joint, or joints, over which it passes. Thus, in the case of the elbow joint where movements occur around a transverse axis only, all muscles which pass anterior to the joint can act as flexors, and all muscles which pass posterior to the joint can act as extensors. When the multi-axial joints are considered, the conditions are found to be much more complicated. Study the attachments of the pectoralis major and its relationship to the shoulder joint when the arm is by the side. Its action is obvious. It is a flexor, because it lies ventral to the transverse axis of the joint; it is an adductor, because it lies below the antero-posterior axis of the joint; and it is a medial rotator, because it passes in front of the vertical axis of the humerus. It must be noted, however, that an alteration in the position of the bone acted upon, may cause an alteration in the relation of a muscle to a particular axis and a consequent alteration in its action. Thus, when the arm is flexed to a right angle, the costo-sternal portion of the pectoralis major acts as an extensor (depressor), although these same fibres act as flexors of the extended arm.

All such mechanical problems are, to a large extent, of academic interest only, for it is movements and not individual muscles which are represented in the

cerebral cortex. The movements at any given joint are never simple, and they almost invariably involve (1) active contraction of a group of **prime movers** to carry out the movement, (2) relaxation of the **antagonists** to enable the movement to be effected, and (3) active contractions of other groups which serve to steady adjoining parts and to obtain efficient working. This group includes two subdivisions. (*a*) **Fixation** muscles steady a movable point of origin, *e.g.* in the early stages of abduction at the shoulder-joint, the trapezius, the serratus anterior, etc., fix the scapula to enable the deltoid and the supraspinatus to act on the humerus. (*b*) **Synergic** muscles are called into play to prevent prime movers from wasting power by acting on such intermediate joints as they pass over, *e.g.* when the fist is clenched, the flexors of the digits are prevented from flexing the wrist by the synergic action of the extensors of that joint.

It becomes apparent, therefore, that the paralysis of any one muscle will not only result in a weakening of the movement, which it can, theoretically, bring about, but will also upset the balance of all movements in which it plays a part as a prime mover or as a synergic or fixation agent.

Topographically, muscles are usually arranged in groups, possessing common or related actions and common sources of nerve-supply. The groups are separated from one another by sheets of connective tissue of varying strength, known as *intermuscular septa.* Muscles of the same group may arise by independent heads of origin and possess a common insertion (*e.g.*, biceps brachii, triceps brachii, and quadriceps femoris).

Muscle Tone.—All living muscle possesses tone, and, by virtue of this property, many skeletal muscles effect an important influence when in the resting state. For example, the abdominal muscles control the position of the abdominal viscera by their tone alone, and, in the same way, the muscles which pass over the elbow joint retain the proximal ends of the radius and ulna in contact with the distal end of the humerus.

Nerve-Supply.—Each muscle is supplied by one or more nerves, which, in their course through it, separate into smaller and smaller branches. Ultimately their terminal filaments (axons) give off numerous collaterals, each of which forms a special end-organ in relation to a muscle cell.

It has been estimated that of the fibres contained in a nerve of supply to a muscle three-fifths are motor and two-fifths are sensory.

FASCIÆ.

Beneath the skin there are two (or in some regions three) layers of tissue which require consideration in relation to the muscular system: the superficial fascia (panniculus adiposus), the deep fascia, and, in animals, the panniculus carnosus (rudimentary in man, and represented chiefly by the *platysma* in the neck).

Fascia Superficialis (Superficial Fascia).—The superficial fascia is a continuous sheet of areolar tissue which underlies the skin of the whole body. It is closely adherent to the cutis vera, and is sometimes termed **panniculus adiposus**, from the fact that, except beneath the skin of the eyelids, penis, and scrotum it is usually more or less impregnated with fat. The cutaneous vessels and nerves ramify in this fascia; and its deep surface, membranous in character, is in loose connexion with the subjacent deep fascia. It is in this layer that dropsical effusions chiefly occur.

Fascia Profunda (Deep Fascia).—Underneath the skin and superficial fascia is a fibrous membrane, bluish white in colour, devoid of fat, and in closest relation to skeleton, ligaments, and muscles. This is the deep fascia. It covers, invests, and in some cases forms the means of attachment of the various muscles. It has a special tendency to become attached to all subcutaneous bony prominences, and to be continuous with the connecting ligaments. It forms septal laminæ, which separate groups of muscles and individual muscles; enclose glands and viscera; and form sheaths for vessels and nerves.

In the distal portions of the upper and lower extremities, where the various

joints are close to one another, special thickenings of the deep fascia are present for the purpose of retaining the tendons in position when their muscles contract. These fascial bands act as pulleys round which the tendons work and they serve to prevent waste of power. This condition is further modified on the flexor aspects of the digits for the same purpose. The fibrous bands are connected to one another and to the phalanges in such a way as to form osteo-fascial tunnels in which the tendons lie.

Vaginæ Mucosæ.—In the situations just described where tendons are retained in place by localised thickening of the deep fascia, mucous sheaths are provided for them to facilitate their movements. Such sheaths may be related to one or more tendons. They are always closed sacs, with a parietal layer lining the space in which the tendon lies and a "visceral" layer closely applied to the tendon itself, so that the two mucous surfaces are in apposition with one another.

In the digital, mucous sheaths, continuity is established between the parietal and visceral layers by means of **vincula tendinum** (p. 391), as well as at the extremities of the sheaths. The vincula tendinum transmit small blood-vessels and may be regarded as incomplete "meso-tendons."

Bursæ Mucosæ.—Simple, closed, mucous sacs are placed between a tendon (or an aponeurosis) and a bony point or ligament over which it plays, or between the distal ends of two or more tendons, when they are inserted in close proximity to one another.

The **panniculus carnosus** is a thin muscular layer enveloping the trunk of animals with a hairy or furry coat. It is strongly developed in the hedgehog. In man it is represented mainly by the (rudimentary) platysma. It is placed between the superficial and the deep fascia.

Description of Muscles.—In studying the muscular system it is necessary to note the following characters in reference to each individual muscle: (1) The *shape* of the muscle—flat, cylindrical, triangular, rhomboidal, etc.; and the character of its extremities—membranous, tendinous, or fleshy. (2) The *attachments* of the muscle. (3) The *relations* of the surfaces and borders of the muscle to bones, joints, muscles, and other important structures. (4) Its *vascular* and *nervous supply*; and (5) *Its actions.*

DESCRIPTION OF THE MUSCLES.

The skeletal muscles may be divided into two series: axial and appendicular. The **axial** muscles comprise the muscles of the trunk, head, and face, including the **panniculus carnosus** (platysma). These muscles are more or less segmental in arrangement, and are grouped around the axial skeleton. The **appendicular muscles**, the muscles of the limbs, are grouped around the appendicular skeleton. They are not segmental in arrangement, they are morphologically separate from the axial muscles, and they are arranged in definite strata in relation to the bones of the limbs.

APPENDICULAR MUSCLES.

THE UPPER LIMB.

FASCIÆ AND SUPERFICIAL MUSCLES OF THE BACK.

Fasciæ.

The **superficial fascia** of the back presents no peculiarity. It is usually of considerable thickness, and contains a quantity of fat.

The **deep fascia** closely invests the muscles. It is attached in the median plane of the back to the ligamentum nuchæ, supraspinous ligaments, and vertebral spines; laterally it is attached to the spine of the scapula and to the clavicle, and is continued over the deltoid region to the arm. In the neck it is attached, above, to the superior nuchal line of the occipital bone, and is continuous, laterally,

with the deep cervical fascia. Below the level of the shoulder it is continuous, round the border of the latissimus dorsi muscle, with the fascia of the axilla and of the abdominal wall. In the back and loin it blends with the **fascia lumbodorsalis** or aponeurosis of the latissimus dorsi. This layer conceals the sacrospinalis muscle, and is attached medially to the vertebral spines, and laterally to the angles of the ribs, and to the iliac crest.

The Superficial Muscles of the Back.

The muscles of the back are arranged in four series according to their attachments: (1) vertebro-scapular and vertebro-humeral; (2) vertebro-costal; (3) vertebro-cranial; and (4) vertebral. The first of this series consists of the posterior muscles connecting the superior extremity to the trunk, and comprises the first two layers of the muscles of the back—(1) trapezius and latissimus dorsi, and (2) levator scapulæ and rhomboidei (major and minor). The deeper (axial) muscles of the back are dealt with later (p. 438).

M. Trapezius.—The **trapezius** is a large triangular muscle which lies in the upper part of the back. It **arises** from the superior nuchal line of the occipital bone in its medial third, from the external occipital protuberance (Fig. 370, p. 445), from the ligamentum nuchæ, from the spines of the seventh cervical and

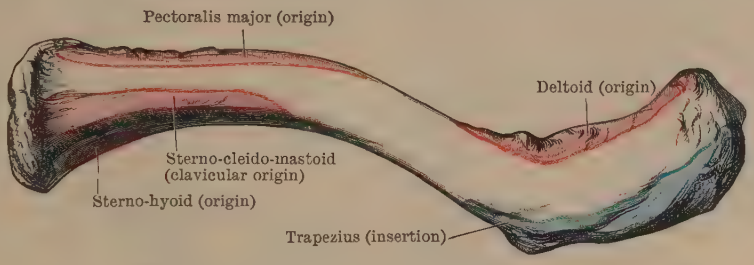

Fig. 301.—Muscle-Attachments to the Right Clavicle (Upper Surface).

all the thoracic vertebræ, and the intervening supraspinous ligaments. The origin is by direct fleshy attachment, except in relation to the occipital bone, the lower part of the neck, and the lower thoracic vertebræ, in which places the origins are tendinous.

From their origins the muscular fibres converge towards the bones of the shoulder, to be **inserted** continuously from before backwards as follows: (1) The occipital and upper cervical fibres—into the posterior aspect of the clavicle in its lateral third (Figs. 301, p. 369, and 305, p. 375); (2) the lower cervical and upper thoracic fibres—into the medial border of the acromion, and the upper border of the spine of the scapula; and (3) the lower thoracic fibres, by a triangular flat tendon, beneath which a bursa is placed—into a rough tuberosity at the base of the spine of the scapula (Fig. 303, p. 371). The fibres inserted into the clavicle, acromion, and the upper border of the spine of the scapula spread over the adjacent subcutaneous surfaces of those bones for a variable distance. The occipital portion of the muscle may be in the form of a separate slip, or may be entirely absent.

The trapezius is superficial in its whole extent. Its upper lateral border forms the posterior limit of the posterior triangle of the neck. The inferior lateral border passes over the upper edge of the latissimus dorsi and the vertebral margin of the scapula, and forms a boundary of the so-called *triangle of auscultation*, which is completed, below, by the latissimus dorsi, and, laterally, by the vertebral margin of the scapula. This space is partly filled up by the rhomboideus major. The muscle overlaps the latissimus dorsi, and covers the rhomboidei, levator scapulæ, splenius capitis, semispinalis capitis, and the deeper axial muscles of the back, along with the ascending and the descending branch of the transverse artery of the neck, the accessory nerve, and muscular branches from the cervical plexus.

Nerve-Supply.—The trapezius has a double nerve-supply: (1) from the terminal fibres of the accessory nerve, and (2) from the cervical plexus (C. 3. and 4.). The cervical nerves communicate with the accessory nerve in the posterior triangle of the neck and beneath the trapezius.

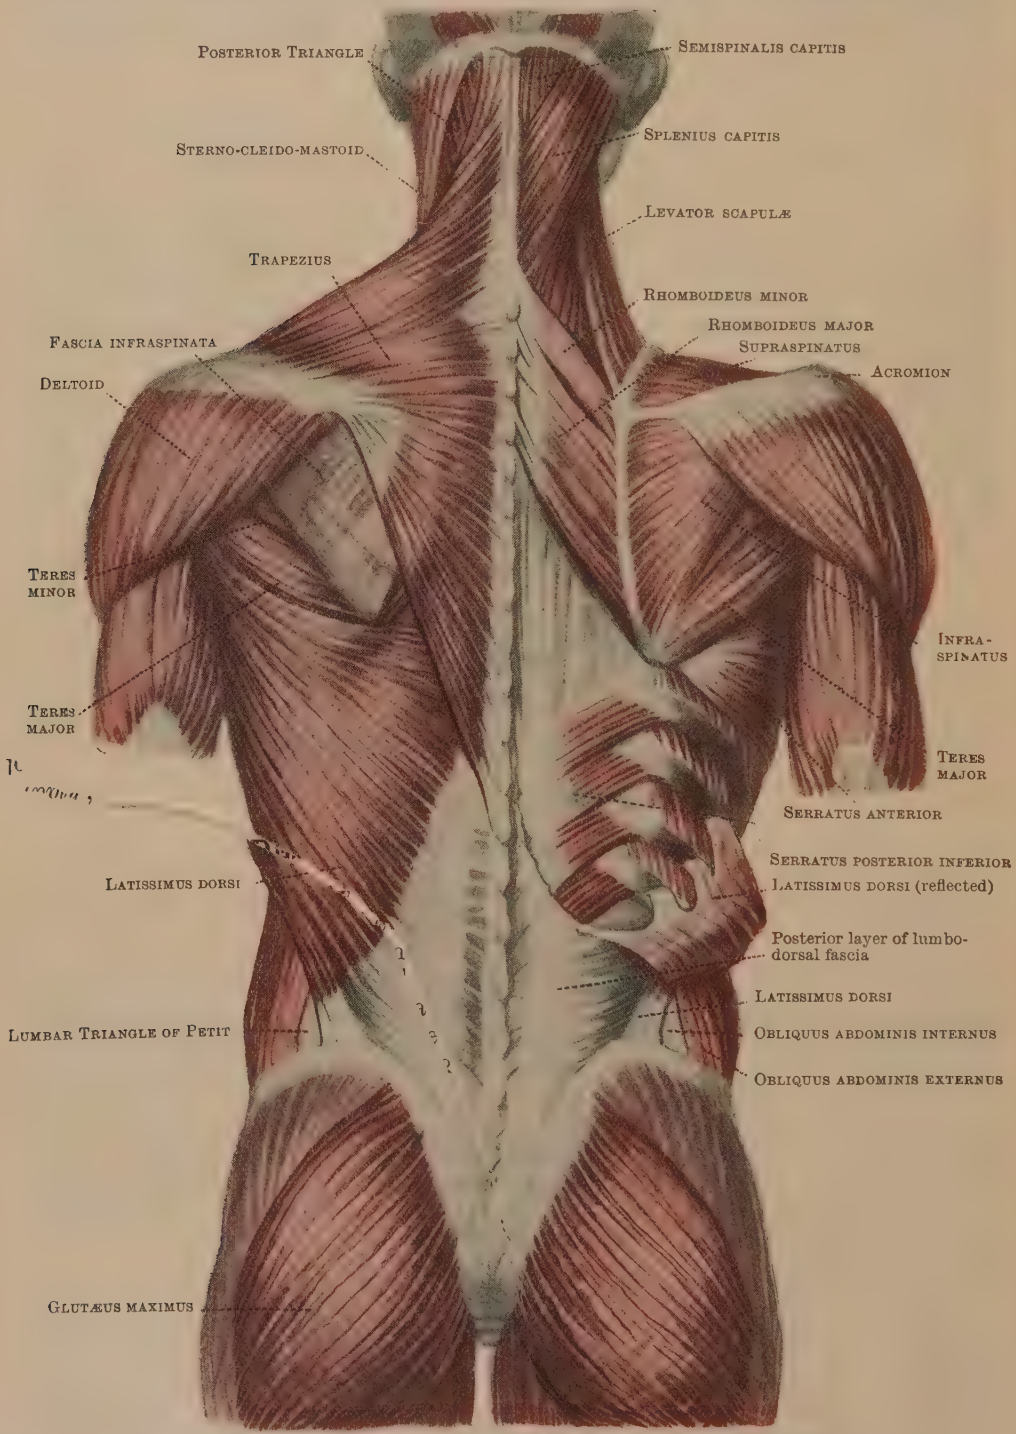

Fig. 302.—Superficial Muscles of the Back, and Vertebro-scapular Muscles.

Actions.—(1) In association with the serratus anterior the trapezius rotates the scapula so that the inferior angle passes laterally and forwards, and it elevates the lateral end of the clavicle. This rotation plays an important part in abduction of the humerus, after the bone has moved through an angle of about 30°. In the initial stage of this movement the trapezius and

serratus anterior play the part of fixation muscles in order to prevent the deltoid and supraspinatus from exerting their action on the scapula instead of the humerus. (2) It assists the rhomboids to approximate the scapulæ, so bracing back the shoulders. (3) The upper fibres, in association with the levator scapulæ, elevate the lateral end of the clavicle and the scapula, as in shrugging movements. (4) The upper fibres, in association with the longissimus capitis, extend the head on the neck.

M. Latissimus Dorsi.—The **latissimus dorsi** is a large triangular muscle occupying the lower part of the back. The greater part of the muscle **arises**—(1) from the spines of the lower six thoracic vertebræ, and from the posterior layer of the lumbo-dorsal fascia (p. 437), so gaining attachment to the spines of the lumbar vertebræ, and the tendon of the sacrospinalis, with which the fascia blends below. It also arises laterally from the posterior part of the outer lip of the iliac crest.

From its origin the muscle is directed upwards and laterally, its fibres converging to the inferior angle of the scapula. In relation to its lateral and upper borders additional fibres arise. (2) *Along the lateral border* muscular slips arise from the lower three or four ribs, interdigitating with the slips of origin of the obliquus abdominis externus. (3) As *the superior border* of the muscle passes, horizontally, over the inferior angle of the scapula, an additional fleshy slip usually takes origin from that part of the bone and joins the muscle on its deep surface (Fig. 303).

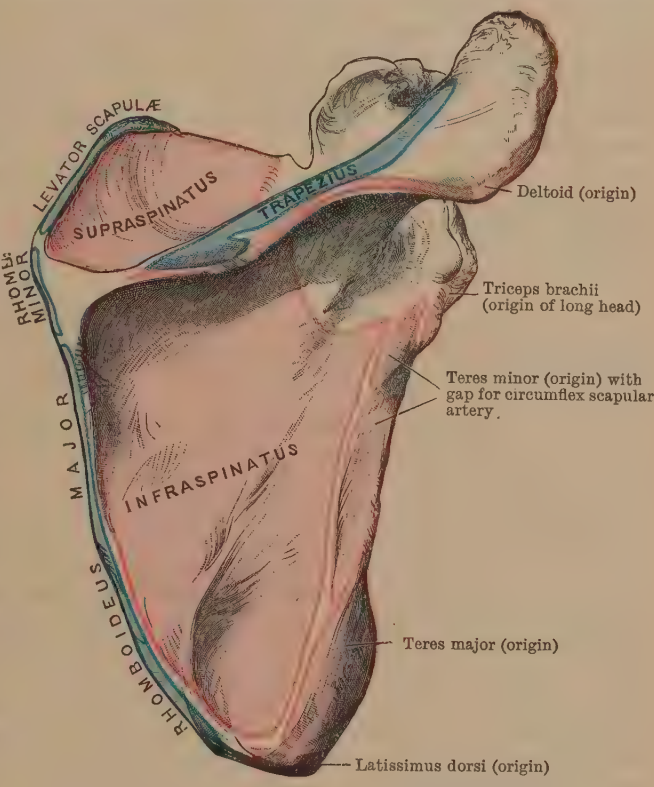

FIG. 303.—MUSCLE-ATTACHMENTS TO THE RIGHT SCAPULA (Dorsal Surface).

Beyond the inferior angle of the scapula the latissimus dorsi, greatly narrowed, curves spirally round the teres major muscle, and forms the prominence of the posterior axillary fold. It ends in a ribbon-like tendon, which is closely adherent, at first, to the teres major, and is **inserted** into the floor of the intertubercular sulcus of the humerus, extending for about three inches distal to the lesser tubercle (Fig. 314, p. 383). It is placed behind the axillary vessels and nerves, and in front of the insertion of the teres major, from which it is separated by a bursa.

In the back the latissimus dorsi is superficial, except in its upper part, which is concealed by the trapezius. It covers part of the lumbo-dorsal fascia, the serratus posterior inferior, the lower ribs, and the inferior angle of the scapula. At its upper border is the so-called *triangle of auscultation*; at its lateral border is the lumbar *triangle of Petit*, a small space bounded by the iliac crest, the latissimus dorsi, and the obliquus abdominis externus. This space is sometimes the site of a lumbar hernia.

Nerve-Supply.—The muscle has a single nerve—the thoraco-dorsal nerve—which supplies it on its deep surface. It is a branch from the posterior cord of the brachial plexus (C. (6.) 7. 8.).

Actions.—The latissimus dorsi is a powerful adductor and extensor of the humerus, so lowering the arm as in swimming. It also assists in medial rotation of the arm. Further, it acts from its insertion under three conditions: (1) It plays an important part in climbing, drawing the body upwards after the arms; (2) it assists the abdominal muscles (p. 486) in violent expiratory efforts; and (3) it is said to act as an accessory muscle of inspiration by elevating the lower ribs.

M. Levator Scapulæ.—The **levator scapulæ** is a strap-like muscle, **arising** by tendinous slips from the posterior tubercles of the transverse processes of the first three or four cervical vertebræ, between the attachments of the scalenus medius in front and the splenius cervicis behind.

It is directed downwards, to be **inserted** into the vertebral margin of the scapula, from the medial angle to the spine (Fig. 303).

It is concealed in its upper third by the sterno-mastoid muscle. Its middle third forms part of the floor of the posterior triangle and is related to the accessory nerve. In its lower third it is hidden by the trapezius, and conceals the dorsal scapular nerve and the descending branch of the transverse cervical artery.

Nerve-Supply.—The levator scapulæ has a double nerve-supply:—(1) from the dorsal scapular nerve from the brachial plexus (C. 5.), which either pierces or goes beneath the muscle, and (2) from the cervical plexus. Small branches from the anterior rami of the third and fourth cervical nerves enter the muscle on its superficial surface near its origin.

M. Rhomboideus Minor.—The **rhomboideus minor** may be regarded as a separated slip of the rhomboideus major, with which it is often continuous. It **arises** from the *ligamentum nuchæ* and the spines of the seventh cervical and first thoracic vertebræ.

Passing obliquely downwards and laterally it is **inserted** into the vertebral margin of the scapula below the levator scapulæ muscle, and opposite to the base of the spine (Fig. 303).

M. Rhomboideus Major.—The **rhomboideus major arises** from the spinous processes of the thoracic vertebræ from the second to the fifth inclusive, and from the corresponding supraspinous ligaments.

It also passes downwards and laterally and is **inserted**, below the rhomboideus minor, into the vertebral margin of the scapula, between the spine and the inferior angle (Fig. 303). The muscle is only inserted directly into the scapula by means of its inferior fibres. Its superior part is attached to a membranous band, which is connected to the vertebral margin of the scapula, for the most part by loose areolar tissue, but it is fixed to the bone at its extremities, above near the apex of the spine, and below at the inferior angle.

The rhomboid muscles are concealed to a large extent by the trapezius. The lower part of the rhomboideus major is superficial in the *triangle of auscultation*. The muscles cover the serratus posterior superior and vertebral aponeurosis.

Nerve-Supply.—The rhomboid muscles are supplied by the dorsal scapular nerve from the brachial plexus (C. 5.), which supplies branches to the deep surface of the muscles.

Actions.—The levator scapulæ and the rhomboids, which are the opponents of the trapezius and serratus anterior, rotate the scapula so that its inferior angle passes medially. Co-operating with the trapezius the levator scapulæ elevates the point of the shoulder, as in shrugging movements. The rhomboids, in association with the trapezius, approximate the two scapulæ, so bracing back the shoulders.

THE FASCIÆ AND MUSCLES OF THE PECTORAL REGION.

FASCIÆ.

The **superficial fascia** of the chest usually contains a quantity of fat, in which the mamma is embedded. The origin of the platysma muscle lies beneath its superior part.

The **deep fascia** is attached above to the clavicle, and, medially to the sternum. Below it is continuous with the fascia of the abdominal wall. It gives origin to the platysma and invests the pectoralis major. At the lateral

border of the great pectoral muscle it is thickened, and forms the floor of the axillary space **(axillary fascia)**, continued posteriorly on to the posterior fold of the axilla and laterally into connexion with the deep fascia of the arm.

Costo-Coracoid Membrane.—Beneath the pectoralis major a deeper stratum of fascia invests the pectoralis minor muscle. At the superior border of this muscle it forms the costo-coracoid membrane, which passes upwards to the inferior border of the subclavius muscle, where it splits into two layers, attached in front of and behind that muscle to the borders of the inferior surface of the clavicle. The membrane traced medially, along the subclavius muscle, is attached to the first costal cartilage; passing laterally, along the upper border of the pectoralis minor, it reaches the coracoid process, and the coraco-clavicular ligament. The part of the membrane extending directly between the first costal cartilage and the coracoid process is thickened and forms the **costo-coracoid ligament.** The costo-coracoid membrane is pierced by the cephalic vein, thoraco-acromial artery, and branches of the lateral anterior thoracic nerve. By its deep surface it is connected to the sheath of the axillary vessels.

At the inferior border of the pectoralis minor there is a further extension of the deep fascia beneath the pectoralis major. It passes downwards to join the fascia forming the floor of the axilla, and is continued laterally into the fascia covering the biceps and coraco-brachialis muscles.

MUSCLES OF THE PECTORAL REGION.

The anterior muscles connecting the upper limb to the axial skeleton comprise the pectoralis major, pectoralis minor, subclavius, serratus anterior, and sterno-cleido-mastoid. The last is described in a later section (p. 459).

M. Pectoralis Major.—The **pectoralis major** is a large fan-shaped muscle **arising** in three parts: (1) *a pars clavicularis* arising from the anterior aspect of the clavicle in its medial half or two-thirds (Figs. 301, p. 369, and 305, p. 375); (2) *a pars sternocostalis*, the largest part of the muscle, arising from the anterior surface of the manubrium and body of the sternum by tendinous fibres decussating with those of the opposite muscle (Fig. 304, p. 374), and, more deeply, from the cartilages of the first six ribs; (3) *a pars abdominalis*, a small and separate slip, arising from the aponeurosis of the obliquus abdominis externus muscle. The abdominal slip, at first separate, soon merges with the sterno-costal portion, but a distinct interval usually remains between the two first-named parts of the muscle.

The fibres converge towards the proximal part of the arm, and are inseparably blended at a point half an inch from their insertion into the lateral border of the sulcus intertubercularis of the humerus.

The arrangement of the fibres of the muscle at its insertion is peculiar. The pars clavicularis is attached to the humerus in front of the pars sternocostalis and blends, inferiorly, with the tendinous insertion of the deltoid, the lateral fibres of origin being inserted proximal to the medial fibres. The upper sterno-costal fibres disappear under cover of the pars clavicularis near its insertion and are blended with the deep surface of its tendon. The lower sterno-costal fibres and the pars abdominalis curve upwards behind the superior sterno-costal fibres, and the latter have the highest attachment to the shaft of the humerus, helping to form a fascial expansion which extends upwards over the biceps tendon to the capsule of the shoulder-joint. In this way a bilaminar tendon is produced, united along its inferior border. The superficial lamina is formed by the superior sterno-costal fibres, blending for the most part with the tendon of the clavicular portion; and the deep lamina by the twisted lower sterno-costal and abdominal fibres.

Placed superficially, the pectoralis major forms the anterior wall and anterior fold of the axilla. Its superior border is separated from the edge of the deltoid muscle by an interval in which lie the cephalic vein and deltoid branches of the a. thoracoacromialis. Its deep surface is in relation with the ribs and intercostal muscles, the costo-coracoid membrane and the structures piercing it, the pectoralis minor, the biceps and coraco-brachialis, the axillary vessels, and the nerves of the brachial plexus.

Nerve-Supply.—The pectoralis major is supplied by both anterior thoracic nerves. The lateral anterior thoracic nerve, derived from the lateral cord of the brachial plexus (C. 5. 6. 7.), divides into two trunks. One pierces the costo-coracoid membrane, and supplies the clavicular part, and superior portion of the sterno-costal part of the muscle. The other branch communicates over the axillary artery with the medial anterior thoracic nerve, a derivative of the medial cord of the brachial plexus (C. 8. T. 1.). They then supply the pectoralis minor and, piercing that muscle, terminate in the lower part of the pectoralis major.

Actions.—The pectoralis major is a powerful adductor and medial rotator of the arm. The clavicular head (*portio attollens*) assists the anterior fibres of the deltoid to flex the humerus, a movement in which the limb is carried forwards and medially. The costo-sternal and abdominal fibres, although taking part in flexion from full extension until the arm reaches the side, are powerful extensors of the fully flexed humerus (*portio deprimens*). Like the latissimus dorsi (p. 371), the pectoralis major plays an important part in climbing and, when the shoulders are fixed, it can assist violent inspiratory efforts by raising the upper ribs.

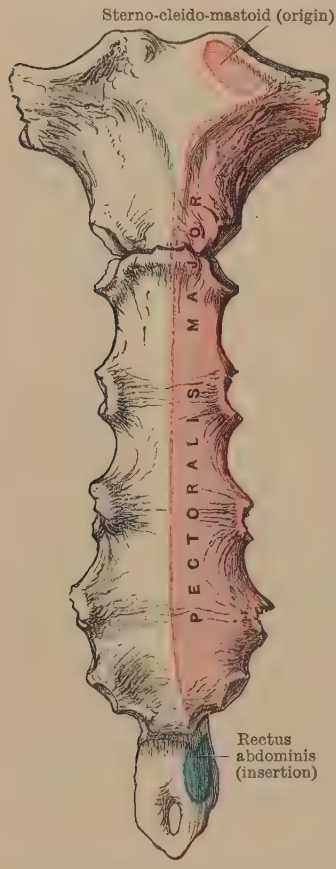

FIG. 304.—MUSCLE-ATTACHMENTS TO THE FRONT OF THE STERNUM.

Sternalis Muscle.—The sternalis is an occasional muscle lying parallel to the sternum upon the sterno-costal origin of the pectoralis major. It has attachments which are very variable both above and below, to the costal cartilages, sternum, rectus sheath, sterno-mastoid, and pectoralis major. Its **nerve-supply** is from one or both of the anterior thoracic nerves. In certain rare cases it has been said to be innervated by intercostal nerves. It is present in 4·4 cases out of 100. It has been regarded by different observers as (1) a vestige of the panniculus carnosus, (2) a homologue of the sterno-mastoid, or (3) a displaced slip of the pectoralis major.

Chondroepitrochlearis, Dorsoepitrochlearis, Axillary Arches, Costocoracoideus.—One or other of the above-named slips is occasionally present, crossing the floor of the axilla in the interval between the latissimus dorsi and the pectoralis major. They take **origin** from the costal cartilages, ribs, or borders of the pectoralis major (*chondroepitrochlearis, axillary arches, costocoracoideus*), or from the border of the latissimus dorsi (*dorsoepitrochlearis, axillary arches, costocoracoideus*). Their **insertion** is variable. The *chondroepitrochlearis* and *dorsoepitrochlearis* are inserted into the fascia of the arm, the medial intermuscular septum, or the medial epicondyle of the humerus. The *axillary arches* are inserted into the border of the pectoralis major, the fascia of the arm, or the coraco-brachialis or biceps muscle. The *costocoracoideus*, arising from the ribs or the aponeurosis of the obliquus externus, or detaching itself from the border of the pectoralis major or latissimus dorsi, is attached to the coracoid process, alone or along with one of the muscles attached to that bone. These variable slips of muscle are supplied by the medial anterior thoracic nerve, the medial cutaneous nerve of the arm, or the intercostobrachial nerve.

M. Pectoralis Minor.—The **pectoralis minor** is a narrow, flat, triangular muscle. It **arises**, under cover of the pectoralis major, from (1) the surfaces and superior borders of the third, fourth, and fifth ribs near their anterior ends, and (2) from the fascia covering the third and fourth intercostal spaces between those ribs. It may have an additional origin from the second rib (Fig. 389, p. 468); and that from the fifth rib is often absent.

Directed obliquely upwards and laterally, it is **inserted** by a short, flat tendon into the lateral half of the medial border and upper surface of the coracoid process (Fig. 307, p. 376), and usually also into the conjoint origin of the biceps brachii and coracobrachialis.

It enters into the formation of the anterior wall of the axilla, lying under cover of the pectoralis major. It crosses the axillary vessels and the cords of the brachial plexus, and is pierced by the medial anterior thoracic nerve. Its fascial sheath is continuous above with the costo-coracoid membrane and below with the axillary fascia.

Either in part or wholly the pectoralis minor may pass over the coracoid process of the scapula, separated from it by a bursa, to pierce the coraco-acromial ligament, and be attached to the capsule of the shoulder-joint (coraco-humeral ligament).

Nerve-Supply.—The pectoralis minor is innervated like the pectoralis major by both anterior thoracic nerves. The lower division of the lateral nerve (C. 5. 6. 7.) communicates with the medial anterior thoracic nerve (C. 8. T. 1.), and the latter pierces and supplies the pectoralis minor, and ends in the pectoralis major.

Action.—The main use of the pectoralis minor is to draw the shoulder forwards. Since the muscle lies under cover of the pectoralis major and is never paralysed alone, it is very difficult to appreciate its action in the living subject.

M. Subclavius.—The **subclavius muscle arises** from the superior surface of the

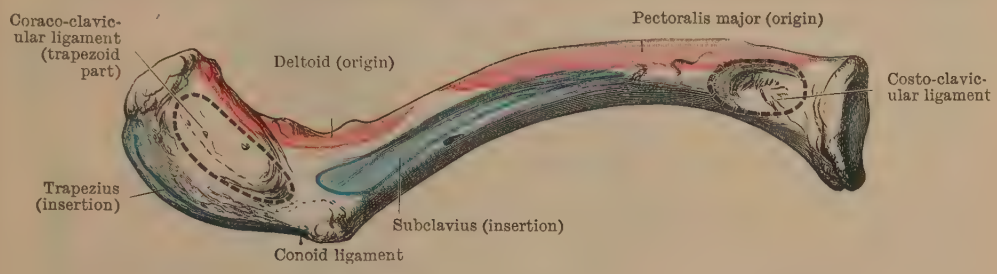

FIG. 305.—MUSCLE-ATTACHMENTS TO THE RIGHT CLAVICLE (Inferior Surface).

first costal cartilage in front of the costo-clavicular ligament, and from the upper surface of the sternal end of the first rib (Fig. 389, p. 468).

It is **inserted** into a groove in the middle third of the inferior surface of the clavicle (Fig. 305).

The muscle is invested by the fascia which forms the costo-coracoid membrane, and is concealed by the clavicle and the clavicular origin of the pectoralis major. It lies in front of the subclavian vein.

Nerve-Supply.—**The nerve to the subclavius** is a fine branch of the brachial plexus (C. 5. 6.), which arises above the clavicle, and passes anterior to the subclavian artery to reach the muscle.

Action.—It acts as a depressor of the lateral end of the clavicle, and, by drawing the bone medially towards the sternum, steadies it in movements of the shoulder-girdle.

The **sternoclavicularis** is a small separate slip, rarely present, extending beneath the pectoralis major from the upper part of the sternum to the clavicle.

M. Serratus Anterior.—The **serratus anterior** is a large curved quadrilateral muscle occupying the side of the chest and medial wall of the axilla. It **arises** by fleshy slips from the lateral aspect of the upper eight and occasionally (as in the figure) from nine ribs. The first slip is a double one, arising from the first two ribs and the fascia covering the intervening space (Fig. 306).

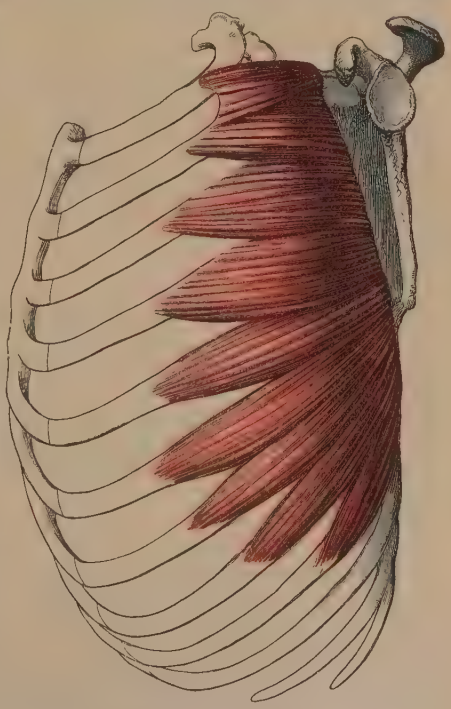

FIG. 306.—THE LEFT SERRATUS ANTERIOR MUSCLE.

The **insertion** of the muscle is threefold. (1) The first portion of the muscle (from the first and second ribs) is directed posteriorly to be inserted into the costal aspect of the medial angle of the scapula. (2) The next three slips of the muscle (from the second, third, and fourth ribs) are inserted into the vertebral margin of the scapula. (3) The last four slips (from the fifth, sixth, seventh, and eighth ribs) are directed obliquely upwards and posteriorly, to be inserted on the costal aspect of the inferior angle of the scapula (Fig. 307).

The lateral surface of the muscle is partly superficial below the axillary space, on the side wall of the chest, where its slips of origin are seen inter-digitating with those of the obliquus externus abdominis. Higher up it forms the medial wall of the axilla and is covered by the infero-lateral part of the mammary gland. It is in contact with the pectoral muscles anteriorly and the subscapularis posteriorly. Its superior border appears in the floor of the posterior triangle, and over it the axillary artery and the cords of the brachial plexus pass in their course through the axilla. The inferior border is oblique, and is in contact with the latissimus dorsi muscle. The muscle may extend higher than usual, so as to be continuous, in the neck, with the levator scapulæ.

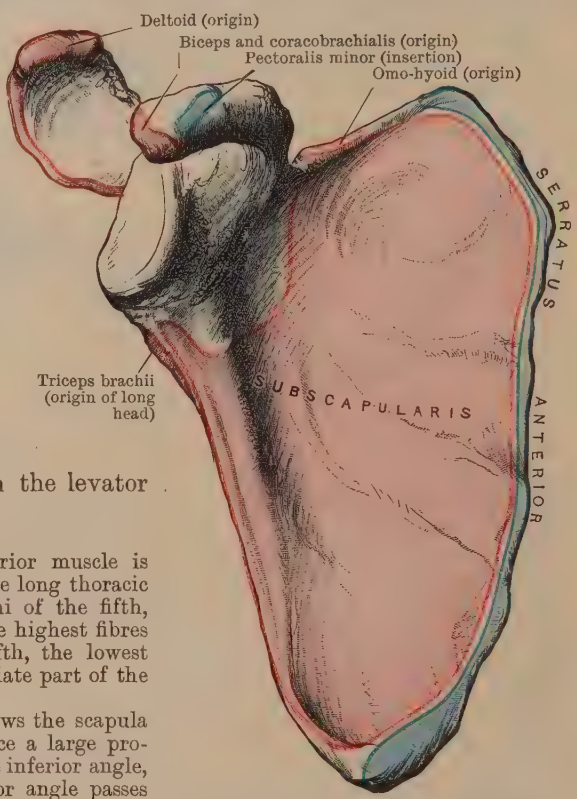

FIG. 307.—MUSCLE-ATTACHMENTS TO THE RIGHT SCAPULA (Anterior Aspect).

Nerve-Supply.—The serratus anterior muscle is supplied, on its superficial aspect, by the long thoracic nerve, a branch from the anterior rami of the fifth, sixth, and seventh cervical nerves. The highest fibres of the muscle are supplied by the fifth, the lowest fibres by the seventh, and the intermediate part of the muscle by the sixth cervical nerve.

Actions.—The serratus anterior draws the scapula forwards round the chest wall and, since a large proportion of its fibres are inserted into the inferior angle, it rotates the bone so that the inferior angle passes forwards and laterally. In association with the trapezius, it is a fixation muscle in the early stages of abduction of the humerus (p. 370) and an active agent in the later stages. By drawing the scapula forwards, it exercises a very important influence on forward pushing or thrusting movements with the hand, so much so that, when the serratus anterior is paralysed, these movements are impossible and attempts to produce them result in a backward projection (*"winging"*) of the scapula. Like other muscles, when its insertion is fixed, it can act on its origin, thus coming into play as an accessory muscle of inspiration.

FASCIÆ AND MUSCLES OF THE SHOULDER.

The **deep fascia** of the shoulder region is especially strong where it covers the infraspinatus and teres minor muscles below the posterior border of the deltoid. In this situation it is tendinous in appearance and is firmly attached to the vertebral and axillary borders of the scapula. Above, it ensheathes the deltoid and is attached to the clavicle, the acromion, and the scapular spine.

Muscles.

The **muscles** proper to the shoulder comprise the deltoid, supraspinatus, infraspinatus, teres minor, teres major, and subscapularis.

M. Deltoideus.—The **deltoid**, a coarsely fasciculated multipennate muscle, has an extensive **origin** from (1) the front of the clavicle in its lateral third (Figs. 301, p. 369, and 305, p. 375); (2) the lateral border of the acromion; (3) the inferior edge of the free border of the spine of the scapula (Figs. 303, p. 371, and 302, p. 370); and (4) from the deep fascia covering the infraspinatus muscle. Its origin embraces the insertion of the trapezius.

The fibres of the muscle converge to the lateral aspect of the body of the humerus, to be **inserted** into a well-marked V-shaped impression above the radial

groove (Fig. 310, p. 379). The insertion is partly united with the tendon of the pectoralis major.

The most anterior part of the deltoid muscle is formed of parallel fibres, not uncommonly separate from the rest of the muscle at their origin from the clavicle. These fibres may be continuous with the trapezius. The most posterior part arises by a fascial origin from the spine of the scapula and the fascia over the infraspinatus muscle. These portions are attached respectively to the front and back of the main tendon of insertion. The intermediate fibres are multipennate, attached above and below to three or four septal tendons, which extend for a variable distance downwards and upwards from the origin and insertion of the muscle. This arrangement increases the number of its constituent fibres and so increases the power of the deltoid. This increased power is necessary owing to the obvious mechanical disadvantage at which the muscle acts, and the fact that its action is usually exerted against the force of gravity.

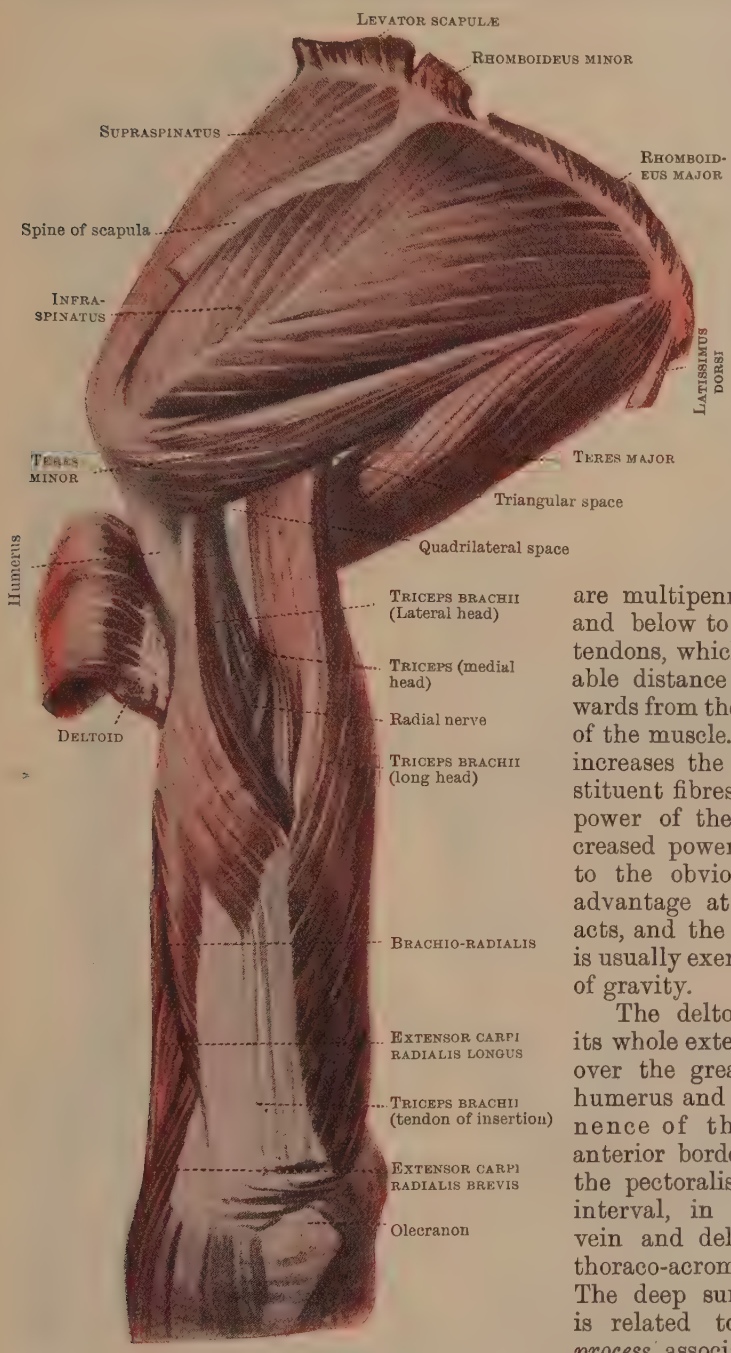

Fig. 308.—Left Scapular Muscles and Triceps.

The deltoid is superficial in its whole extent. It is spread out over the greater tubercle of the humerus and so forms the prominence of the shoulder. Its anterior border is separated from the pectoralis major by a narrow interval, in which the cephalic vein and deltoid branch of the thoraco-acromial artery are placed. The deep surface of the muscle is related to (1) the *coracoid process*, associated with which are the coraco-acromial ligament, and the attachments of the pectoralis minor, the coracobrachialis, and the short head of the biceps brachii; (2) the capsule of the *shoulder-joint* covering the *head of the humerus*, associated with which are the long head of the biceps, and the attachments of the subscapularis, supraspinatus, infraspinatus, and teres minor; and (3) the proximal part of the lateral surface of the *body of the humerus* associated with which are the posterior circumflex vessels of the humerus and

the axillary nerve. The *subacromial bursa* intervenes between the middle fibres of the deltoid, the acromion, and the coraco-acromial ligament, on the one hand, and the supraspinatus, infraspinatus, and subscapularis tendons on the other.

Nerve-Supply.—The deltoid muscle is supplied by the terminal branches of the axillary (O.T. circumflex) nerve from the fifth and sixth cervical nerves.

Actions.—The deltoid is the principal abductor of the humerus. In this movement the arm is carried forwards and laterally (p. 366), and in the early stages the deltoid and supraspinatus are the active agents, the serratus anterior and trapezius playing the rôle of fixation muscles (p. 367). After the arm has been moved through an angle of 30°, further abduction is accompanied, *pari passu*, by rotation of the scapula.

The anterior fibres assist the clavicular head of the pectoralis major to produce flexion and medial rotation of the humerus; the posterior fibres act with the extensors and lateral rotators.

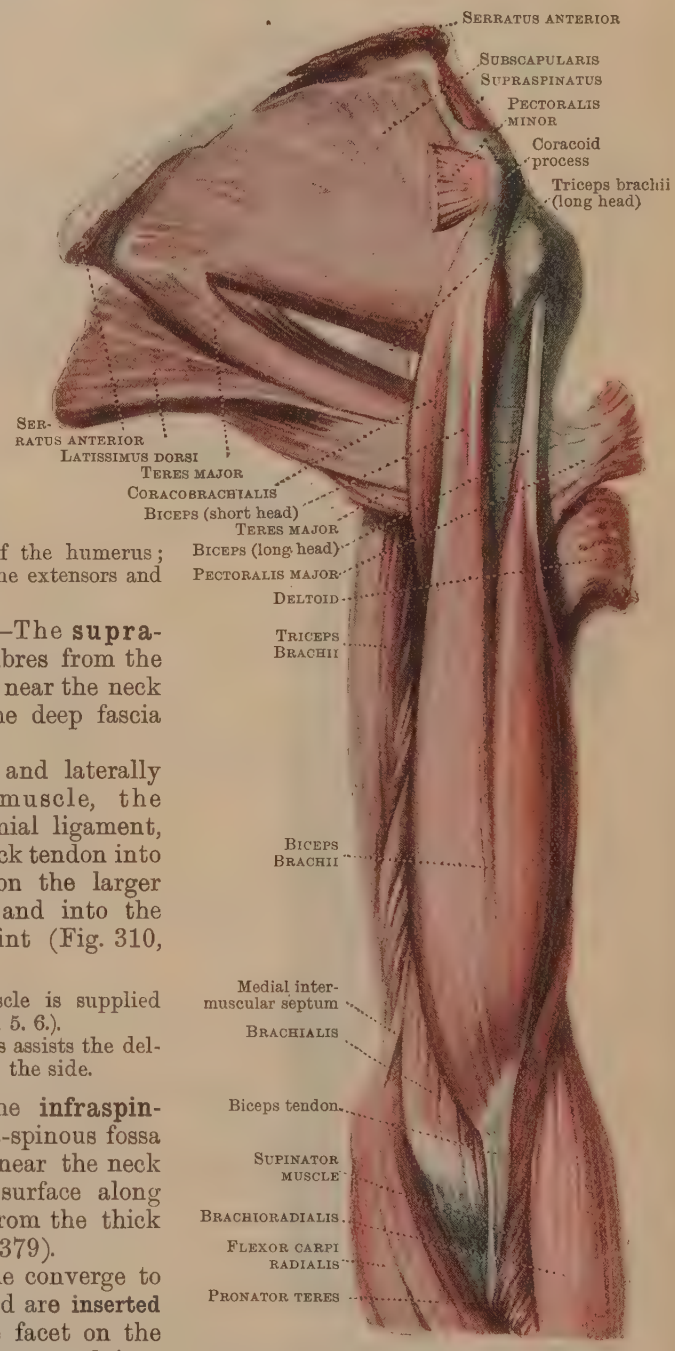

Fig. 309.—Muscles of Posterior Wall of Left Axilla and Front of Arm.

M. Supraspinatus.—The **supraspinatus arises** by fleshy fibres from the supra-spinous fossa (except near the neck of the bone) and from the deep fascia over it (Fig. 311, p. 379).

It is directed forwards and laterally under the trapezius muscle, the acromion and coraco-acromial ligament, to be **inserted** by a broad thick tendon into the most proximal facet on the larger tubercle of the humerus, and into the capsule of the shoulder-joint (Fig. 310, p. 379).

Nerve-Supply.—The muscle is supplied by the supra-scapular nerve (C. 5. 6.).

Action.—The supraspinatus assists the deltoid in abducting the arm from the side.

M. Infraspinatus.—The **infraspinatus arises** from the infra-spinous fossa of the scapula (excepting near the neck of the bone and the flat surface along the axillary margin) and from the thick fascia over it (Fig. 311, p. 379).

The fibres of the muscle converge to the neck of the scapula, and are **inserted** by tendon into the middle facet on the larger tubercle of the humerus, and into the capsule of the shoulder-joint (Fig. 315, p. 383). A bursa separates the muscle from the neck of the scapula, and, in a minority of cases, communicates with the synovial cavity of the shoulder-joint.

The supraspinatus and the upper part of the infraspinatus muscles are concealed by the trapezius, acromion, and deltoid. They cover the neck of the scapula, the

transverse scapular artery and supra-scapular nerve, and the capsule of the shoulder-joint.

Nerve-Supply.—Supra-scapular nerve.
Action.—The infraspinatus is a powerful lateral rotator of the humerus.

M. Teres Minor.—The **teres minor** is a small muscle, arising by fleshy fibres from the proximal two-thirds of the flat surface on the dorsal aspect of the axillary margin of the scapula, and from fascial septa separating it from the infraspinatus and teres major muscles (Fig. 311, p. 379).

Lying alongside the lateral border of the infraspinatus, it is **inserted**, under cover of the deltoid, by a thick flat tendon, into the most distal of the three facets on the larger tubercle of the humerus and into the capsule of the shoulder-joint, and, by fleshy fibres, into the posterior aspect of the surgical neck and body of the humerus distal to the tubercle for about an inch (Fig. 315, p. 383).

It is separated from the teres major by the long or scapular head of the triceps brachii, and

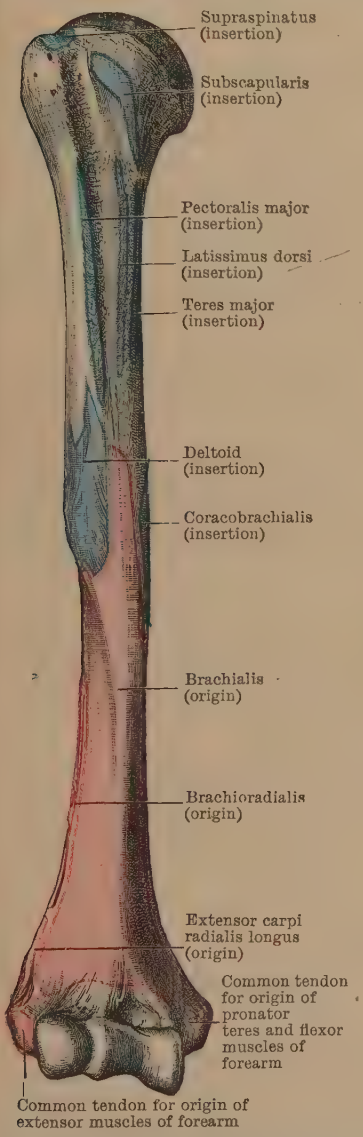

FIG. 310.—MUSCLE-ATTACHMENTS TO THE ANTERIOR ASPECT OF THE RIGHT HUMERUS.

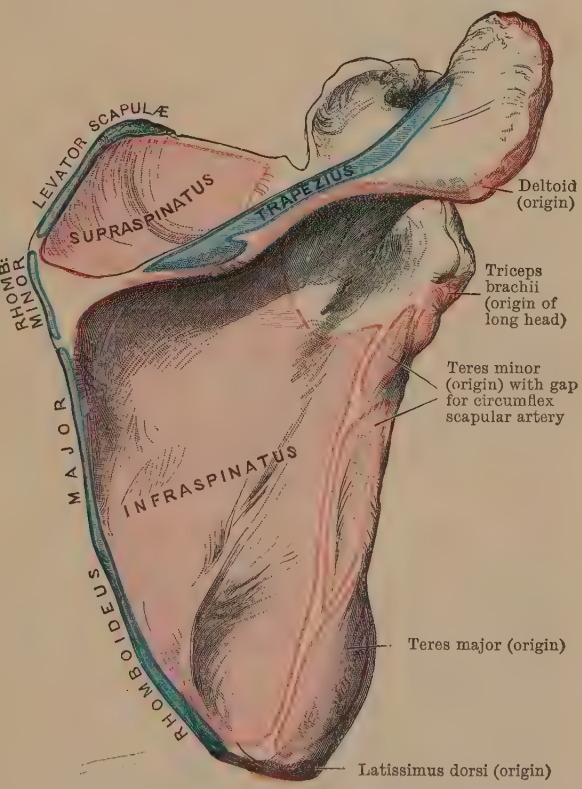

FIG. 311.—MUSCLE-ATTACHMENTS TO THE RIGHT SCAPULA (Dorsal Surface).

by the posterior circumflex vessels of the humerus and the axillary nerve. Its origin is pierced by the circumflex scapular artery. The muscle is invested by the deep fascia enclosing the infraspinatus, and is sometimes inseparable from that muscle.

Nerve-Supply.—The teres minor is supplied by a branch of the axillary nerve (C. 5. 6.). The nerve has a pseudo-ganglion, a fibrous swelling on it in its course to the muscle.
Action.—The muscle is a lateral rotator and adductor of the humerus.

M. Teres Major.—The **teres major** is much larger than the preceding muscle.

It **arises**, by fleshy fibres, from the lower third of the flat, dorsal surface of the axillary margin of the scapula (except for a small area at the inferior angle), and from fascial septa, which separate it on the one side from the subscapularis, and on the other from the infraspinatus and teres minor (Fig. 311).

The muscle is directed along the axillary margin of the scapula to the front of the body of the humerus, where it is **inserted**, by a broad flat tendon, into the medial border of the sulcus intertubercularis medial to the latissimus dorsi muscle (Fig. 314). Just before its insertion it is closely adherent to the tendon of the latissimus dorsi.

The teres major lies below the subscapularis muscle in the posterior wall of the axilla. The latissimus dorsi muscle, sweeping round from the back, covers its axillary surface on its way to its insertion. The muscle forms the inferior boundary of a **triangular space** in the posterior wall of the axilla, of which the other boundaries are, above, the borders of the subscapularis and teres minor muscles, and laterally the surgical neck of the humerus. This space is subdivided by the long head of the triceps brachii, which passes behind the teres major muscle, into (*a*) a **quadrilateral space** above, for the passage of the axillary nerve and posterior circumflex artery of the humerus; and (*b*) a **smaller triangular space** below, for the circumflex scapulæ artery.

Nerve-Supply.—The teres major is supplied, along with part of the subscapularis muscle, by the lower subscapular nerve (C. 5. 6.).

Action.—A medial rotator and adductor of the humerus.

M. Subscapularis.—The **subscapularis** is a large triangular muscle which covers the costal surface of the scapula. It **arises** by fleshy fibres from the whole of the subscapular fossa and the groove along the axillary margin, excepting the surfaces at the angles of the bone (Fig. 307, p. 376). Springing from several ridges in the fossa are fibrous septa projecting into the substance of the muscle, which increase the extent of its attachment.

Converging to the head of the humerus, the muscular fibres are **inserted** by a broad, thick tendon into the smaller tubercle of the humerus and into the capsule of the shoulder-joint, and by fleshy fibres into the surgical neck and the body of the humerus distal to the tubercle for about an inch, under cover of the coracobrachialis and short head of the biceps (Fig. 314, p. 383).

This muscle forms the greater part of the posterior wall of the axilla. Its medial or anterior surface is in contact with the serratus anterior and the axillary vessels and nerves. It is separated from the neck of the scapula by a bursa, which is in direct communication with the synovial cavity of the shoulder-joint.

Nerve-Supply.—There are two and often three nerves supplying the subscapularis, viz., the upper subscapular (C. 5. 6.), which is often double; and the lower subscapular (C. 5. 6.), which, after supplying its lateral (lower) portion, ends in the teres major.

Actions.—The subscapularis is a medial rotator of the humerus, but, when the arm is abducted through 90°, the relation of the muscle to the axes of movements becomes altered and it can then act with the pectoralis major to draw the arm forwards.

The principal action of the above group of muscles is on the shoulder-joint. They have also secondary actions in relation to movements of the trunk and limbs.

Movements of the Shoulder.—In all free movements of the arm the acromio- and sterno-clavicular joints are affected in addition to the shoulder-joint itself, and, in limited movements, the shoulder girdle must be steadied by the appropriate fixation muscles.

In considering these movements it must be observed that, in the erect posture, the anterior surface of the humerus is directed medially as well as forwards and that the line of the shoulder-joint passes backwards and laterally and is not parallel to the sagittal plane. It follows that the movement of flexion carries the humerus forwards and medially in front of the body and that the movement of abduction carries it forwards as well as laterally. Flexion occurs in a plane at right angles to the costal surface of the scapula and is limited to a range of 90°, since rotation of the scapula cannot effect any influence upon it. Abduction, on the other hand, occurs in the same plane as the scapula and, although the movement of the humerus on the glenoid fossa is limited to about 90°, rotation of the scapula gives the arm an additional range of just under 90°. Combina-

tions of flexion and abduction give ranges varying between these two extremes, the range becoming greater as the degree of abduction is increased.

In relation to the trunk and limbs, the shoulder muscles, by fixing the humerus, have auxiliary power on the one hand in movements of the trunk, such as forced inspiration; on the other hand, acting along with muscles fixing the elbow-joint, they stiffen the limb so as to permit of the more refined movements of the wrist and fingers.

FASCIÆ AND MUSCLES OF THE ARM.

FASCIÆ.

The **superficial fascia** presents no features of importance. There is a bursa beneath it over the olecranon, and occasionally another over the medial epicondyle of the humerus.

The **deep fascia** forms a strong tubular investment for the muscles on the anterior and posterior aspects of the humerus. It is continuous above with the deep fascia of the shoulder and axilla, and is further strengthened by fibres derived from the insertions of the pectoralis major, latissimus dorsi, and deltoid muscles. At the elbow it becomes continuous with the deep fascia of the forearm, and gains attachment to the epicondyles of the humerus and the olecranon of the ulna; it is strengthened also by important bands associated with the insertions of the biceps anteriorly and the triceps posteriorly, to which reference will be made in the account of these muscles.

About the middle of the arm on the medial side, the deep fascia is perforated for the passage of the basilic vein and the medial cutaneous nerve of the forearm.

The **intermuscular septa** are processes of the deep fascia attached to the epicondylic ridges of the humerus. The **medial** and stronger **septum** is placed between the brachialis muscle anteriorly and the medial head of the triceps posteriorly, and gives origin to both. It extends proximally to the insertion of the coracobrachialis (which is often continued into it), and its proximal part is pierced by the ulnar nerve and superior ulnar collateral vessels. The **lateral septum** is thinner. It separates the brachialis muscle and brachioradialis in front from the medial and lateral heads of the triceps behind, and gives origin to those muscles. It extends proximally to the insertion of the deltoid, and is pierced by the radial nerve and profunda brachii vessels.

MUSCLES OF THE ARM.

The muscles of the arm comprise the biceps, coracobrachialis, and brachialis on the anterior aspect, and the triceps brachii on the posterior aspect of the humerus. Except at its extremities, the biceps brachii is superficial, and forms a rounded fleshy mass on the anterior aspect of the arm. The coracobrachialis is visible on its medial side in the proximal half of the arm, particularly when the arm is raised. The brachialis is concealed by the biceps. The triceps brachii forms the thick mass of muscle covering the posterior surface of the humerus.

M. Coracobrachialis.—The **coracobrachialis** is a rudimentary muscle. It **arises** under cover of the deltoid from the tip of the coracoid process, by fleshy fibres, in common with the short head of the biceps, and also frequently from the tendon of insertion of the pectoralis minor muscle.

The fleshy belly is pierced by the musculo-cutaneous nerve, and ends in a flat tendon which is **inserted** into a faint linear impression about an inch in length on the middle of the medial border of the body of the humerus (Fig. 314, p. 383). It is often continued into the medial intermuscular septum.

The **coracobrachialis** is the remains of a *threefold muscle*, of which only two elements are usually present in man, but of which in anomalous cases all the parts may be more or less fully developed. The passage of the musculo-cutaneous nerve through the muscle is an indication of its natural separation into two parts, which represent the persistent middle and distal elements.

The commonest variety is one in which the more superficial (distal) part of the muscle extends more distally than usual, so as to be inserted into the medial intermuscular septum, or even into

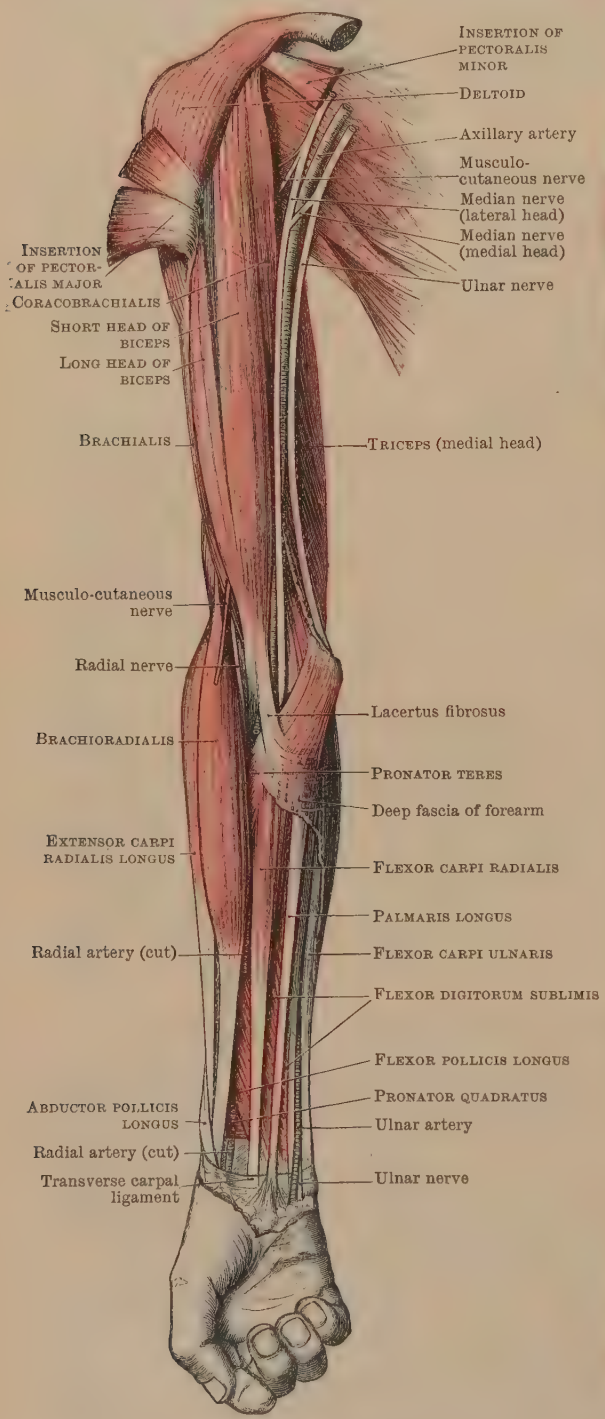

Fig. 312.—Superficial Muscles on the Anterior Aspect of the Right Arm and Forearm.

Fig. 313.—The Muscles on the Posterior Sid of the Left Arm, Forearm, and Hand.

the medial epicondyle of the humerus. A third slip (**coracobrachialis superior** or **brevis, rotator humeri**) may more rarely be present, forming a short muscle **arising** from the root of the coracoid process, and **inserted** into the medial side of the humerus just distal to the capsule of the shoulder-joint.

Nerve-Supply.—The nerve to the coracobrachialis comes from the 7th or 6th and 7th cervical nerves. Incorporated with the musculo-cutaneous, the nerve separates to supply the muscle before the latter nerve pierces it.

Action.—The muscle assists in flexion and adduction of the arm. In addition, when the humerus is rotated laterally, it can produce medial rotation until the position of rest is reached.

M. Biceps Brachii.—The **biceps brachii arises** by two tendinous *heads*. (1) The **short head (caput breve)** is attached in common with the coracobrachialis to the tip of the coracoid process of the scapula (Fig. 307, p. 376). Concealed by the deltoid and tendinous at first, this head forms a separate fleshy belly, which is united to the long head by an investment of the deep fascia. (2) The **long head (caput longum)** arises by a round tendon from the supraglenoidal tuberosity at the root of the coracoid process and from the labrum glenoidale on each side. Its tendon passes through the cavity of the shoulder-joint, and, emerging from the capsule beneath the transverse humeral ligament (invested by a prolongation of the synovial membrane), it occupies the intertubercular groove of the humerus where it is covered by a fascial prolongation of the tendon of the pectoralis major. In the arm it forms a fleshy belly which unites with the short head just distal to the middle of the arm.

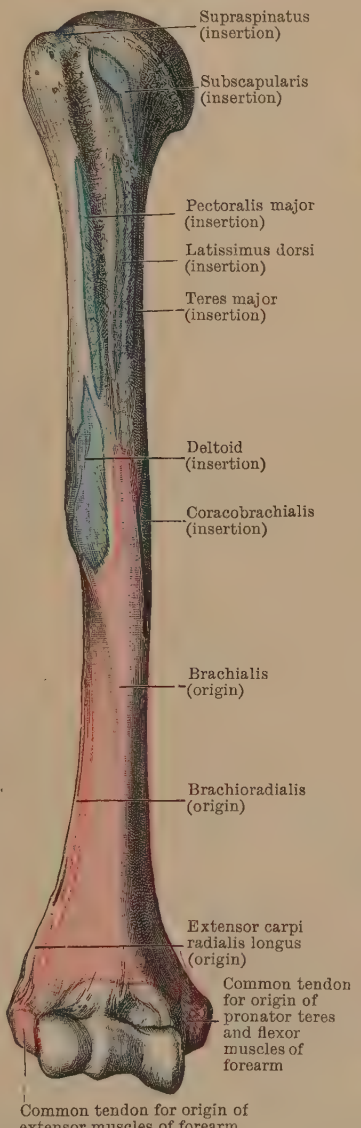

FIG. 314.—MUSCLE-ATTACHMENTS TO THE ANTERIOR ASPECT OF THE RIGHT HUMERUS.

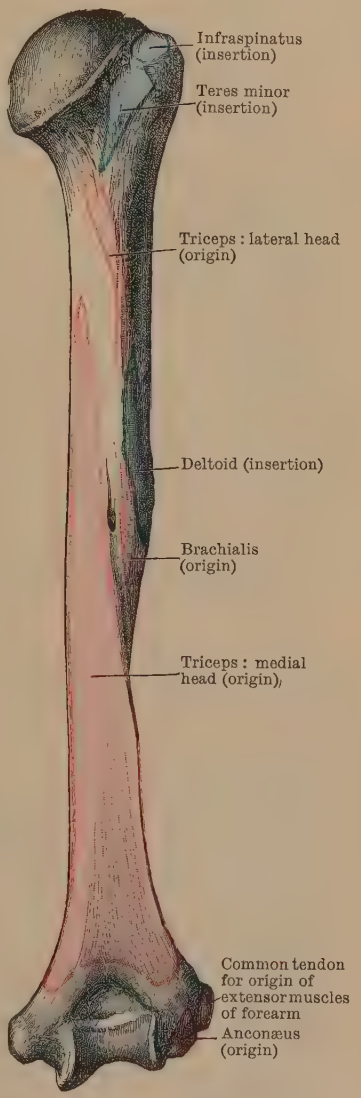

FIG. 315.—MUSCLE-ATTACHMENTS TO THE POSTERIOR SURFACE OF THE RIGHT HUMERUS.

The **insertion** of the muscle is likewise twofold. (1) The two bellies become connected to a strong *tendon*, attached deeply in the hollow of the elbow to the rough dorsal portion of the tubercle of the radius (Figs. 322, p. 392, and 329, p. 400). A bursa separates the tendon from the volar portion of the tuberosity. (2) From the medial and anterior part of the tendon, and partly in continuity with the fleshy fibres of the muscle, a strong *membranous band* (**the lacertus fibrosus**) extends, distally and medially, over the hollow of the elbow

to join the deep fascia covering the origins of the flexor and pronator muscles of the forearm. Its proximal part is thickened and can be felt subcutaneously as a crescentic border which crosses in front of the brachial artery and the median nerve.

In the arm the biceps conceals the brachialis muscle and the musculo-cutaneous nerve. Its medial border is the guide to the position of the brachial artery and median nerve.

A **third head of origin** is common (10 per cent), and usually arises from the humerus, between the insertions of the deltoid and coracobrachialis. Two or even three additional heads may be present at the same time. The long head of the muscle may be absent, or may take origin from the intertubercular groove. The muscle may have an additional insertion into the medial epicondyle of the humerus, or into the fascia of the forearm.

Nerve-Supply.—Each head receives a branch from the musculo-cutaneous nerve (C. 5. 6.).

Actions.—The principal actions of the biceps are exerted on the elbow and radio-ulnar joints. It is a strong flexor of the forearm and acts to best advantage as a supinator when the elbow-joint is flexed. The actions on the shoulder-joint are weak, the short head helping in flexion and adduction, and the long head in abduction.

M. Brachialis.—The **brachialis** is a large muscle **arising** from the distal two-thirds of the anterior aspect of the body of the humerus and from the intermuscular septum on each side (Fig. 314, p. 383).

Clasping the insertion of the deltoid proximally, it ends distally in a strong tendon, which is **inserted**, deep in the hollow of the elbow, into the anterior ligament of the elbow-joint, the distal surface of the coronoid process, and slightly into the immediately adjacent part of the volar surface of the body of the ulna (Fig. 322, p. 392). The lateral part of the muscle, arising from the lateral epicondylic ridge and lateral intermuscular septum, forms a slip more or less separate, which may be partially fused with the brachioradialis muscle.

It is concealed for the most part by the biceps muscle in the arm. It forms the floor of the cubital fossa, and covers the anterior aspect of the elbow-joint.

Nerve-Supply.—It is supplied by the musculo-cutaneous nerve (C. 5. 6.); and also (in most instances) at its lateral border by a fine branch of the radial nerve (C. (5.) 6.).

Action.—This muscle is a flexor of the elbow-joint.

M. Triceps Brachii.—The **triceps brachii** is the only muscle on the posterior aspect of the arm. It **arises** by three heads: a lateral and a medial head, from the humerus, and a long head from the scapula. (1) The **long head** (**caput longum**) begins as a strong tendon attached to the infra-glenoidal tuberosity (Figs. 307, p. 376, and 311, p. 379). This gives rise to a fleshy belly which, after passing between the teres major and teres minor muscles, occupies the middle of the back of the arm. (2) The **lateral head** is attached by fibres, partly tendinous and partly fleshy, to the curved lateral border of the humerus from the insertion of the teres minor proximally to the radial groove distally, and receives additional fibres from the posterior surface of the lateral intermuscular septum (Fig. 313, p. 382). Its fibres are directed distally and medially over the radial groove, concealing the radial (musculo-spiral) nerve, the profunda brachii artery, and the medial head of the muscle. (3) The **medial head** arises by fleshy fibres from an elongated triangular area on the posterior surface of the humerus, extending proximally to the level of the insertion of the teres major, and distally nearly to the margin of the olecranon fossa (Fig. 315, p. 383). It also arises, on each side, from the intermuscular septum,—from the whole length of the medial septum, and from the part of the lateral septum which is below the passage of the radial nerve.

The three heads of origin are **inserted**, by a broad and membranous common tendon, into an impression occupying the posterior part of the proximal end of the olecranon of the ulna (Fig. 329, p. 400), and into the deep fascia of the forearm on each side of it. The long and lateral heads join the borders of the tendon of insertion, and the medial head is attached to its deep surface. A small thick-walled bursa separates the tendon of the triceps from the posterior ligament of the elbow-joint and the proximal end of the olecranon.

The muscle is superficial in almost its whole extent. The long (scapular) head is concealed at its origin by its relation to the teres muscles, between which it passes.

The **subanconæus** is a small muscle occasionally present. It consists of scattered fibres **arising** from the distal end of the posterior surface of the humerus, deep to the triceps, and it is **inserted** into the posterior ligament of the elbow-joint.

Nerve-Supply.—The several heads of the muscle are supplied separately by branches of the radial nerve. The lateral head receives fibres from C. (6.) 7. 8.; the long and medial head from C. 7. 8. The medial head has a double supply. One nerve enters its proximal part, another (ulnar collateral nerve of Krause) enters the distal part of the muscle.

Actions.—The triceps is the extensor muscle of the elbow-joint. The long head also acts as an adductor of the humerus at the shoulder-joint.

FASCIÆ AND MUSCLES OF THE FOREARM AND HAND.

Fasciæ.

The **superficial fascia** in the forearm presents no exceptional features. On the dorsum of the hand it is loose and thin; in the palm it is generally well furnished with fat, forming pads for the protection of the vessels and nerves. Numerous fibrous septa penetrate its substance, passing between the palmar aponeurosis and the skin, especially along the lines of flexure. A band of transverse fibres (*superficial transverse metacarpal ligament*) crosses the distal part of the palm, being enclosed within the skin folds which form the webs of the fingers and connected to the volar aspects of the fibrous digital sheaths.

M. Palmaris Brevis.—The **palmaris brevis** is a quadrilateral subcutaneous muscle which lies in the medial side of the hand, under the superficial fascia. It **arises** from the medial border of the thick central portion of the palmar aponeurosis and from the volar surface of the transverse carpal ligament and is **inserted** into the skin of the medial border of the hand for a variable distance. It covers the ulnar artery and nerve, branches of which supply it. Its action is to wrinkle the skin of the medial border of the hand, and by raising up the skin and superficial fascia, to deepen the hollow of the hand.

The **deep fascia** of the forearm and hand is continuous above with the deep fascia of the arm. In the proximal part of the forearm it is strengthened in front, by fibres from the lacertus fibrosus (semilunar fascia) of the biceps; behind, by the fascial insertions of the triceps; and laterally, by fibres derived from the humeral epicondyles in relation to the common tendons of origin of the flexor and extensor muscles of the forearm which in part take their origin from them. It is attached to the dorsal margin of the ulna, and affords increased attachment to the flexor and extensor carpi ulnaris and the flexor digitorum profundus muscles. A second layer of fascia is closely associated with the volar surface of the flexor digitorum sublimis. Thin in the proximal part of the forearm, it becomes considerably thickened near the wrist, where it lies deep to the tendons of the flexor carpi radialis, palmaris longus, and flexor carpi ulnaris and the ulnar vessels and nerve. These two layers become partially blended on the volar aspect of the carpus to constitute the transverse carpal ligament. On the dorsal aspect of the wrist, the deep fascia is strengthened by a number of oblique fibres and forms the dorsal carpal ligament.

Ligamentum Carpi Transversum.—The **transverse carpal ligament** is a band about an inch and a half in depth, continuous, proximally and distally, with the deep fasciæ of the forearm and the palm of the hand. It is attached laterally to the navicular and large multangular bones; medially to the pisiform and os hamatum; and it forms a membranous arch binding down, in the hollow of the carpus, the flexor tendons of the digits, and the median nerve. It is divided into *two compartments*, the larger accommodating the tendons of the flexors of the digits and the median nerve, the smaller (placed laterally) containing the tendon of the flexor carpi radialis. There are *three synovial membranes* in these compartments: one for the flexor carpi radialis tendon, and two others, which often communicate together, enveloping the tendon of the flexor pollicis longus and the flexor tendons of the fingers respectively. The surface of the ligament is crossed by the

palmar branches of the median and ulnar nerves; by the tendon of the palmaris longus muscle, which is attached to its surface; and by the ulnar artery and nerve, which are again bridged over and protected by a band of fibrous tissue continuous proximally with the investing layer of the deep fascia. This is called the *volar carpal ligament*, and it passes from the pisiform bone to the surface of the transverse carpal ligament. The distal border of the ligament is continuous with the palmar aponeurosis in the centre, and its sides give origin to the superficial muscles of the thumb and the muscles of the little finger.

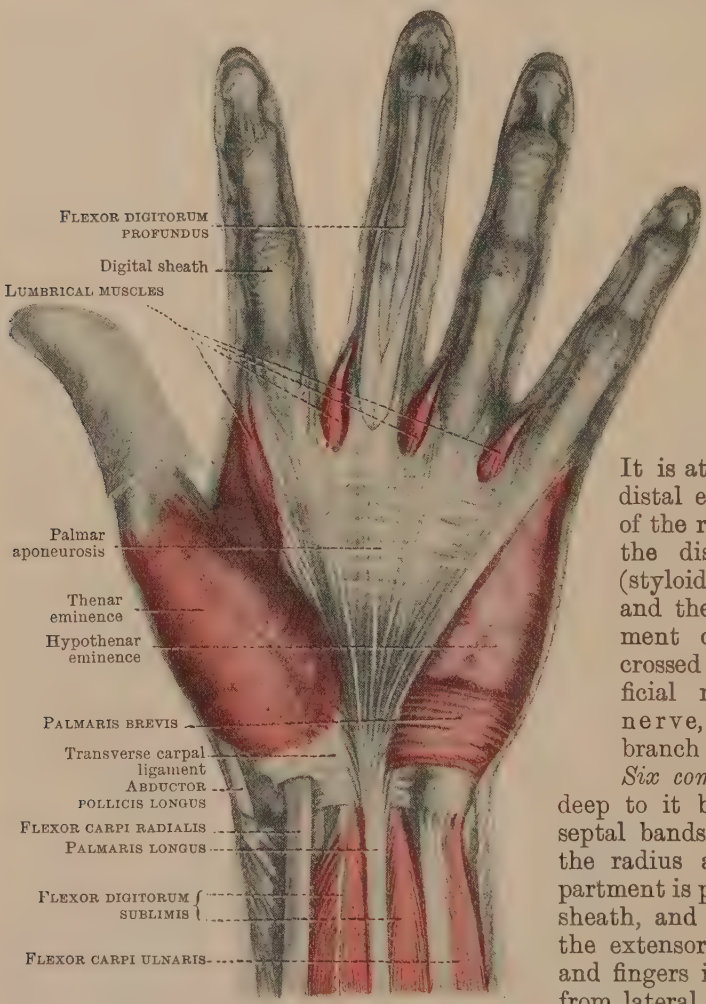

Fig. 316.—The Palmar Aponeurosis.

Ligamentum Carpi Dorsale.—The **dorsal carpal ligament** is placed at a more proximal level than the transverse carpal ligament. It consists of an oblique band of fibres about an inch broad, continuous proximally and distally with the deep fascia of the forearm and hand. It is attached laterally to the distal end of the volar border of the radius, and medially to the distal end of the ulna (styloid process), the carpus, and the ulnar collateral ligament of the wrist. It is crossed by veins, by the superficial ramus of the radial nerve, and by the dorsal branch of the ulnar nerve. *Six compartments* are formed deep to it by the attachment of septal bands to the distal ends of the radius and ulna. Each compartment is provided with a mucous sheath, and they serve to transmit the extensor tendons of the wrist and fingers in the following order from lateral to medial side:—

(1) Abductor pollicis longus and extensor pollicis brevis, (2) Extensores carpi radiales, longus and brevis, (3) Extensor pollicis longus, (4) Extensor digitorum communis and extensor indicis proprius, (5) Extensor digiti quinti proprius, (6) Extensor carpi ulnaris.

The thin deep fascia of the dorsum of the hand is lost over the expansions of the extensor tendons on the fingers. Between the metacarpal bones a strong layer of fascia covers and gives attachment to the interossei muscles.

Aponeurosis Palmaris.—The **palmar aponeurosis** is of considerable importance. In the centre of the palm it forms a thick triangular membrane, the apex of which joins the distal edge of the transverse carpal ligament, and, more superficially, receives the insertion of the tendon of the palmaris longus muscle. The fascia separates below into four slips, one for each finger. The slips are connected together on their deep surfaces by transverse fibres, which cover the lumbricals and the digital vessels and nerves (**fasciculi transversi**). More distally

each slip separates into two parts, to be connected to the sides of the metacarpo-phalangeal joints and the first phalanx of the medial four digits. In the cleft between the two halves of each slip the **digital fibrous sheath** is attached and extends distally on to the finger. The lateral borders of this triangular central portion of the palmar aponeurosis are continuous with thin layers of deep fascia, which cover and envelop the muscles of the thenar and hypothenar eminences. The medial border gives origin to the palmaris brevis muscle (p. 385).

The **digital fibrous sheaths** (vaginæ fibrosæ) are tubular envelopes extending along the palmar aspect of the digits and enclosing the flexor tendons. Each consists of a fibrous sheath attached to the lateral borders of the phalanges and inter-phalangeal joints, and continuous proximally with the palmar aponeurosis. Opposite each inter-phalangeal articulation the digital sheath is loose and thin; opposite the first two phalanges (the first only in the case of the thumb) it becomes extremely thick, and gives rise to the **ligamenta vaginalia**, which serve to keep the tendons closely applied to the bones during flexion of the fingers. Within each sheath are the flexor tendons, enveloped in a **mucous sheath (vagina mucosa)** which surrounds the tendons and lines the interior of the fibrous sheath. The mucous linings of the digital sheaths extend a short distance proximally in the palm, and in some cases communicate with the large mucous sheaths enclosing the flexor tendons beneath the transverse carpal ligament.

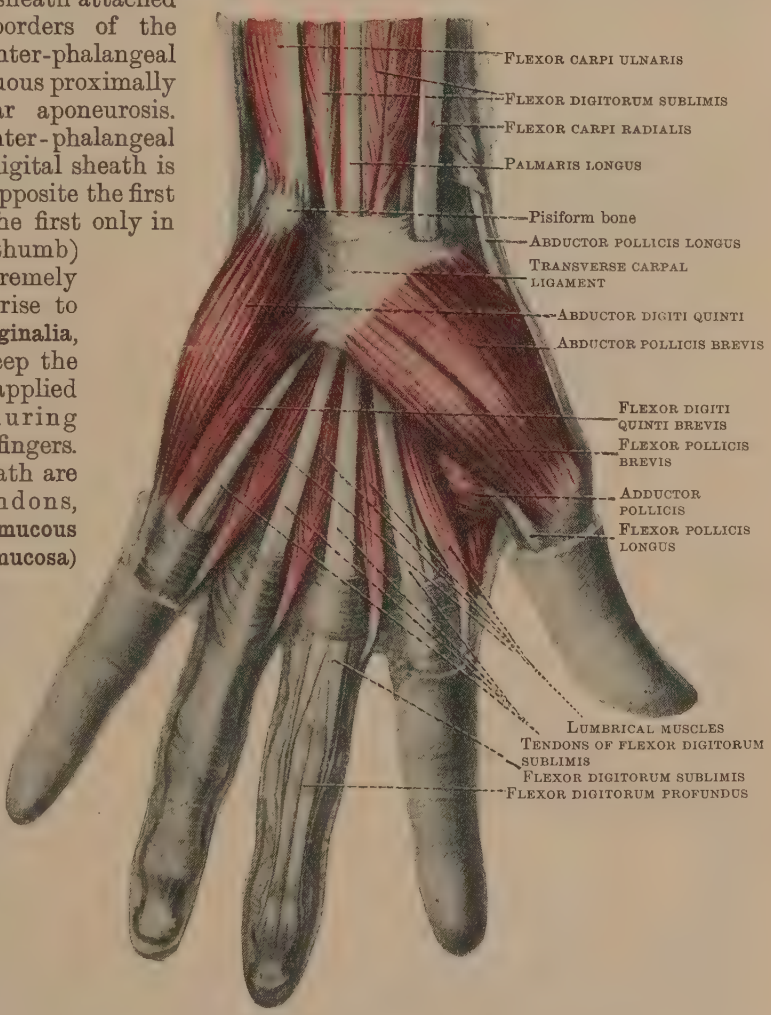

Fig. 317.—Superficial Muscles and Tendons in the Palm of the Left Hand.

There may be a separate distinct mucous sheath for each digit; but most commonly only the sheaths for the three middle digits are separate; those of the flexor pollicis longus and the flexor tendons of the little finger usually communicate with the mucous sheaths placed beneath the transverse carpal ligament.

Regarded as a whole, the transverse carpal ligament, the palmar aponeurosis, and the fibrous digital sheaths form a continuous sheet, which serves to increase the efficiency of the flexor muscles of the digits and wrist and to increase the power of prehension. The fascial thickenings retain the tendons in position and provide pulleys over which they act. When the flexor muscles of the digits contract, their tendons do not raise ridges under the skin, which would interfere with the

efficiency of the hand as a gripping instrument, and, as a result, the extent of the movements of the phalanges is directly proportional to the amount of shortening of the muscles concerned.

THE MUSCLES ON THE ANTERIOR AND MEDIAL ASPECTS OF THE FOREARM.

The muscles on the anterior and medial aspects of the forearm comprise the pronators and the flexors of the wrist and fingers. In the forearm they are arranged in three strata: (1) a superficial layer consisting of four muscles which radiate from the medial epicondyle of the humerus, from which they take origin by a common tendon. They are named, from radial to ulnar side, pronator teres, flexor carpi radialis, palmaris longus, and flexor carpi ulnaris. These muscles conceal the muscle which by itself constitutes (2) the intermediate stratum—the flexor digitorum sublimis, and this again conceals, for the most part, (3) the deep layer of muscles, including the flexor digitorum profundus covering the ulna, the flexor pollicis longus on the radius, and the pronator quadratus, which is more deeply placed than the previous muscles, and stretches across the forearm between the distal portions of the radius and ulna.

I. Superficial Muscles.

M. Pronator Teres.—The **pronator teres** is the shortest muscle of this group. It has a double **origin**: (1) a *superficial head* (**caput humerale**), the main origin, partly fleshy, partly tendinous, from the most distal part of the medial epicondylic ridge of the humerus and from the medial intermuscular septum, from the medial epicondyle of the humerus, from the fascia over it, and from an intermuscular septum between it and the flexor carpi radialis (Fig. 310, p. 379); (2) a *deep head* (**caput ulnare**), a slender tendinous slip from the medial side of the coronoid process of the ulna, which joins the superficial origin of the muscle on its deep surface (Fig. 322, p. 392). The median nerve separates the two heads from one another.

The muscle passes distally and laterally to be **inserted** by tendon into an oval impression on the middle of the lateral surface of the body of the radius (Figs. 322, p. 392, and 329, p. 400). The fibres of the muscle are twisted on themselves, so that the most proximal humeral fibres form the most distal fibres of the tendon of insertion, and the most distal humeral fibres and those arising from the coronoid process are most proximal at the insertion.

The pronator teres forms the medial boundary of the hollow of the elbow. It is superficially placed, except near its insertion, where it is covered by the brachioradialis muscle and by the radial vessels and superficial branch of the radial nerve.

Nerve-Supply.—Median nerve (C. 6.).
Action.—The muscle is a pronator of the forearm and assists in flexion of the elbow joint.

M. Flexor Carpi Radialis.—The **flexor carpi radialis** muscle takes its **origin** from the common tendon from the medial epicondyle of the humerus, from the fascia over it, and from the intermuscular septa on either side.

About the middle of the forearm, the fleshy belly gives place to a flattened tendon, which becomes more cord-like as it approaches the wrist. Entering the hand, the tendon splits the transverse carpal ligament into its two constituent layers and occupies the groove on the greater multangular bone, where it is surrounded by a mucous sheath. Finally it is inserted into the base of the second and usually into the adjoining part of the base of the third metacarpal bone (Fig. 325, p. 395).

The muscle is superficial except near its insertion. Its tendon, in the distal half of the forearm, is an important guide to the radial vessels, which are placed to its radial side. After passing beneath the transverse carpal ligament the tendon is concealed by the origins of the short muscles of the thumb, and is crossed, from medial to lateral side, by the tendon of the flexor pollicis longus. Besides the

mucous sheath enveloping the tendon beneath the ligament, a mucous bursa is placed beneath the insertion of the tendon.

Nerve-Supply.—Median nerve (C. 6.).

Actions.—This muscle acts primarily with the flexor carpi ulnaris to flex the wrist, but an important function is to steady the wrist during extension of the fingers; *i.e.* in association with the ulnar flexor of the wrist, it is a synergic muscle for the extensors of the digits. In addition, it may co-operate with the radial extensors of the wrist to produce abduction of the hand, and with the pronators or flexors of the elbow to produce pronation or flexion of the forearm, as the case may be.

M. Palmaris Longus.—The **palmaris longus arises** also from the common flexor tendon from the medial epicondyle of the humerus, from the fascia over it, and from intermuscular septa on each side.

It forms a short fusiform muscle, which ends, in the middle of the forearm, in a long flat tendon. This passes superficial to the transverse carpal ligament, and is **inserted** (1) into the surface of the transverse carpal ligament, and (2) into the apex of the thick central portion of the palmar aponeurosis. A tendinous slip is frequently sent to the short muscles of the thumb and the fascia covering them.

The palmaris longus is the smallest muscle of the forearm. In the distal third of the forearm its tendon is placed directly over the median nerve, along the radial border of the tendons of the flexor digitorum sublimis.

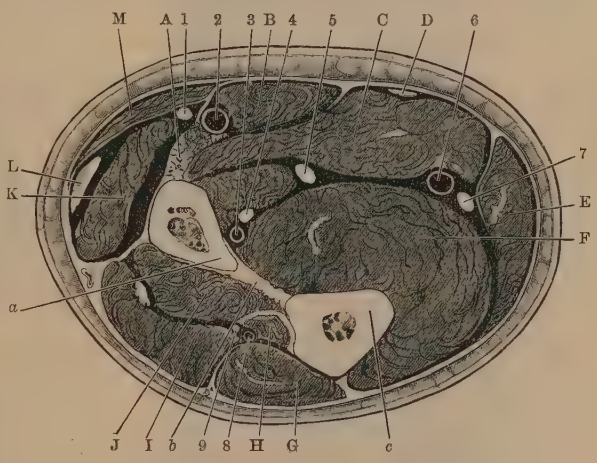

FIG. 318.—DISTAL SURFACE OF A SECTION ACROSS THE RIGHT FOREARM IN THE MIDDLE THIRD.

A, PRONATOR TERES (insertion); B, FLEXOR CARPI RADIALIS; C, FLEXOR DIGITORUM SUBLIMIS; D, PALMARIS LONGUS; E, FLEXOR CARPI ULNARIS; F, FLEXOR DIGITORUM PROFUNDUS; G, EXTENSOR CARPI ULNARIS; H, EXTENSOR POLLICIS LONGUS; I, EXTENSOR DIGITORUM COMMUNIS AND EXTENSOR DIGITI QUINTI PROPRIUS; J, ABDUCTOR POLLICIS LONGUS; K, EXTENSOR CARPI RADIALIS BREVIS; L, EXTENSOR CARPI RADIALIS LONGUS; M, BRACHIORADIALIS. *a*, Radius; *b*, Interosseous membrane; *c*, Ulna. 1, Superficial ramus of radial nerve; 2, Radial artery; 3, Volar interosseous artery; 4, Volar interosseous nerve (underneath flexor pollicis longus); 5, Median nerve; 6, Ulnar artery; 7, Ulnar nerve; 8, Dorsal interosseous artery; 9, Dorsal interosseous nerve.

The palmaris longus is the most variable muscle in the body, and is often absent (10 per cent). It represents a flexor of the first phalanges, but in man it has become very much reduced, owing to differentiation of the other digital flexors and to finer control of the lumbricals and interossei.

Nerve-Supply.—Median nerve (C. 6.).

Actions.—The muscle assists in flexion of the elbow and wrist. It also acts as a tensor of the palmar aponeurosis.

M. Flexor Carpi Ulnaris.—The **flexor carpi ulnaris** muscle has a double **origin**, from the humerus and from the ulna. (1) It arises from the common tendon attached to the medial epicondyle of the humerus, from the fascia over it, and from a lateral intermuscular septum. (2) By means of the deep fascia of the forearm it obtains an attachment to the medial border of the olecranon and the dorsal margin of the ulna in its proximal three-fifths.

The fleshy fibres join a tendon which lies on the anterior border of the muscle and is **inserted** into the pisiform bone, and in the form of two ligamentous bands (piso-hamate and piso-metacarpal) into the hamulus of the os hamatum, and the proximal end of the fifth metacarpal bone (Fig. 325, p. 395).

The muscle is superficially placed along the medial border of the forearm. It conceals the flexor digitorum profundus muscle, the ulnar nerve (which enters the forearm between the two heads of origin of the muscle), and the ulnar artery. The tendon serves as a guide to the artery in the distal half of the forearm.

Nerve-Supply.—Ulnar nerve (C. 8. T. 1.).

Actions.—The flexor carpi ulnaris is a flexor and adductor of the wrist, and an accessory flexor of the elbow-joint. It steadies the pisiform bone during contractions of the abductor digiti quinti and, like the flexor carpi radialis, acts as a synergic muscle during extension of the fingers.

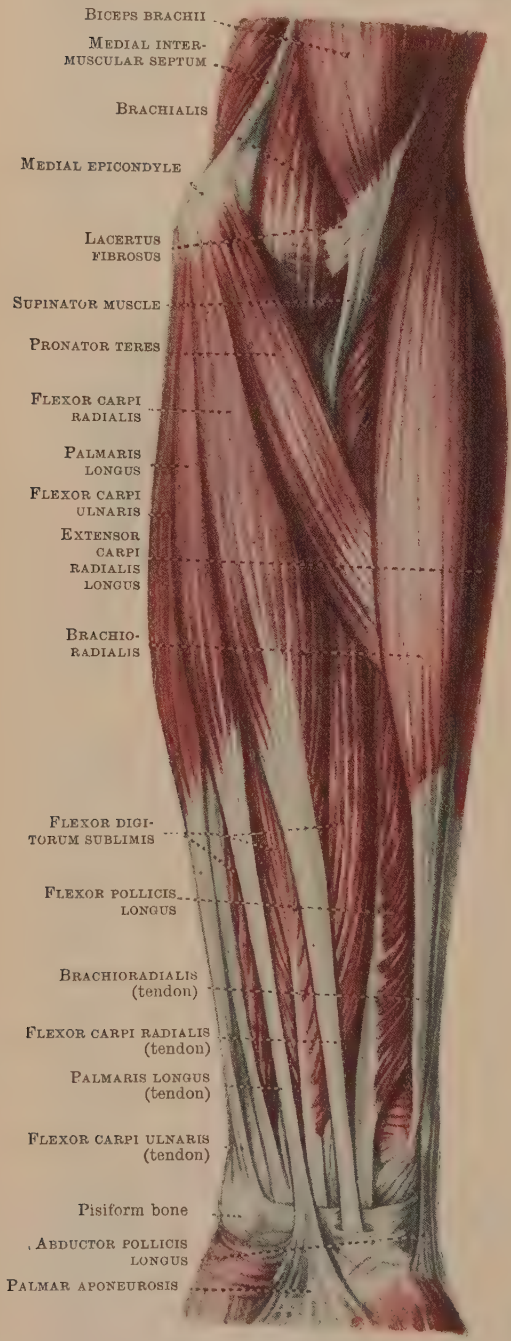

Fig. 319.—The Superficial Muscles of the Left Forearm.

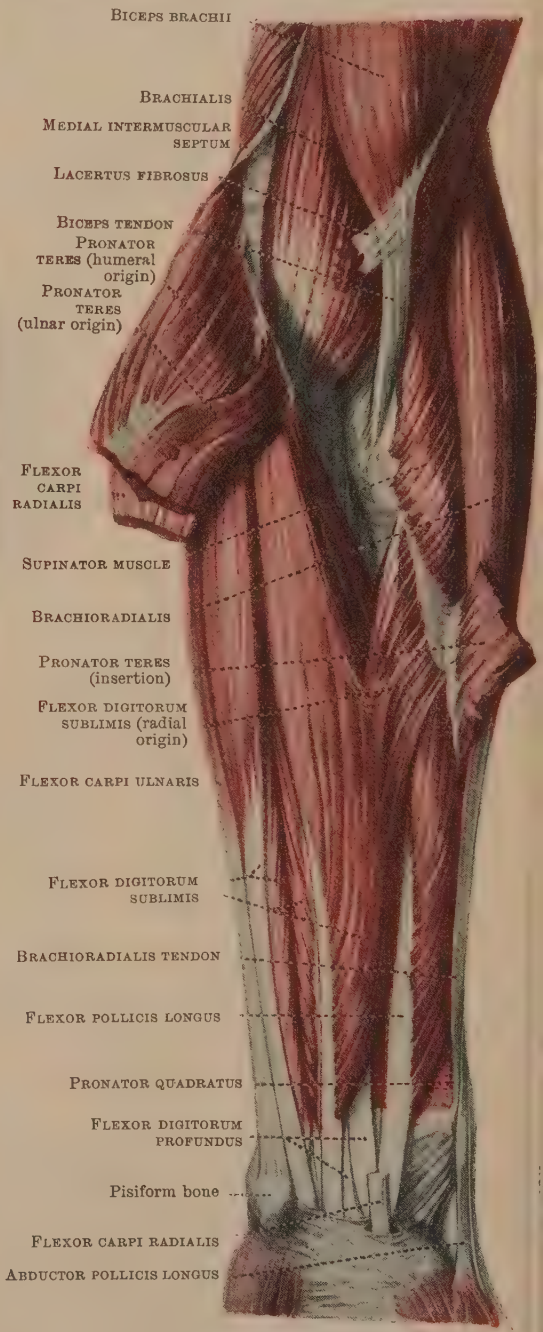

Fig. 320.—Deeper Muscles of the Left Forearm.

2. Intermediate Layer.

M. Flexor Digitorum Sublimis.—The **flexor digitorum sublimis** occupies a deeper plane than the four previous muscles. It has a wide **origin**, from the humerus, radius, and ulna. (1) The chief or humero-ulnar head of origin is from

the medial epicondyle of the humerus by the common tendon, from adjacent intermuscular septa, and from the *ulnar collateral* ligament of the elbow, by a slender fasciculus, from the medial border of the coronoid process of the ulna, proximal and medial to the origin of the pronator teres (Fig. 322, p. 392). (2) The *radial* head of origin is from the proximal two-thirds of the volar margin of the radius by a thin fibro-muscular attachment (Fig. 322, p. 392).

In the distal third of the forearm the muscle gives rise to four tendons, one for each of the four medial digits. Those for the middle and ring fingers lie side by side and are placed superficial to the tendons for the index and the little finger. The proximal part of the muscle is similarly subdivisible into two strata, of which the more superficial comprises the radial and part of the humeral head. The whole of the radial head is destined for the middle finger. The same arrangement holds at the wrist, where the tendons pass under cover of the transverse carpal ligament and are enclosed in a large mucous sheath together with the tendons of the flexor digitorum profundus.

Under cover of the palmar aponeurosis the tendons diverge and, in company with the corresponding tendon of the deep flexor, each enters the digital sheath of its own digit. Opposite the first phalanx, the tendon is split into two parts by the tendon of the flexor digitorum profundus; after surrounding that tendon the two parts are partially reunited on its deep surface, and are **inserted**, after partial decussation, in two portions into the sides of the second phalanx.

The **vincula tendinum** form additional insertions of the muscle. They consist of delicate bands of connective tissue enveloped in folds of the mucous sheath, and are known as the **vincula longa** and **brevia**. The vinculum breve is a triangular band of fibres containing yellow elastic tissue (ligamentum subflavum), occupying the interval between the tendon and the digit for a short distance close to the insertion. It is attached to the front of the interphalangeal articulation and the head of the first phalanx. The vinculum longum is a long narrow band extending from the back of the tendon to the proximal part of the palmar surface of the first phalanx.

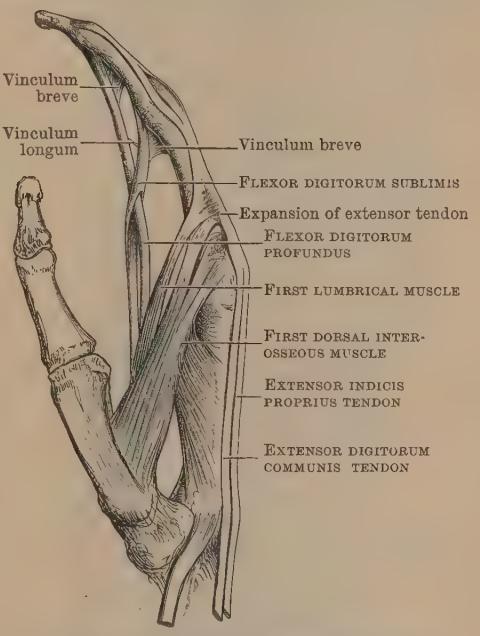

Fig. 321.—The Tendons attached to the Index Finger.

Nerve-Supply.—Median nerve (C. 6.).

Actions.—The muscle is a flexor of the proximal interphalangeal and metacarpo-phalangeal joints. When this action is strongly opposed, the muscle assists in flexing the wrist joint.

3. Deep Layer.

M. Flexor Digitorum Profundus.—The **flexor digitorum profundus** is a large muscle **arising** from the ulna, the interosseous membrane, and the deep fascia of the forearm, under cover of the flexor digitorum sublimis and the flexor carpi ulnaris. Its ulnar origin is from the volar and medial surfaces of the bone in its proximal two-thirds, extending proximally so as to include the medial side of the olecranon, and to embrace the insertion of the brachialis muscle into the coronoid process. It arises laterally from the medial half of the interosseous membrane in its middle third (Figs. 322, p. 392, and 323, p. 393), and medially from the deep fascia of the forearm dorsal to the origin of the flexor carpi ulnaris.

The muscle forms a broad thick tendon which passes beneath the transverse

carpal ligament, covered by the tendons of the flexor digitorum sublimis, and enveloped in the same mucous sheath, and divides, in the palm, into four tendons for **insertion** into the terminal phalanges of the fingers. The tendon associated with the forefinger is usually separate in its whole length, and is mainly derived from those fibres which arise from the interosseous membrane.

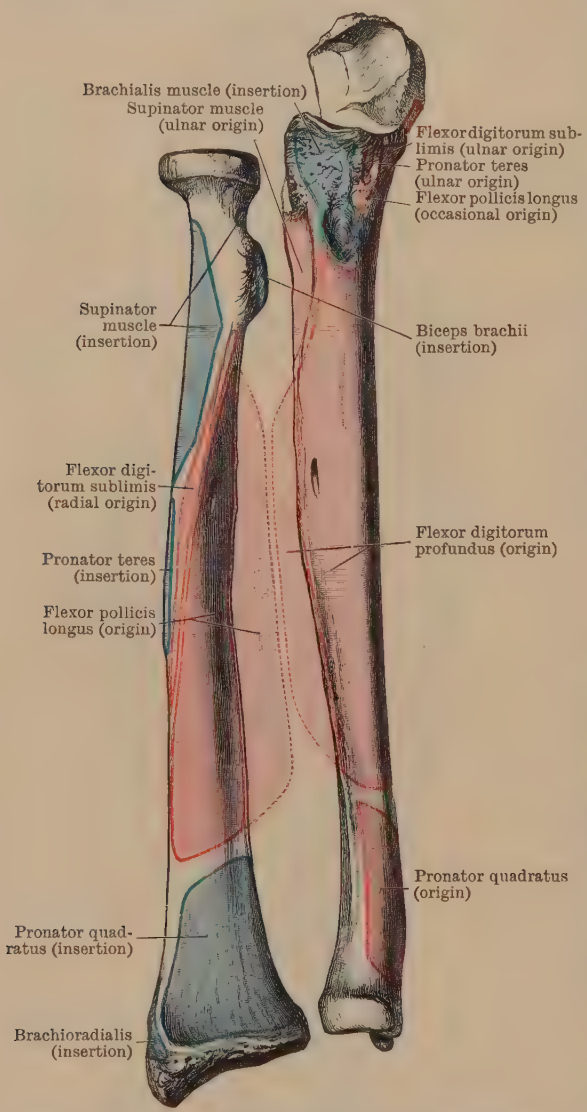

FIG. 322.—MUSCLE-ATTACHMENTS TO THE RIGHT RADIUS AND ULNA (Volar Aspects).

Each tendon enters the digital sheath of the finger deep to the tendon of the flexor digitorum sublimis, which it pierces opposite the first phalanx, and is finally inserted into the base of the terminal phalanx. Like the tendons of the flexor sublimis, those of the deep flexor are provided with vincula, viz., **vincula brevia** attached to the capsule of the second interphalangeal articulation, and **vincula longa**, which are in this case connected to the tendons of the subjacent flexor digitorum sublimis.

Mm. Lumbricales. — The **lumbricales** are four small cylindrical muscles associated with the tendons of the flexor digitorum profundus in the palm of the hand. *The two lateral muscles* **arise**, each by a single head, from the radial sides of the tendons of the flexor digitorum profundus destined respectively for the fore and middle fingers. *The two medial muscles* **arise**, each by two heads, from the adjacent sides of the second and third, and third and fourth tendons.

From their origins the muscles are directed distally to the lateral side of each of the metacarpo-phalangeal joints, to be **inserted** into the capsules of these articulations, the lateral border of the first phalanx, and chiefly into the lateral side of the extensor tendon on the dorsum of the phalanx. The lumbricales vary considerably in number, and may be increased to six or diminished to two.

Nerve-Supply.—The flexor digitorum profundus is supplied in its lateral part by the volar interosseous branch of the median nerve (C. 7. 8. T. 1.); and in its medial part by the ulnar nerve (C. 8. T. 1.). The lateral two lumbricales are supplied by the median nerve (C. 8. T. 1.), and the medial two muscles by the ulnar nerve (C. 8. T. 1.).

Actions.—Primarily the flexor digitorum profundus is a flexor of the distal phalanges, and it helps to produce flexion of the second and first phalanges. Secondarily, it is a flexor of the wrist joint, this action being brought out when the movement is effected against strong resistance.

The lumbrical muscles act as flexors of the fingers at the metacarpo-phalangeal joints, and, at the same time (by their attachment to the extensor tendons), they act as extensors of the fingers, acting on both inter-phalangeal joints. In this fine movement, which is utilised in making the upward stroke in writing, the interossei participate as well as the lumbricals.

M. Flexor Pollicis Longus.—The **flexor pollicis longus arises**, beneath the flexor digitorum sublimis, by fleshy fibres, from the volar surface of the body of the radius in its middle two-fourths, and from a corresponding portion of the interosseous membrane. It has an additional origin, occasionally, from the medial border of the coronoid process of the ulna (Fig. 322, p. 392). Its radial origin is limited proximally by the oblique origin of the radial head of the flexor digitorum sublimis, and distally by the insertion of the pronator quadratus muscle.

The muscle ends, proximal to the wrist, in a tendon, which passes over the pronator quadratus into the hand beneath the transverse carpal ligament, and is enveloped in a special mucous sheath.

In the palm the tendon is directed distally along the medial side of the thenar eminence, between the flexor brevis and adductor muscles of the thumb, to be **inserted** into the base of the terminal phalanx of the thumb on its volar surface.

The muscle is placed deeply in the forearm, being concealed by the superficial layer of muscles and by the flexor digitorum sublimis.

Nerve-Supply.—Volar interosseous branch of the median (C. 7. 8. T. 1.).

Actions.—The muscle is a flexor of the thumb, acting on the metacarpal bone and both phalanges.

M. Pronator Quadratus.—The **pronator quadratus** is a quadrilateral fleshy muscle, occupying the distal fourth of the forearm. It is placed beneath the deep flexor tendons, and **arises** from the distal fourth of the volar margin and surface of the ulna (Fig. 322, p. 392).

Its fibres run transversely to be **inserted** into the distal fourth of the volar surface of the radius, and into the narrow triangular area on its medial side, in front of the attachment of the interosseous membrane (Fig. 322, p. 392).

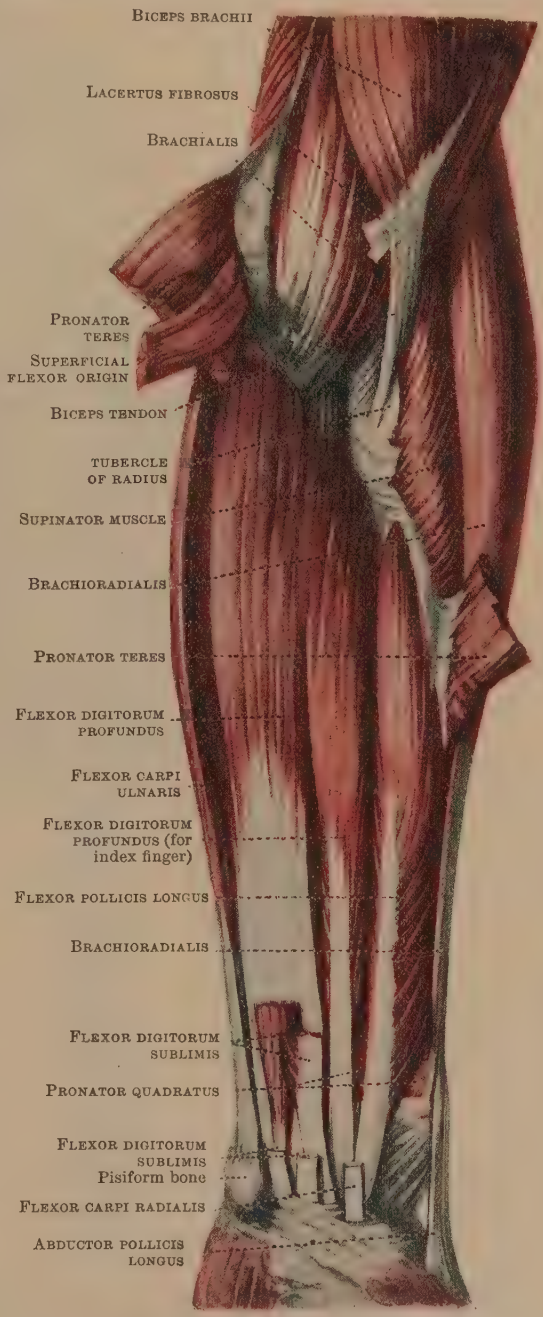

Fig. 323.—The Deepest Muscles on the Volar Aspect of the Left Forearm.

The pronator quadratus is subject to considerable variations. It frequently consists of two strata, separated by the terminal part of the volar interosseous nerve; it may be increased in size, having an additional origin from radius or ulna, or from both bones, and an insertion into the carpus; it may even be absent.

The muscle is placed deeply in the distal part of the forearm, and is wholly concealed by the tendons of the muscles which descend, under cover of the

transverse carpal ligament, to the wrist and fingers. The radial artery and its accompanying veins pass over it at its insertion into the radius.

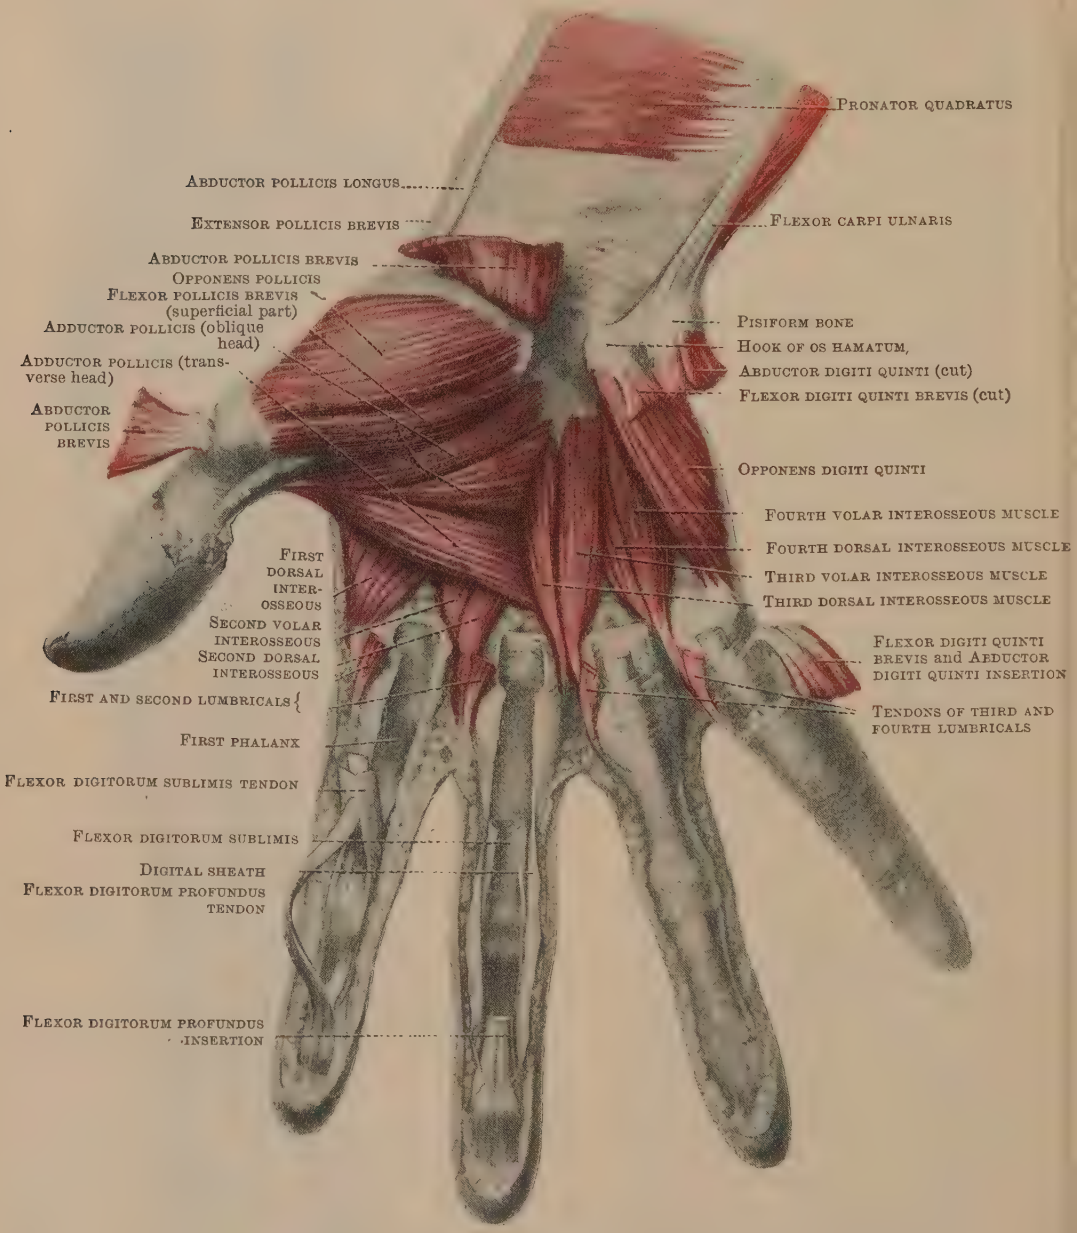

Fig. 324.—The Palmar Muscles (Right Side)

Nerve-Supply.—Volar interosseous branch of the median nerve (C. 7. 8. T. 1.).

Action.—The muscle acts along with the pronator teres in producing pronation of the forearm.

SHORT MUSCLES OF THE HAND.

The short muscles belonging to the hand, in addition to the palmaris brevis and the lumbrical muscles, already described, include the four muscles of the thumb which produce the thenar eminence, the three muscles of the little finger, which form the hypothenar eminence, and the interossei muscles, which are deeply placed between the metacarpal bones.

Muscles of the Thumb.

The abductor pollicis brevis, the opponens pollicis, the flexor pollicis brevis, and the adductor pollicis constitute the muscles of the thumb.

M. Abductor Pollicis Brevis.—The **abductor pollicis brevis** (O.T. **abductor pollicis**) **arises** by fleshy fibres from the tubercle of the navicular bone, the ridge of the greater multangular bone, the volar surface of the transverse carpal ligament,

FIG. 325.—MUSCLE-ATTACHMENTS TO THE VOLAR ASPECT OF THE CARPUS AND METACARPUS.

and from tendinous slips derived from the insertions of the palmaris longus and abductor pollicis longus muscles (Fig. 325, p. 395). Strap-like in form, and superficial in position, it is **inserted** by a short tendon into the radial side of the first phalanx of the thumb at its proximal end, and into the lateral border of the tendon of the extensor pollicis longus muscle.

Nerve-Supply.—Median nerve (C. 6. 7.).

Actions.—The muscle acts on all the joints of the thumb. The movement of abduction, which it produces, occurs at the carpo-metacarpal joint, and the thumb moves in the direction of its radial border. Owing to the fact that the first metacarpal bone is placed with its volar surface directed medially, abduction of the thumb carries it forwards away from the palm. In addition, the abductor pollicis brevis assists in flexion of the metacarpo-phalangeal and in extension of the interphalangeal joint.

M. Opponens Pollicis.—The **opponens pollicis arises** by fleshy and tendinous fibres from the volar surface of the transverse carpal ligament and from the ridge on the greater multangular bone. It is partially concealed by the preceding muscle.

Extending distally and laterally it is **inserted** into the whole length of the radial border and the radial half of the volar surface of the first metacarpal bone (Fig. 325).

Nerve-Supply.—Median nerve (C. 6. 7.).

Action.—It acts solely on the first metacarpal bone, which is drawn medially and forwards, at the same time being rotated medially. As a result of these combined movements, in which the flexores and the adductor pollicis participate, the thumb can be opposed to each of the other digits.

M. Flexor Pollicis Brevis.—The **flexor pollicis brevis** consists of two parts. (*a*) *The superficial part of the muscle*, partly concealed by the abductor pollicis brevis, **arises**, by fleshy and tendinous fibres, from the distal border of the transverse carpal ligament, and sometimes from the ridge of the greater multangular bone.

It is **inserted** into the radial side of the base of the first phalanx of the thumb, a sesamoid bone being present in the tendon of insertion.

(*b*) *The deep part of the muscle* is blended at its origin with the lateral part of the oblique head of the adductor pollicis, but, separating from that muscle, it passes distally and laterally, deep to the flexor pollicis longus tendon, to be inserted in common with the superficial head.

Nerve-Supply.—Median nerve (C. 6. 7.).
Actions.—It is a flexor of the thumb and assists also in the movement of opposition of the thumb to the fingers.

N.B.—Many English anatomists regard the deep head, above described, as a part of the oblique adductor. They look on the first volar interosseous muscle (p. 397) **as the deep head of the flexor pollicis brevis and therefore describe only three volar interossei.**

M. Adductor Pollicis.—The **adductor pollicis** is separated into two parts by the radial artery.

(1) The **oblique head** lies deeply in the palm, covered by the tendons of the long flexors of the thumb and fingers. It **arises** by fleshy fibres from the volar surfaces of the greater and lesser multangular and capitate bones, from the sheath of the tendon of the flexor carpi radialis, from the volar surfaces of the bases of the second, third, and fourth metacarpal bones, and from the volar ligaments connecting these bones together (Fig. 325, p. 395).

It is **inserted** by a tendon, in which a sesamoid bone is developed, into the medial side of the base of the first phalanx of the thumb.

(2) The **transverse head,** lying deeply in the palm beneath the flexor tendons, **arises** by fleshy fibres from the medial ridge on the volar aspect of the body of the third metacarpal bone, in its distal two-thirds (Fig. 325, p. 395), and from the fascia covering the interosseous muscles in the second and third spaces.

Triangular in form, it is directed laterally, over the interossei muscles of the first two spaces, to be **inserted** by tendon into the medial side of the base of the first phalanx of the thumb along with the oblique head.

Nerve-Supply.—Deep branch of the ulnar nerve (C. 8. (T. 1.)).
Actions.—Adduction and opposition of the thumb.

Muscles of the Little Finger.

The short muscles of the little finger are the abductor, opponens, and flexor brevis digiti quinti.

M. Abductor Digiti Quinti.—The **abductor digiti quinti** is most superficial. It **arises** from the pisiform bone and from the tendon of the flexor carpi ulnaris and its ligamentous continuations (Fig. 325, p. 395).

It is **inserted** by tendon into the medial side of the base of the first phalanx of the little finger.

Nerve-Supply.—Deep branch of the ulnar nerve (C. 8. (T. 1.)).
Actions.—The muscle separates the little finger from the ring finger, and assists in flexion of the finger at the metacarpo-phalangeal joint.

M. Opponens Digiti Quinti.—The **opponens digiti quinti arises** under cover

of the preceding muscle, by tendinous fibres, from the transverse carpal ligament and from the hamulus of the os hamatum.

It is **inserted** into the medial margin and medial half of the volar surface of the fifth metacarpal bone in its distal three-fourths (Fig. 325, p. 395).

Nerve-Supply.—Deep branch of the ulnar nerve (C. 8. (T. 1.)).

Action.—The muscle acts only on the metacarpal bone, drawing it forward, so as to deepen the hollow of the hand.

M. Flexor Digiti Quinti Brevis.—The **flexor digiti quinti brevis** may be absent or incorporated with either the opponens or abductor digiti quinti. It **arises**, by tendinous fibres, from the transverse carpal ligament and from the hamulus of the os hamatum (Fig. 325, p. 395).

It is **inserted** along with the abductor into the medial side of the first phalanx of the little finger.

Nerve-Supply.—The deep branch of the ulnar nerve (C. 8. (T. 1.)).

Actions.—Flexion of the little finger at the metacarpo-phalangeal joint.

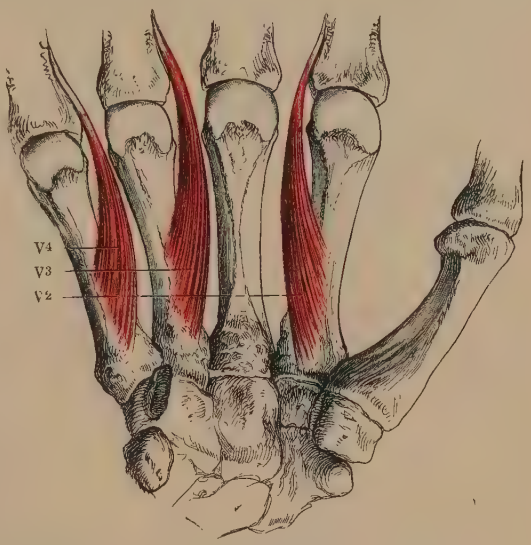

FIG. 326.—THE VOLAR INTEROSSEOUS MUSCLES (Right Side).

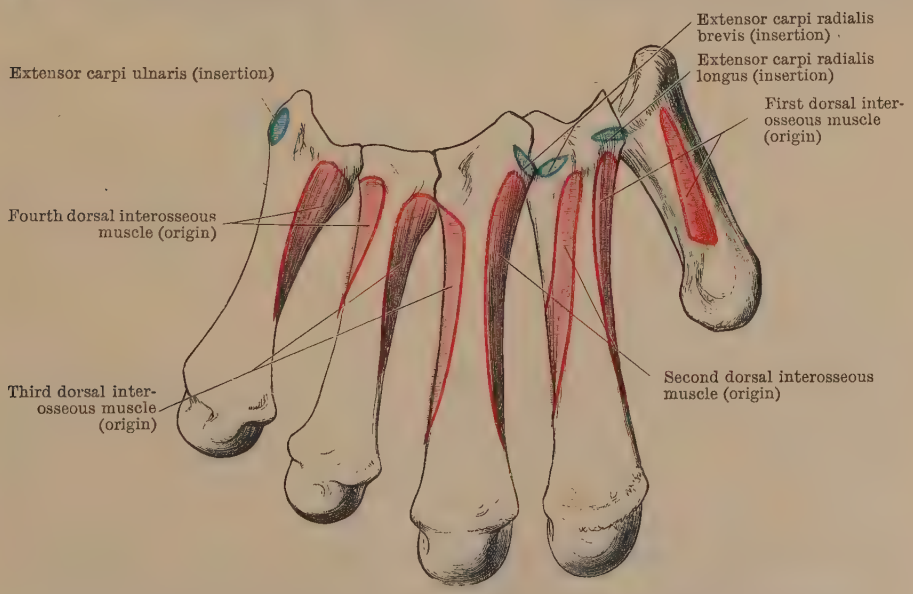
V^2, second; V^3, third, and V^4, fourth volar interosseous muscles. The first volar interosseous muscle is shown in Fig. 328.

The Interosseous Muscles.

The interosseous muscles of the hand occupy the spaces between the metacarpal bones. They are arranged in two sets, volar and dorsal.

Mm. Interossei Volares.—The **volar** (O.T. **palmar**) **interossei** are four in



Extensor carpi radialis brevis (insertion)

Third dorsal interosseous muscle (origin)
Second dorsal interosseous muscle (origin)

FIG. 327.—MUSCLE-ATTACHMENTS TO THE DORSAL ASPECT OF THE RIGHT METACARPUS.

number. Each **arises** by a single head; the *first* from the medial side of the base of the first metacarpal bone; the *second* from the medial side of the body of the second metacarpal bone; the *third* and *fourth* from the lateral sides of the bodies

of the fourth and fifth metacarpal bones respectively (Fig. 327, p. 397). The first volar interosseous muscle lies deeply between the lateral head of the first dorsal interosseous muscle and the oblique head of the adductor pollicis, and is inserted, in common with the latter muscle, into the ulnar side of the base of the first phalanx of the thumb (see note on p. 396). Each of the remaining three ends in a tendon which is directed distally behind the deep transverse metacarpal ligament, to be **inserted** into the dorsal expansion of the extensor tendon, the capsule of the metacarpo-phalangeal articulation, and the side of the first phalanx of the finger; the *second* is **inserted** into the medial side of the second finger; the *third* and *fourth* into the lateral sides of the fourth and fifth fingers.

Mm. Interossei Dorsales.—The **dorsal interossei** are four in number. Each **arises** by two heads from the sides of the metacarpal bones bounding each interosseous space (Figs. 327, p. 397, and 328, p. 398).

Each forms a fleshy mass, ending in a membranous tendon which, passing distally, behind the deep transverse metacarpal ligament, is **inserted**, exactly like the volar muscles, into the dorsal aspect of each of the four fingers. The insertion of the *first* dorsal interosseous muscle is into the lateral side of the index finger;

the *second* muscle is attached to the lateral side of the middle finger; the *third* muscle to the medial side of the same finger; and the *fourth* muscle to the medial side of the ring finger.

The interosseous muscles of the hand in some cases have a disposition similar to that of the corresponding muscles of the foot (p. 437).

Nerve-Supply.—The deep branch of the ulnar nerve (C. 8. (T. 1.)).

Actions.—The interossei muscles act in a similar way to, and along with, the lumbricales, flexing the fingers at the metacarpo-phalangeal joints, and extending them at the inter-phalangeal joints. In addition, the **dorsal** interossei serve to **abduct** the fingers into which they are inserted (fore, middle, and ring fingers) from the middle line of the middle finger; the **volar** muscles on the other hand, with the exception of the first, **adduct** the fingers into which they are inserted (fore, ring, and little finger) towards the middle line of the middle finger. The first volar interosseous muscle helps in flexion of the thumb at the metacarpo-phalangeal joint.

THE MUSCLES ON THE DORSAL SURFACE OF THE FOREARM.

The group of muscles occupying the lateral side of the elbow and the dorsal surface of the forearm and hand include the supinator muscles of the forearm and the extensors of the wrist and digits. They are divisible into a **superficial** and a **deep layer.**

The **superficial layer** comprises seven muscles, which are in order, from the

radial to the ulnar side of the forearm, the brachioradialis, the two radial extensors of the carpus, the extensor digitorum communis and extensor digiti quinti proprius, the extensor carpi ulnaris, and the anconæus. With the exception of the brachioradialis and the anconæus, these muscles share a common tendon of origin, which is attached to the anterior and distal aspects of the lateral epicondyle of the humerus (Fig. 315, p. 383).

The **deep muscles** are five in number: one, the supinator, extends between the proximal parts of the ulna and radius; the others are the special extensors of the thumb and forefinger, viz., the abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis, and extensor indicis proprius. They cover the dorsal surface of the bones of the forearm and the interosseous membrane, and are almost wholly concealed by the superficial muscles. Only the abductor pollicis longus and the extensor pollicis brevis become superficial in the distal part of the forearm, where they emerge between the radial extensors of the carpus and the extensor digitorum communis.

Superficial Muscles.

M. Brachioradialis.—The **brachioradialis arises**, by fleshy fibres, from the anterior aspect of the proximal two-thirds of the lateral epicondylic ridge of the humerus, and from the anterior surface of the lateral intermuscular septum (Fig. 314, p. 383).

The muscle lies in the lateral side of the hollow of the elbow, passes distally along the lateral border of the forearm, and ends about the middle of the forearm in a narrow, flat tendon. It is **inserted**, under cover of the tendons of the abductor pollicis longus and extensor pollicis brevis, into the lateral side of the distal extremity of the radius, proximal to the styloid process (Figs. 322, p. 392, and 329, p. 400).

Nerve-Supply.—The muscle is supplied by a branch of the radial nerve (C. 5. 6.) in the hollow of the elbow.

Actions.—The muscle is primarily, and, according to Beevor, solely, a flexor of the elbow-joint. It may also act as a semi-pronator and semi-supinator of the forearm, bringing the limb from the supine or prone position, into a position in which the radius lies volar to the ulna.

M. Extensor Carpi Radialis Longus.—The **extensor carpi radialis longus arises**, by fleshy fibres, from the anterior aspect of the distal third of the lateral epicondylic ridge of the humerus, from the anterior surface of the lateral intermuscular septum, and from the common tendon of origin of the extensor muscles (Figs. 314 and 315, p. 383).

In the distal half of the forearm, it ends in a tendon which passes beneath the dorsal carpal ligament, to be **inserted** into the dorsal surface of the base of the second metacarpal bone on its radial side (Fig. 327, p. 397).

The muscle is concealed in its proximal part by the brachioradialis, and its tendon, in the distal half of the forearm, is crossed, obliquely, by the abductor pollicis longus and by the extensor pollicis brevis.

Nerve-Supply.—The muscle is supplied by a branch of the radial nerve in the hollow of the elbow (C. (5.) 6. 7. 8.).

M. Extensor Carpi Radialis Brevis.—The **extensor carpi radialis brevis arises** from the common tendon, from the *radial collateral* ligament of the elbow, from the fascia over it, and from intermuscular septa on either side.

It passes distally, in the dorsal surface of the forearm and under the dorsal carpal ligament, in close relation to the previous muscle, to be **inserted**, by a tendon, into the bases of the second and third metacarpal bones (Fig. 327, p. 397). A bursa is placed beneath the two radial extensor tendons close to their insertion.

It is practically concealed, in the forearm, by the extensor carpi radialis longus, and in the distal half is crossed obliquely by the abductor pollicis longus and the extensor pollicis brevis. The tendons of the two muscles are crossed, on the dorsum of the wrist, by the tendon of the extensor pollicis longus.

Nerve-Supply.—The deep branch of the radial nerve (C. (5.) 6. 7. (8.)).

Actions.—Both muscles are extensors of the wrist and they assist the flexor carpi radialis to produce abduction of the hand. In association with the extensor carpi ulnaris, they are

synergic muscles for flexion of the fingers, as they counteract the effect which the digital flexors would otherwise produce on the wrist.

M. Extensor Digitorum Communis.—The **extensor digitorum communis arises** from the common tendon, from the fascia over it, and from intermuscular septa on either side. Extending along the dorsum of the forearm it ends, proximal to the wrist, in four tendons, of which the most lateral often has a separate fleshy belly. After passing under the dorsal carpal ligament, in a compartment along with the extensor indicis proprius, the tendons separate on the dorsum of the hand, where the three most medial tendons are joined together by two obliquely placed bands. One passes distally and laterally, and connects together the third and second tendons; the other is a broader and shorter band, which passes also distally and laterally, and joins the fourth to the third tendon. In some cases a third band is present which passes distally and medially from the first to the second tendon; and, frequently, the tendon for the little finger is joined to the tendon for the ring finger, and separates from it only a short distance above the distal end of the metacarpal bone.

FIG. 329.—MUSCLE-ATTACHMENTS TO THE RIGHT RADIUS AND ULNA (Dorsal Aspect).

The tendons are **inserted** in the following manner:—On the finger each tendon spreads out so as to form a membranous expansion over the knuckle and on the dorsum of the first phalanx. The border of the tendon is indefinite over the metacarpo-phalangeal articulation, of which it replaces the dorsal ligament. On the dorsum of the first phalanx the tendon receives at its sides the insertions of the interosseous and lumbrical muscles. At the distal end of the first phalanx it splits into ill-defined median and collateral slips, which pass over the dorsum of the first interphalangeal articulation, where they replace the dorsal ligament. The median slip is inserted into the dorsum of the base of the second phalanx, while the two lateral pieces become united to form a membranous tendon on the dorsum of the second phalanx, which, after passing over the second interphalangeal articulation, is inserted into the base of the terminal phalanx.

The muscle is placed superficially in the forearm, between the extensors of the carpus and the proper extensor of the little finger (Fig. 330, p. 402).

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).

Actions.—The muscle extends the fingers and wrist. On account of the attachment together

of the tendons to the third, fourth, and fifth fingers by accessory bands on the dorsum of the hand, these three fingers can only be fully extended together, while extension of the index finger can take place separately. In extension of the interphalangeal joints the muscle is aided by the interossei and lumbrical muscles. When the dorsal interossei are paralysed, the fingers can be abducted by the extensor digitorum communis, but this movement is always associated with hyperextension at the metacarpo-phalangeal joints.

M. Extensor Digiti Quinti Proprius.—The **extensor digiti quinti proprius** has an **origin**, similar to and closely connected with that of the preceding muscle, from the common tendon, the fascia over it, and from intermuscular septa.

It passes along the dorsum of the forearm, as a narrow fleshy slip, between the extensor digitorum communis and the extensor carpi ulnaris, and ends in a tendon, which occupies a groove between the radius and ulna in a special compartment of the dorsal carpal ligament. On the dorsum of the hand the tendon is split into two parts, of which the more lateral is joined by the most medial tendon of the extensor digitorum communis, and both are finally **inserted** into the expansion of the extensor tendon on the dorsum of the first phalanx of the little finger.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).
Actions.—The muscle extends the little finger and wrist.

M. Extensor Carpi Ulnaris.—The **extensor carpi ulnaris** has a double **origin**: (1) from the common tendon from the lateral epicondyle of the humerus, from the fascia over it, and from the intermuscular septa; and (2), through the medium of the deep fascia, from the dorsal margin of the ulna in its middle two-fourths.

Lying in the forearm upon the medial part of the dorsal surface of the ulna, it ends in a tendon which occupies a groove on the dorsal surface of the ulna in a special compartment of the dorsal carpal ligament, and is **inserted** into the medial side of the base of the fifth metacarpal bone (Fig. 327, p. 397).

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).
Actions.—The muscle is an extensor of the wrist, and at the same time, acting with the flexor carpi ulnaris, it is a powerful adductor of the wrist. Together with the radial extensors of the wrist, it is a synergic muscle for flexion of the fingers (p. 399).

M. Anconæus.—The **anconæus** is a small triangular muscle. It **arises**, by a separate tendon, from the distal part of the dorsal surface of the lateral epicondyle of the humerus (Fig. 315, p. 383) and from the dorsal part of the capsule of the elbow-joint.

It partially conceals the posterior ligament of the elbow-joint, the annular ligament of the radius, and the proximal part of the ulna, and is **inserted**, by fleshy fibres, into a triangular surface on the lateral aspect of the olecranon and dorsal surface of the ulna, as far distally as the oblique line (Fig. 329, p. 400). It is also inserted into the fascia which covers it.

Nerve-Supply.—The muscle is supplied by the terminal branch of the nerve to the medial head of the triceps muscle from the radial (C. 7. 8.).
Actions.—The anconæus is an extensor of the elbow.

Deep Muscles.

M. Supinator.—The **supinator muscle** is the most proximal of the deeper muscles. It is almost wholly concealed by the superficial muscles, and has a complex **origin**—(1) from the lateral epicondyle of the humerus; (2) from the radial collateral ligament of the elbow-joint and the annular ligament of the radius; and (3) from the dorsal part of the triangular surface on the shaft of the ulna just distal to the radial notch.

From this origin the muscle spreads laterally and distally dorsal to the proximal part of the radius, which it envelops almost completely, and is **inserted** into the volar and lateral surfaces of the bone. This attachment extends as far forwards as the tubercle of the radius, as far proximally as the neck, and as far distally as the oblique line and the insertion of the pronator teres (Figs. 322, p. 392, and 328, p. 400).

The muscle is divisible into *superficial* and *deep parts* with humeral and ulnar

origins, between which the deep branch of the radial nerve passes in its course to the dorsal aspect of the forearm.

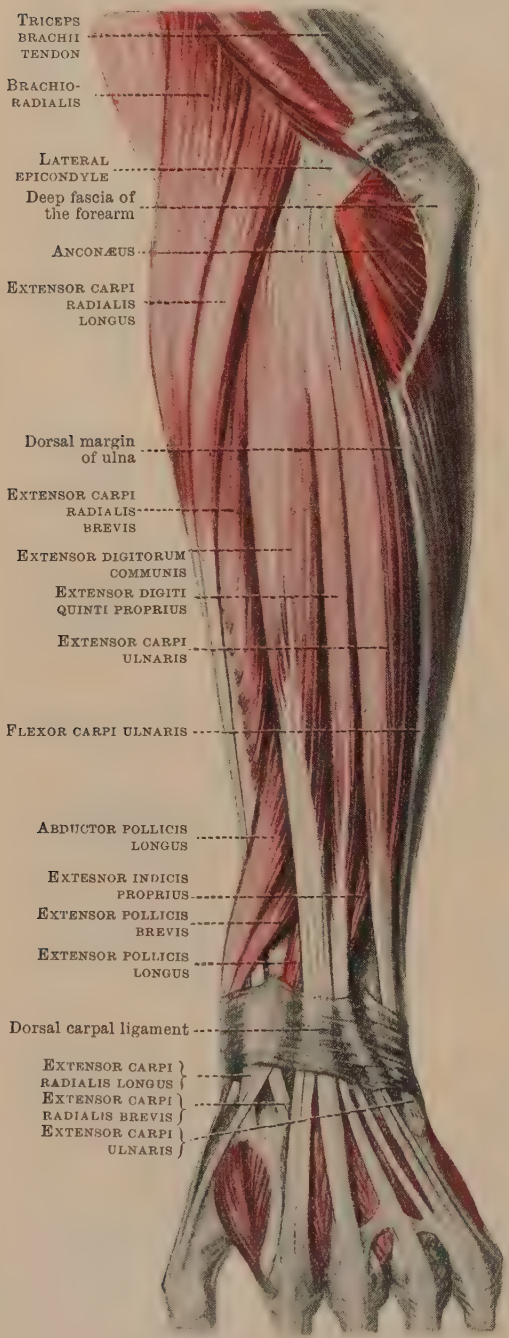

Fig. 330.—Superficial Muscles on the Dorsum of the Left Forearm.

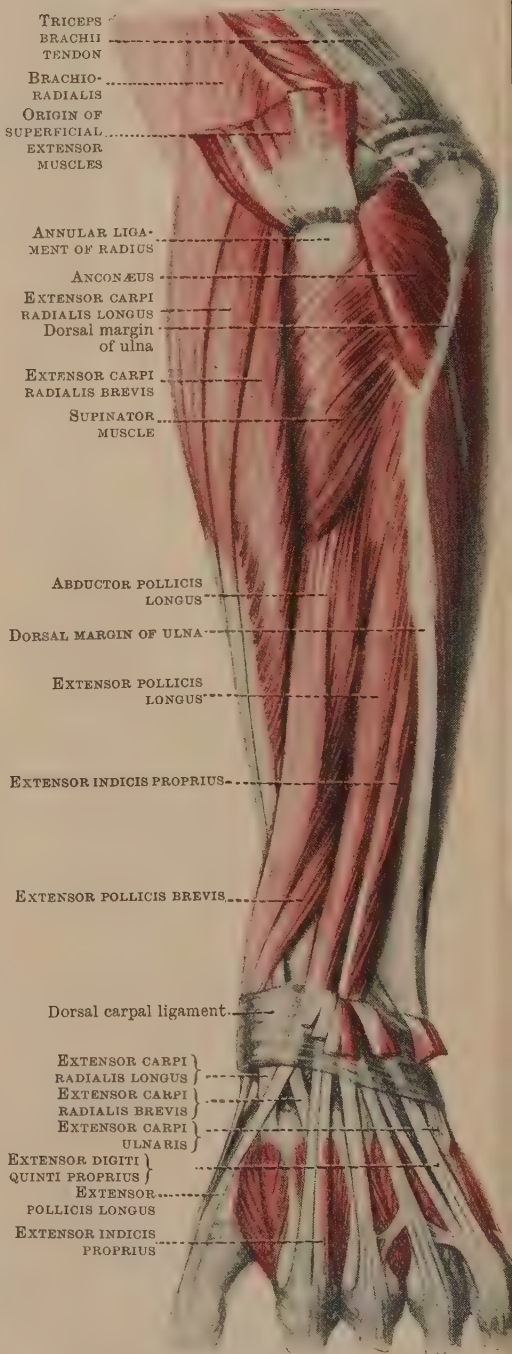

Fig. 331.—Deep Muscles on the Dorsum of the Left Forearm.

Nerve-Supply.—The supinator is supplied by a branch from the deep branch of the radial nerve, which arises from the nerve before the main trunk enters the muscle (C. 5. 6.).

Action.—The muscle is the main supinator of the forearm, and in this action it is assisted by the biceps.

M. Abductor Pollicis Longus.—The **abductor pollicis longus** (O.T. **extensor ossis metacarpi pollicis**) arises by fleshy fibres, distal to the supinator muscle,

from the most proximal of the narrow impressions on the lateral half of the dorsal surface of the ulna; from the middle third of the dorsal surface of the radius; and from the intervening portion of the interosseous membrane (Fig. 329, p. 400).

The muscle passes obliquely, distally, and laterally, and becomes superficial in the distal part of the forearm, where it emerges between the radial extensors of the wrist and the common extensor of the fingers. With the extensor pollicis brevis tendon closely applied to its medial side, the tendon covers the insertion of the brachioradialis and passes through the most lateral compartment of the dorsal carpal ligament. It next covers the styloid process of the radius and the radial collateral ligament of the wrist joint, from which it is separated by the radial artery, and is **inserted** into the lateral side of the base of the first metacarpal bone (Fig. 325, p. 395). From the tendon, close to its insertion, a tendinous slip passes to the abductor pollicis brevis and the fascia over the thenar eminence, and another is frequently attached to the greater multangular bone.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).
Actions.—The muscle abducts and extends the metacarpal bone of the thumb, and assists in abduction and flexion of the wrist.

M. Extensor Pollicis Brevis.—The **extensor pollicis brevis**, an essentially human muscle, is a specialised portion of the previous muscle. It **arises** from a rhomboid impression on the dorsal surface of the radius, and from the interosseous membrane, distal to the abductor pollicis longus (Fig. 329, p. 400). It is closely adherent to that muscle, and accompanies it deep to the dorsal carpal ligament and over the radial artery to the thumb.

Its tendon is then continued along the dorsal surface of the first metacarpal bone, to be **inserted** into the dorsal surface of the base of the first phalanx of the thumb. Before reaching its insertion the tendon helps to form the capsule of the metacarpo-phalangeal joint.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).
Actions.—The muscle extends the thumb (or the metacarpo-phalangeal joint), and assists in abduction of the wrist.

M. Extensor Pollicis Longus.—The **extensor pollicis longus arises** from the lateral part of the dorsal surface of the ulna, in its middle third, and from the interosseous membrane, distal to the abductor pollicis longus (Fig. 329, p. 400). Its tendon grooves the dorsal surface of the radius, and occupies a special compartment under cover of the dorsal carpal ligament.

Extending obliquely across the dorsal surface of the hand, the tendon crosses the radial artery, helps to form the capsule of the first metacarpo-phalangeal articulation, and is **inserted** into the dorsal surface of the base of the second phalanx of the thumb.

At the wrist the tendons of the muscles of the thumb, the abductor pollicis longus and extensor pollicis brevis laterally, and the extensor pollicis longus medially, bound a hollow (the "anatomical snuff-box") best seen in extension of the thumb. In this situation the pulsation of the radial artery can readily be felt.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).
Actions.—This muscle is an extensor of the thumb and of the wrist, and assists in abduction of the hand.

M. Extensor Indicis Proprius.—The **extensor indicis proprius arises**, distal to the extensor pollicis longus, from the most distal impression on the dorsal surface of the ulna, extending distally from the middle of the body to within two inches of its distal end, and sometimes also from the interosseous membrane (Fig. 329, p. 400). Its tendon passes through a compartment of the dorsal carpal ligament along with the tendons of the extensor digitorum communis.

On the dorsum of the hand the tendon lies on the ulnar side of the tendon of the common extensor destined for the forefinger, and is **inserted** into the membranous expansion of that tendon on the dorsum of the first phalanx.

Nerve-Supply.—The dorsal interosseous nerve (C. (5.) 6. 7. 8.).
Actions.—The muscle is an extensor of the forefinger and wrist.

Movements of the Upper Limb.—The characteristic features of the movements of the upper limb are their range and refinement. The hand, in addition to its intrinsic powers, can be moved through a wide range and in several planes by the muscles acting on the wrist and radio-ulnar joints; this range is increased by the fore and aft movements at the elbow-joint, and the extensive movements of which the shoulder and clavicular joints are capable. The result is that the hand can be brought into a position to cover and guard any portion of the body. The precision and refinement of movement is made possible by the co-ordinate movements of the various muscles acting upon the several joints, so that actions can be performed (as raising the food to the mouth) in which all the articulations of the limb are brought into play; while others (such as writing) are possible by movements at the joints of the wrist and fingers along with fixation of the elbow-joint.

The power of the grip, which is such an important feature of the human hand, is due, in no small measure, to the existing ability to oppose the thumb to the other digits. This movement is only possible (1) because the metacarpal bone of the thumb is set in a plane at right angles to the plane in which the other metacarpals lie, and (2) because the carpo-metacarpal joint of the thumb allows a wide range of movement. As a result of the set of the thumb, flexion carries it medially across the palm, and a very small degree of rotation of its metacarpal bone enables the movement of opposition to be effected. When the fingers encircle a small object, the grip is strengthened by the overlapping thumb, which can then be opposed to the dorsal aspects of the third and, if the object be small enough, second phalanges of the index and middle fingers.

THE LOWER LIMB.

FASCIÆ AND MUSCLES OF THE THIGH AND BUTTOCK.

FASCIÆ.

The **superficial fascia** of the thigh and buttock is continuous above with the fascia of the abdomen and back, medially with that of the perineum, and distally with that of the leg. It presents noticeable features in the buttock and groin.

In the buttock the superficial fascia is of considerable thickness, and is usually loaded with fat, whereby it assists in forming the contour of the buttock and the fold of the nates.

In the groin it is divisible into *two layers*: a **superficial fatty layer**, continuous with a similar layer on the anterior surface of the abdominal wall above, and over the perineum medially, and a **deeper membranous layer**, which is attached above to the medial half of the inguinal ligament, and to the deep fascia of the thigh just distal to the lateral half of that ligament. Medially it is attached to the pubic arch, and below the level of the femoral triangle it blends inseparably with the superficial fatty layer. The separation of these two layers of the superficial fascia is occasioned by the presence between them of the inguinal and superficial subinguinal lymph glands, the great saphenous vein and its tributaries, and some small arteries. The attachment of the deeper layer of the fascia to the pubic arch and the inguinal ligament cuts off the superficial tissues of the thigh from the perineum and the abdominal wall, and prevents the passage into the thigh of fluid collected in the perineum or beneath the fascia of the abdominal wall.

The **deep fascia** or **fascia lata** forms a tubular investment for the muscles and vessels of the thigh and buttock. It is firmly attached above to the iliac crest, the sacro-tuberous ligament, the ischium, the pubic arch, the pubic symphysis and crest, and the inguinal ligament. In the distal part of the thigh it forms the inter-muscular septa; and in relation to the knee, it is continuous with the deep fascia of the leg, gains attachment to the patella, the condyles of the tibia and the head of the fibula, and forms the collateral ligaments of the patella.

On the front of the thigh the deep fascia is thick and strong. It is pierced by numerous openings for vessels and nerves, the most important of which is the **fossa ovalis** (O.T. **saphenous opening**) for the passage of the great saphenous vein. A femoral hernia passes through this opening to reach the groin and anterior abdominal wall. It is an oval opening, of variable size, situated just distal to the medial half of the inguinal ligament, and immediately anterior to the femoral vessels. It is covered by the superficial fascia, and by a special layer of fascia, the **fascia cribrosa**, a thin perforated lamina attached to the margins of the opening. The lateral edge of the opening (*margo falciformis*) is formed by the sharp margin of the *iliac portion* of the fascia lata, which is attached above to the iliac crest and the inguinal ligament:

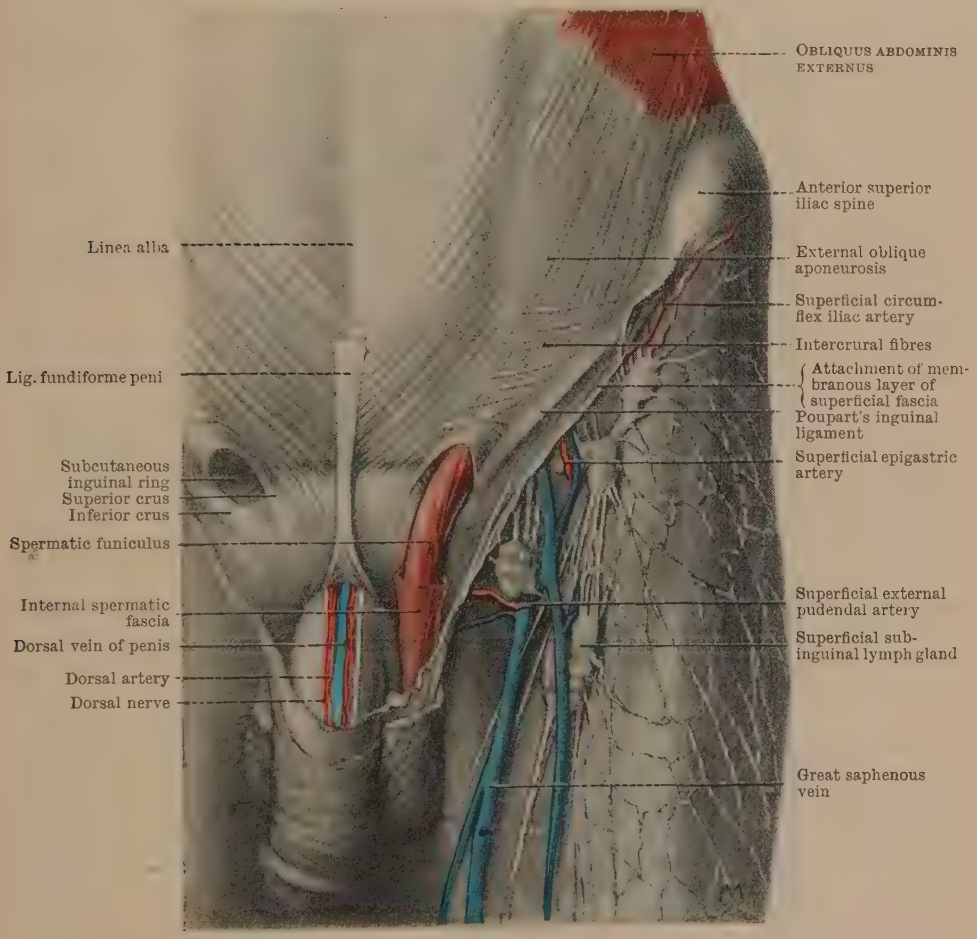

Fig. 332.—Superficial Anatomy of the Left Groin.

the ill-defined medial edge is formed by the *fascia pectinea* which is continued proximally, behind the femoral sheath, over the pectineus muscle to the iliopectineal line and the capsule of the hip-joint. These two parts of the fascia lata are continuous at the distal concave margin of the fossa ovalis, forming a distinct **inferior cornu** over which the great saphenous vein passes immediately before it terminates in the femoral vein (Fig. 333, p. 406). As they pass proximally towards the pelvis they occupy different planes, the iliac portion being in front of the sheath of the femoral vessels, while the pectineal fascia is behind it. The **superior cornu** of the fossa ovalis, placed in front of the sheath, is derived solely from the iliac portion of the fascia lata. It forms a strong triangular band of fascia known as the **falciform margin**, attached above to the medial half of the inguinal ligament. It has an important share in directing the course of a femoral hernia upwards on to the abdominal wall.

On the medial side of the thigh the fascia lata is thin where it covers the adductor muscles. At the knee it is associated with the tendons of the vasti muscles, and forms the **collateral ligaments of the patella**, attached to the borders of the patella and to the condyles of the tibia. On the lateral side of the thigh it forms the **tractus iliotibialis**—a broad thick layer of fascia which is attached above to the iliac crest, and receives the insertions of the tensor fasciæ latæ, and part of the glutæus maximus muscles; its distal attachment is to the capsule of the knee-joint and the lateral condyle of the tibia. A strong band of fascia continued proximally from the ilio-tibial tract, beneath the tensor fasciæ latæ muscle, joins the tendon of origin of the rectus femoris and the capsule of the hip-joint.

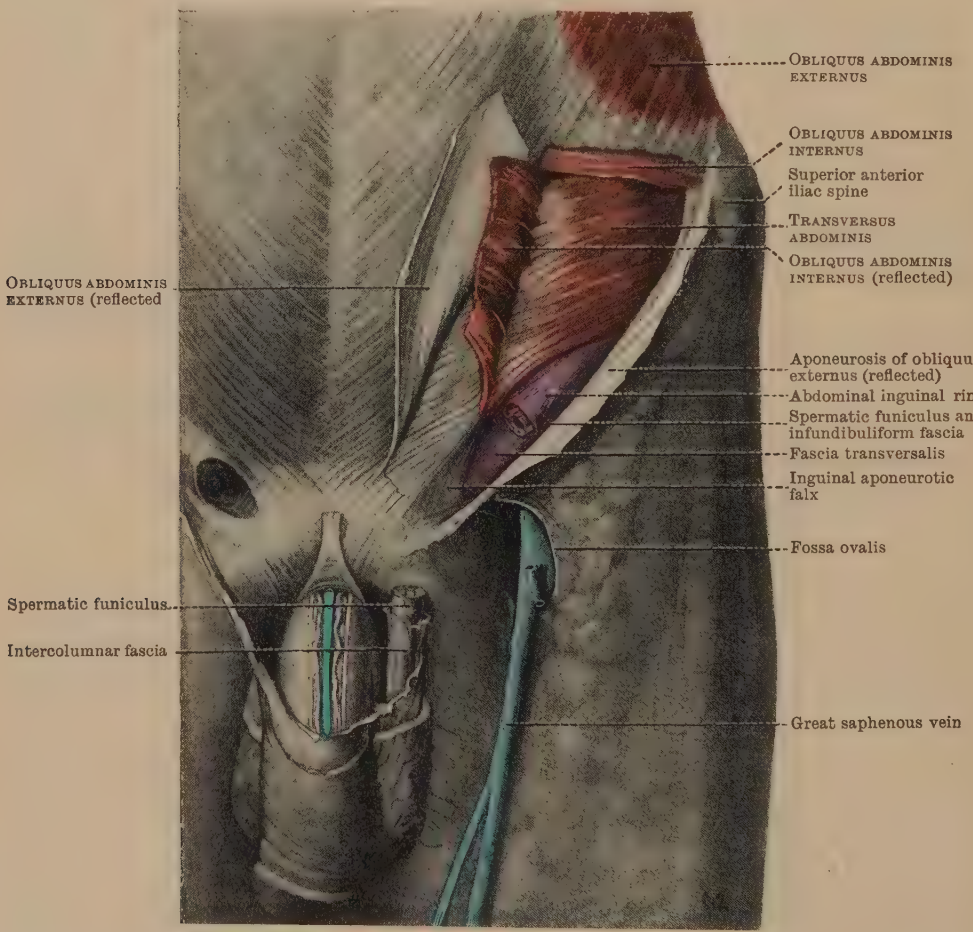

Fig. 333.—The Dissection of the Left Inguinal Canal.

On either side of the thigh above the knee an intermuscular septum is formed. The **lateral intermuscular septum** extends medially from the ilio-tibial tract to the lateral epicondylic line and linea aspera of the femur, and gives attachment to the vastus lateralis and vastus intermedius anteriorly, and the short head of the biceps posteriorly. The **medial intermuscular septum** in the distal third of the thigh is associated with, and to a large extent represented by, the tendon of insertion of the adductor magnus muscle. It is also related to the fascia which envelops the adductor muscles, and forms the sheaths for the sartorius and gracilis muscles. In the middle third of the thigh the fascia under the sartorius is greatly thickened by transverse fibres and binds together the vastus medialis and adductor longus and adductor magnus muscles. This layer of fascia roofs over the femoral vessels in their course through the *adductor canal* (Hunter's).

The **fascia lata of the buttock** is thick anteriorly where it covers and gives

origin to the glutæus medius, but is much thinner posteriorly, where it splits to enclose the glutæus maximus muscle. Over the greater trochanter it becomes continuous with that part of the ilio-tibial tract, into which most of the fibres of the glutæus maximus gain insertion.

On the **posterior surface of the thigh** and over the **popliteal fossa** the fascia is strengthened by transverse fibres derived from the hamstring muscles. The **popliteal fascia** forming the roof of the popliteal fossa is specially thick, and is usually pierced by the small saphenous vein.

Femoral Sheath.—This is a conical membranous investment, derived from the fascial lining of the abdominal cavity, the fascia transversalis being carried distally in front of, and the fascia iliaca behind, the femoral vessels as they pass from the pelvis into the femoral triangle. The sheath is about an inch and a half in length, and is divided into three compartments—a lateral compartment for the artery, an intermediate compartment for the vein, and a medial compartment containing lymph vessels and fat, and named the **femoral canal.** This canal is the passage through which a femoral hernia enters the thigh. Its mouth or proximal limit is the **femoral ring,** bounded anteriorly by the inguinal ligament, posteriorly by the origin of the pectineus muscle from the pubis, medially by the *ligamentum lacunare* (*Gimbernati*), and laterally by the femoral vein. In front of it the fascia transversalis forming the sheath is thickened to form the **deep femoral arch.** The part of the inguinal ligament in front of the ring is called the **superficial femoral arch.** The inferior epigastric artery separates the ring from the abdominal inguinal ring. The canal ordinarily contains fat which is continuous above with the extra-peritoneal tissue. The ring is filled by a plug of fat or a lymph gland, constituting the **femoral septum.**

The femoral canal ends behind the fossa ovalis, covered by the fascia cribrosa, while the falciform margin crosses over it and conceals its proximal portion. The course of a femoral hernia is determined by this band. The hernia descends through the femoral ring, pushing the femoral septum before it; after passing through the femoral canal, it is directed forwards through the fossa ovalis. The anterior part of the hernia being pressed upon and retarded by the femoral arches, and by the falciform margin, the posterior part pushes onwards, hooks round the falciform margin, and is directed upwards over the inguinal ligament. The coverings of a femoral hernia, in addition to peritoneum and extra-peritoneal tissue (femoral septum), are femoral sheath, fascia cribrosa, superficial fascia, and skin.

MUSCLES OF THE THIGH AND BUTTOCK.

The muscles of the thigh and buttock are divisible into four main groups by their situation, action, and nerve-supply. On the **anterior surface** of the thigh are the quadriceps femoris, the sartorius, ilio-psoas, and pectineus muscles; on the **medial side** of the thigh are the adductor muscles; in the region of the **buttock** are the glutæi and rotators of the hip-joint; and on the **posterior aspect** of the thigh are the hamstring muscles.

THE MUSCLES ON THE ANTERIOR ASPECT OF THE THIGH.

The chief muscle on the anterior aspect of the thigh is the quadriceps femoris, which occupies the space between the tensor fasciæ latæ and ilio-tibial tract laterally, and the sartorius medially. The sartorius crosses the thigh obliquely; it separates the quadriceps femoris from the adductor muscles; it forms in the proximal third of the thigh the lateral boundary of the femoral triangle, and in the middle third of the thigh, the roof of the adductor canal (Hunter's). The ilio-psoas, passing into the thigh beneath the inguinal ligament, helps the pectineus and adductor longus to form the floor of the femoral triangle.

M. Sartorius.—The **sartorius,** a long strap-like muscle, **arises** from the anterior superior spine of the ilium and half of the margin of the notch below it (Fig. 343).

It passes obliquely across the front of the thigh, and, reaching its medial side, descends vertically across the medial side of the knee. It is **inserted,** by

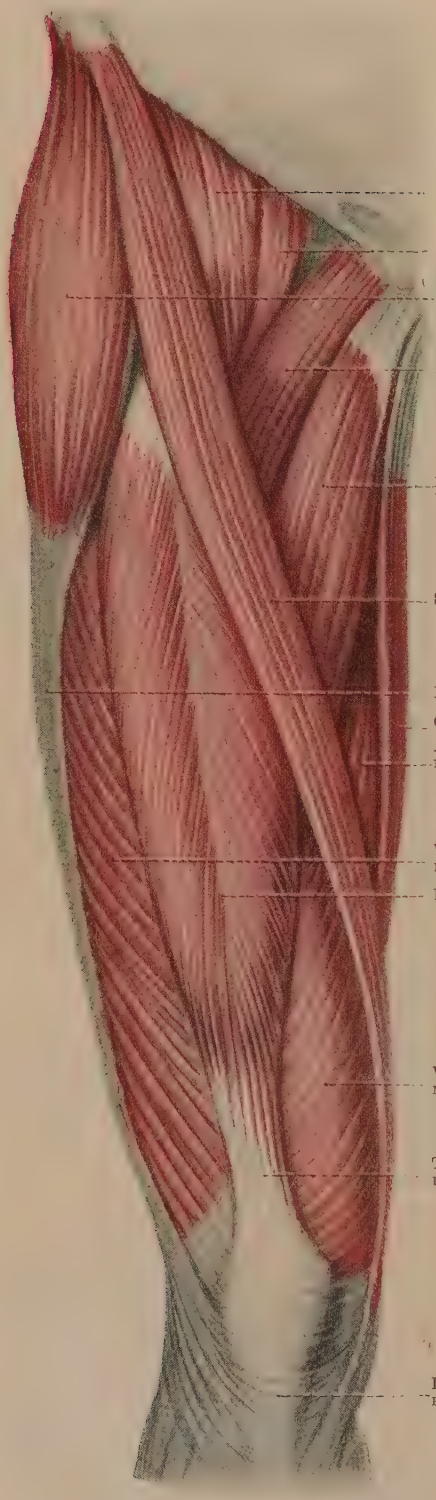

Fig. 334.—The Muscles of the Anterior Aspect of the Right Thigh.

aponeurotic fibres, into the medial surface of the body of the tibia just distal to the medial condyle, and by its borders into fascial expansions which join the capsule and the tibial collateral ligament of the knee-joint, and the fascia lata of the leg (Fig. 334).

The sartorius is superficial in its whole extent. Its proximal third forms the lateral boundary of the femoral triangle; its middle third forms the roof of the adductor canal and covers the femoral vessels; and its distal third is separated from the tendon of the gracilis muscle by the saphenous nerve and the saphenous branch of the arteria genu suprema. A bursa lies beneath the tendon at its insertion.

Nerve-Supply.—The sartorius is supplied by two sets of nerves associated with the two intermediate cutaneous branches of the femoral nerve (L. 2. 3.).

Actions.—The sartorius, "the tailor's muscle," is a flexor of the hip and knee joints. It also adducts the thigh and rotates it laterally, and assists in medial rotation of the tibia.

M. Quadriceps Femoris.—The **quadriceps femoris** is composed of four muscles—the rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis.

The rectus femoris is superficial except at its origin, which is covered by the glutæi, sartorius, and tensor fasciæ latæ muscles. The vasti lie on either side of the rectus muscle, the vastus lateralis being partially concealed by the tensor fasciæ latæ and ilio-tibial tract, the vastus medialis by the sartorius muscle. The vastus intermedius envelops the femur, and is concealed by the other muscles.

M. Rectus Femoris.—The **rectus femoris** has a double tendinous **origin.** (1) The *straight head* arises from the anterior inferior spine of the ilium (Fig. 214, p. 250); (2) the *reflected head* springs from a rough groove on the dorsum ilii just above the highest part of the acetabulum

(Fig. 343, p. 417). A bursa lies beneath this head of origin. The two heads,

bound together and connected to the capsule of the hip-joint by a band of fascia derived from the deep surface of the tensor fasciæ latæ (ilio-tibial tract), give rise to a single tendon which extends, for some distance, on the anterior surface of the muscle, and from which the muscular fibres arise. The muscular fibres springing from this tendon, and also from a median septal tendon, present a bipennate arrangement, and end below in a broad tendon which passes proximally, for some distance, along the posterior surface of the muscle. This tendon gradually narrows towards the knee, and spreading out again, is **inserted** into the proximal border of the patella. It receives laterally and medially parts of the insertions of the lateral and medial vasti muscles, and on its deep surface is joined by the insertion of the vastus intermedius.

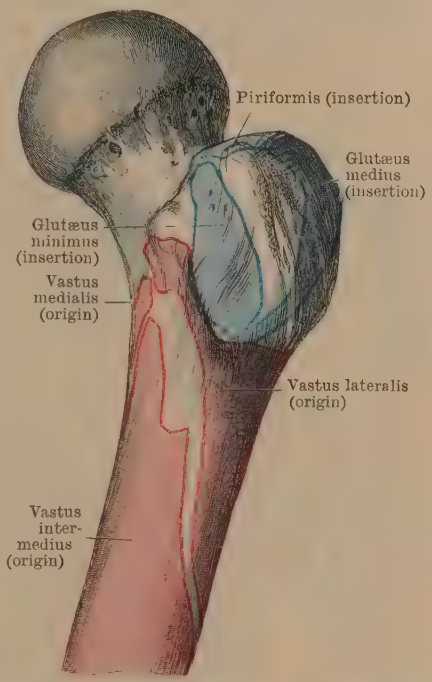

FIG. 335.—MUSCLE-ATTACHMENTS TO THE ANTERIOR SURFACE OF THE PROXIMAL PART OF THE LEFT FEMUR.

M. Vastus Lateralis. — The **vastus lateralis** has an **origin**, partly fleshy, partly membranous, from (1) the capsule of the hip-joint, (2) the tubercle of the femur, (3) a concave area on the anterior surface of the shaft of the bone medial to the greater trochanter, (4) the distal border of the greater trochanter, (5) the lateral margin of the gluteal tuberosity of the femur and the tendon of the glutæus maximus, (6) the proximal half of the linea aspera, and (7) the fascia lata and lateral intermuscular septum (Fig. 220, p. 262).

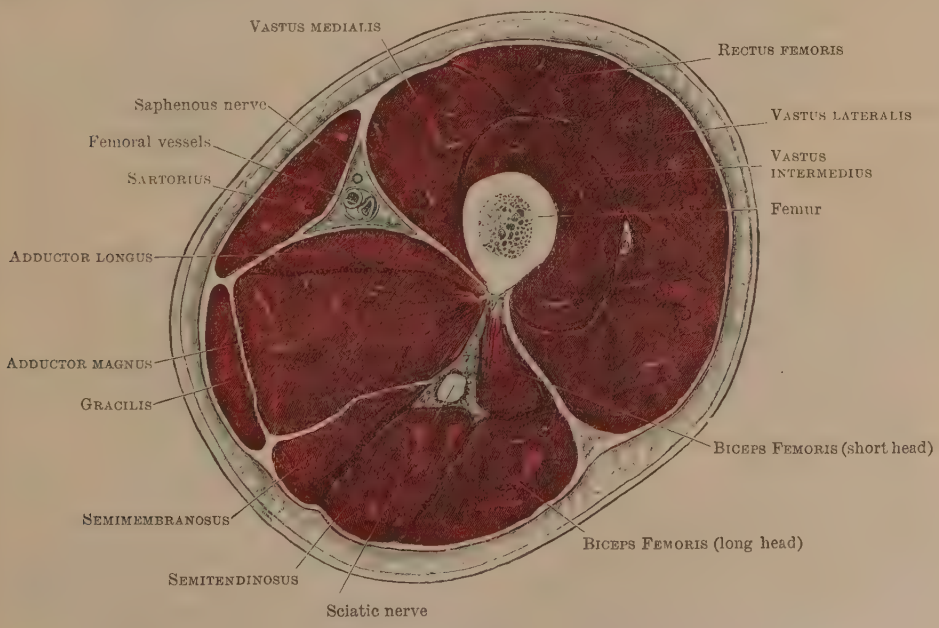

FIG. 336.—TRANSVERSE SECTION OF THE THIGH (HUNTER'S ADDUCTOR CANAL).

It forms a thick, broad muscle directed distally and forwards, and is **inserted** by a broad membranous tendon into (1) the lateral border of the tendon of the rectus femoris, (2) the proximal and lateral border of the patella, and (3) the

front of the lateral condyle of the tibia, covering, and to a large extent replacing, the antero-lateral part of the capsule of the knee-joint.

M. Vastus Medialis.—The **vastus medialis** is larger than the vastus lateralis and has a more extensive **origin**, from (1) the distal two-thirds or more of the spiral line, the linea aspera, and the proximal two-thirds of the line leading from the linea aspera to the medial condyle of the femur; and (2) the medial intermuscular septum and the tendon of the adductor magnus (Fig. 221, p. 263, and 344, p. 418).

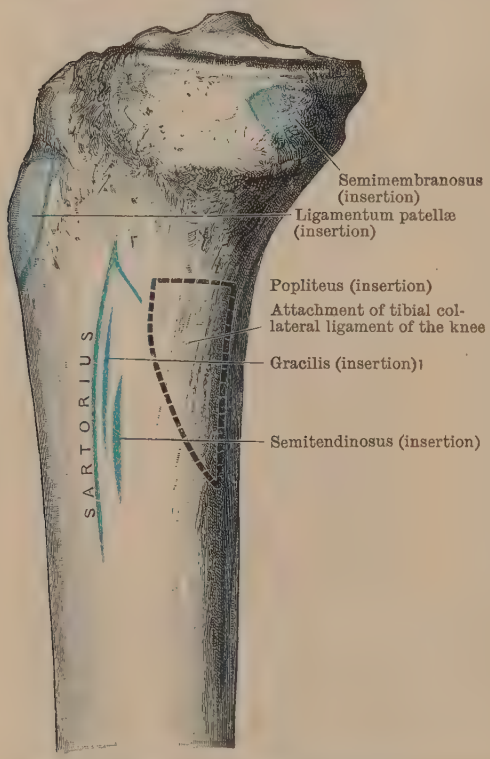

FIG. 337.—MUSCLE-ATTACHMENTS TO THE MEDIAL SIDE OF THE PROXIMAL PART OF THE RIGHT TIBIA.

From its origin the muscle is directed distally and laterally towards the knee, the most distal fibres being nearly horizontal; it is **inserted** by a strong aponeurotic tendon into (1) the medial border of the rectus tendon; (2) into the proximal and medial border of the patella; and (3) the front of the medial condyle of the tibia, covering and replacing the antero-medial part of the capsule of the knee-joint. The muscle conceals the medial side of the body of the femur and the vastus intermedius, with which it is closely incorporated in its distal two-thirds.

M. Vastus Intermedius. — The **vastus intermedius muscle** (O.T. **crureus**) **arises** by fleshy fibres from (1) the proximal two-thirds of the body of the femur on the anterior and lateral surfaces—but not the medial surface; (2) the distal half of the lateral lip of the linea aspera and the proximal part of the line leading therefrom to the lateral condyle; and (3) a corresponding portion of the lateral intermuscular septum (Figs. 219, p. 261, and 220, p. 262).

For the most part deeply placed, the muscle is directed distally to an **insertion** into the deep surface of the tendons of the rectus and vasti muscles by means of fibres which join a membranous expansion on its surface. It is closely adherent to the vastus lateralis muscle in the middle third of the thigh; it is inseparable from the vastus medialis below the proximal third. In the distal third of the thigh it conceals the articularis genu muscle, and the proximal prolongation of the synovial membrane of the knee-joint, which constitutes the suprapatellar bursa.

M. Articularis Genu.—The **articularis genu** (O.T. **subcrureus**) muscle consists of a number of separate bundles of muscular fibres **arising** deep to the vastus intermedius from the distal fourth of the anterior surface of the femur, and **inserted** into the synovial membrane of the knee-joint.

The four elements composing the quadriceps femoris muscle have been traced in their convergence to the patella. Their ultimate **insertion** is into the tubercle of the tibia (Fig. 350), by means of the **ligamentum patellæ**, and the vasti muscles are in addition connected with the **collateral ligaments of the patella.** The patella, indeed, is in one sense a sesamoid bone formed in the tendon of the muscle, the ligamentum patellæ being the real tendon of insertion, and the collateral ligaments fascial expansions from its borders. The insertion of the muscle forms the anterior part of the capsule of the knee-joint.

Nerve-Supply.—The parts of the quadriceps extensor are supplied by separate branches of the femoral nerve (L. 3. 4.).

Actions.—The quadriceps muscle is the great extensor of the leg at the knee-joint. The tendency for the patella to be pulled laterally as well as proximally is counteracted by the distal, horizontal fibres of the vastus medialis. The articularis genu draws proximally the synovial sheath of the joint during this movement.

When the knee is extended, the rectus femoris is in addition a flexor of the hip-joint. The

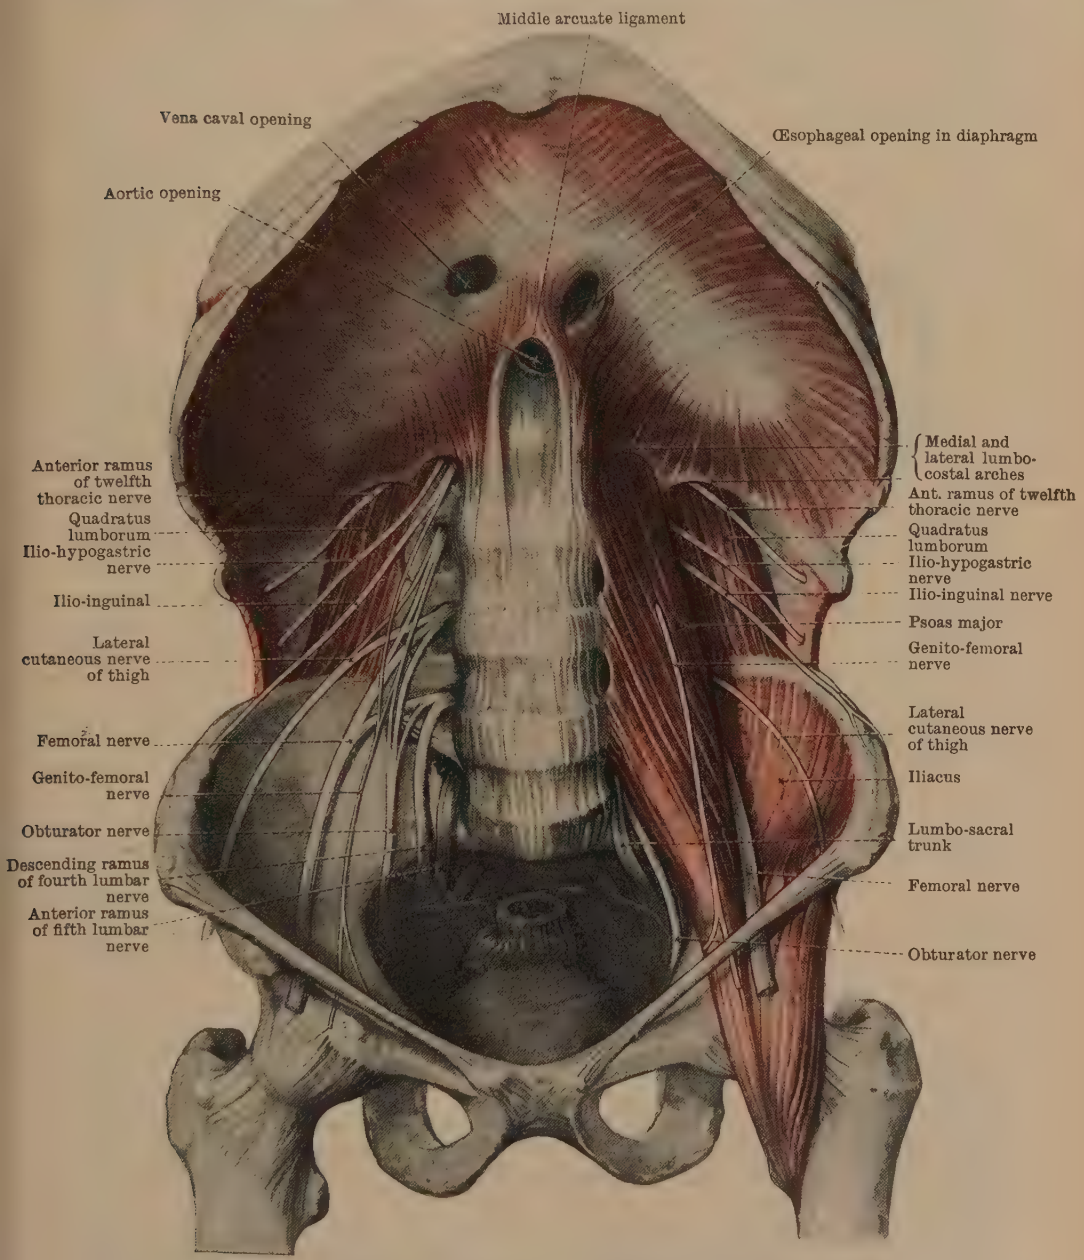

FIG. 338.—THE VESSELS AND NERVES ON THE POSTERIOR ABDOMINAL WALL.

straight head is taut when the movement begins, but it becomes somewhat relaxed and the reflected head is tightened when the thigh becomes bent.

When the body is in the recumbent position, with the knees extended, the two recti assist the ilio-psoas muscles to flex the body on the hips.

The **ilio-psoas muscle** is a compound muscle, consisting of two elements,—**psoas (major and minor)**, connecting the femur and pelvic girdle to the axial skeleton; and another element, the **iliacus**, extending between the hip bone and the femur. The muscles chiefly occupy the posterior wall of the abdomen

and pelvis major, only their lower parts appear in the thigh below the inguinal ligament, in the lateral part of the femoral triangle.

M. Psoas Major.—The **psoas major** is a large piriform muscle, which has an extensive **origin**, by fleshy fibres, from the vertebral column in the lumbar region. It arises from (1) the intervertebral fibro-cartilages above each lumbar vertebra, and the adjacent margins of the vertebræ—from the inferior border of the 12th thoracic to the superior border of the 5th lumbar vertebra; (2) from four aponeurotic arches which pass over the sides of the bodies of the first four lumbar vertebræ; and (3) from the transverse processes of all the lumbar vertebræ. The fibres form a fusiform muscle which at first is closely applied to the side of the vertebral column. Inferiorly, it follows the superior aperture of the pelvis and passes behind the inguinal ligament, to end in a tendon which is **inserted** into the apex of the lesser trochanter of the femur (Fig. 339). A bursa, which may be continuous with the synovial cavity of the hip-joint, separates the tendon from the pubis and the capsule of the hip-joint.

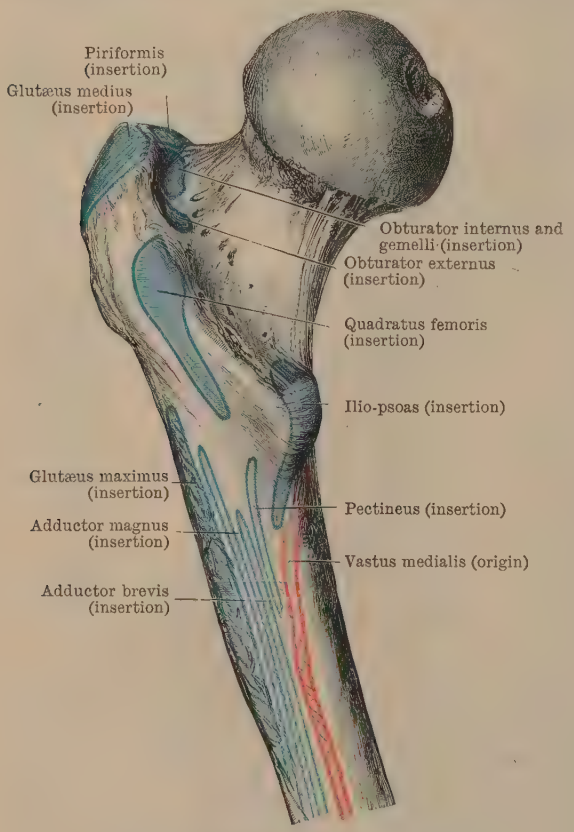

FIG. 339.—MUSCLE-ATTACHMENTS TO THE POSTERIOR ASPECT OF THE PROXIMAL PART OF THE LEFT FEMUR.

M. Psoas Minor.—The **psoas minor** is often absent (40 per cent). It **arises** from the intervertebral fibro-cartilage between the last thoracic and first lumbar vertebræ, and from the contiguous margins of those vertebræ. The muscle is closely apposed to the anterior surface of the psoas major.

It forms a slender fleshy belly, and is **inserted**, by a narrow tendon, into the middle of the linea terminalis and the ilio-pectineal eminence, its margins blending with the fascia covering the psoas major.

M. Iliacus. — The **iliacus muscle arises** in the pelvis major by fleshy fibres, mainly from a horseshoe-shaped origin around the margin of the iliac fossa; it has additional origins also from the ala of the sacrum, the anterior sacro-iliac, lumbo-sacral, and ilio-lumbar ligaments, and outside the pelvis, from the proximal part of the capsule of the hip-joint (ilio-femoral ligament). It is a fan-shaped muscle, and its fibres pass distally over the hip-joint towards the lesser trochanter of the femur.

Lying lateral to the psoas muscle, it passes through the femoral triangle, and is **inserted** by fleshy fibres (1) into the lateral side of the tendon of the psoas major; (2) into the concave anterior and upper surfaces of the lesser trochanter; and (3) into the body of the femur distal to the lesser trochanter for about an inch (Fig. 339); and (4) by its most lateral fibres into the capsule of the hip-joint. These fibres are often separate, forming the **iliacus minor**, or **iliocapsularis.**

Nerve-Supply.—The **psoas major** is supplied directly by branches from the anterior rami of the second and third lumbar nerves with additional branches in some cases from the first and fourth. The **psoas minor** receives a nerve from the first or second lumbar nerve. The **iliacus** is supplied by branches from the femoral nerve (L. 2. 3. 4.) within the abdomen.

Actions.—The psoas major and the iliacus flex the hip-joint, and this movement is

accompanied by a slight degree of medial rotation. (N.B.—The axis of rotation does not correspond to the shaft of the femur but to a line drawn from the middle of its head to the centre of the intercondylic fossa.) In addition, acting from their insertions, they can flex the trunk on the lower limbs, and the psoas major can produce lateral flexion of the vertebral column.

The psoas minor assists in the latter movement, and can flex the pelvis on the vertebral column, or the vertebral column on the pelvis.

M. Pectineus.—The **pectineus** muscle **arises** by fleshy fibres from (1) the sharp anterior portion of the pectineal line of the pubis, and the triangular surface of the pubic bone in front of that line (Fig. 340, p. 414), and (2) the pectineal portion of the fascia lata which covers it.

Forming a broad muscular band, which lies in the floor of the femoral triangle, medial to the ilio-psoas, it is **inserted** by a thin flat tendon, about two inches in length, into the proximal half of the pectineal line, leading from the back of the lesser trochanter of the femur towards the linea aspera (Fig. 339, p. 412); its distal attachment being placed in front of the insertion of the adductor brevis muscle. The muscle may be occasionally divided into medial and lateral parts, the former innervated by the obturator, the latter by the femoral nerve.

Nerve-Supply.—The pectineus is always supplied by a branch of the femoral nerve (L. 2. 3.) which passes medially behind the femoral vessels to enter its lateral border. It receives in some instances an additional nerve from the obturator, or when that is present, the accessory obturator nerve.

Actions.—The muscle is mainly an adductor of the hip-joint. It is also a flexor of the hip.

THE MUSCLES ON THE MEDIAL SIDE OF THE THIGH.

The muscles on the medial side of the thigh include the adductor longus, the adductor brevis, the adductor magnus and the gracilis. The obturator externus also can be conveniently considered with this group.

The gracilis is superficially placed along the medial side of the thigh. The adductor muscles are placed in the medial part of the thigh between the hip bone and the femur, and in different vertical planes. The adductor longus is in the same plane as the pectineus and lies superficially in the femoral triangle; the adductor brevis, on a more posterior plane, is in contact with the obturator externus, and along with it is largely concealed by the pectineus and adductor longus; the adductor magnus, the largest and most posterior of these muscles, is in contact with the other adductors and the sartorius anteriorly, while its posterior surface is in relation to the hamstring muscles on the back of the thigh.

M. Gracilis.—The **gracilis muscle** is a long flat band placed on the medial side of the thigh and knee. It **arises** by a tendon from the lower half of the edge of the symphysis pubis, and for a similar distance along the border of the pubic arch (Fig. 340, p. 414).

Its tapering belly passes distally, on the medial side of the thigh to the knee, to end in a tendon, placed between the sartorius and semitendinosus, which expands to be **inserted** into the medial surface of the body of the tibia just distal to the medial condyle, behind the sartorius, and proximal to and in front of the semitendinosus (Fig. 339, p. 412). It is separated from the sartorius tendon by a bursa, and deep to its tendon is another bursa, common to it and the semitendinosus. It is superficial in its whole extent.

Nerve-Supply.—The anterior division of the obturator nerve (L. 2. 3.).

Actions.—The gracilis has a threefold action. It flexes the knee and adducts the thigh. When the knee is flexed, it can act as a medial rotation of the tibia.

M. Adductor Longus.—The **adductor longus** is a triangular muscle which lies in the floor of the femoral triangle and the floor of adductor canal (Hunter's). It **arises** from the anterior surface of the body of the pubis in the angle between the crest and symphysis (Fig. 340, p. 414).

It extends distally and laterally, it is **inserted** into the middle two-fourths of the medial lip of the linea aspera in front of the adductor magnus.

Nerve-Supply.—Obturator nerve (L. 2. 3.), anterior division.

M. Adductor Brevis.—The **adductor brevis** is a large muscle which **arises** from an elongated oval surface on the front of the body and upper part of the inferior ramus of the pubic bone, surrounded by the other muscles of this group (Fig. 340).

Directed distally and laterally the muscle expands, to be **inserted**, by a short aponeurotic tendon, behind the insertion of the pectineus, into the distal two-thirds of the line leading from the lesser trochanter of the femur to the linea aspera, and to the proximal fourth of the linea aspera itself (Fig. 339, p. 412).

Nerve-Supply.—Obturator nerve (L. 2. 3. 4.).

Actions.—Both muscles are adductors of the thigh, and assist in flexion and lateral rotation.

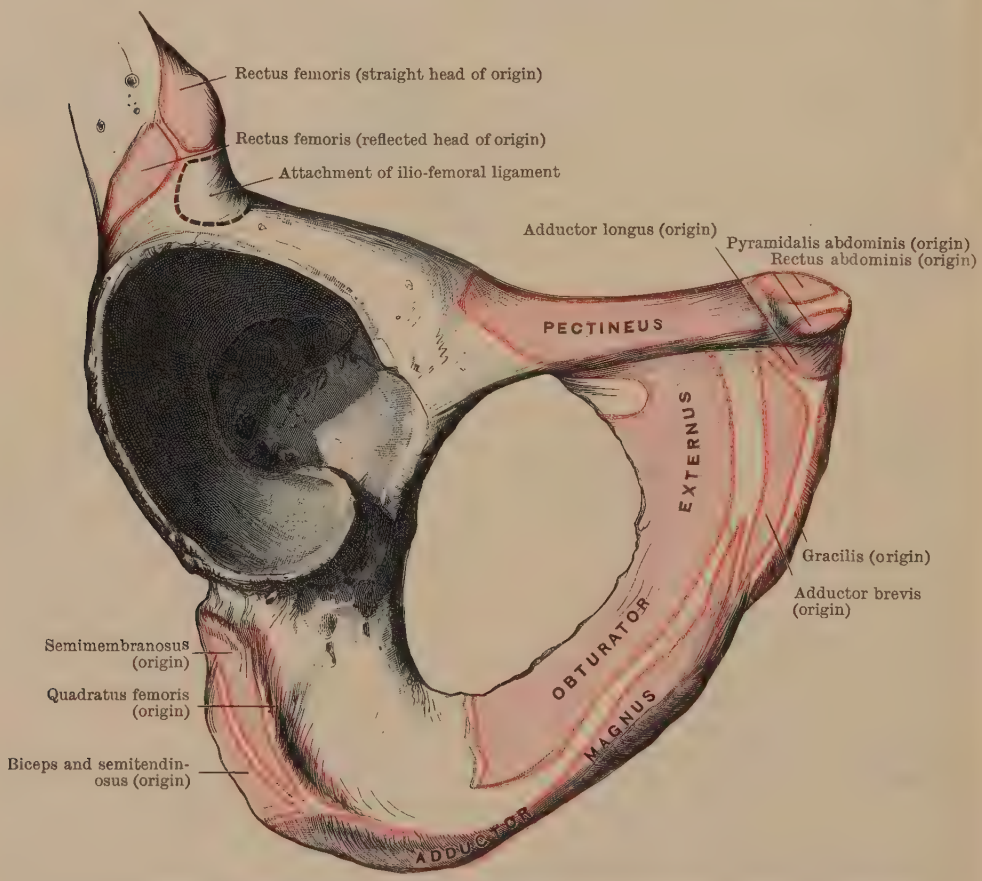

FIG. 340.—MUSCLE-ATTACHMENTS TO THE OUTER SURFACE OF THE RIGHT PUBIS AND ISCHIUM.

M. Adductor Magnus.—The **adductor magnus**, the largest of the adductor group, is a roughly triangular muscle. It **arises**, mainly by fleshy fibres, by a curved origin from the lower part of the lateral border and a large portion of the adjoining inferior surface of the sciatic tuberosity, from the edge of the inferior ramus of the ischium, and from the anterior surface of the inferior ramus of the pubic bone, its most anterior fibres arising between the obturator externus and adductor brevis (Fig. 340). Its upper fibres are directed horizontally and laterally from the pubic bone towards the proximal part of the femur; the lowest fibres are directed distally from the sciatic tuberosity to the medial condyle of the femur; while the intermediate fibres radiate obliquely laterally and distally.

The muscle is **inserted** by tendinous fibres (1) into the space distal to the insertion of the quadratus femoris, proximal to the linea aspera; (2) into the whole length of the linea aspera; (3) into the medial epicondylic line of the femur; and (4) into the adductor tubercle on the medial condyle of the femur, by means of a strong tendon, derived from the fibres which arise from the tuber

ischiadicum, and closely connected with the tibial collateral ligament of the knee-joint. The part of the muscle attached to the space proximal to the linea aspera is often separated from the rest as the **adductor minimus.** The attachment to the linea aspera is interrupted by a series of tendinous arches which are thrown over the perforating branches of the profunda femoris artery, and the attachment to the epicondylic ridge is interrupted for the passage of the femoral vessels into the popliteal fossa.

The muscle is covered, anteriorly, by the other adductors and by the sartorius muscle. The profunda femoris artery separates it from the adductor longus muscle,

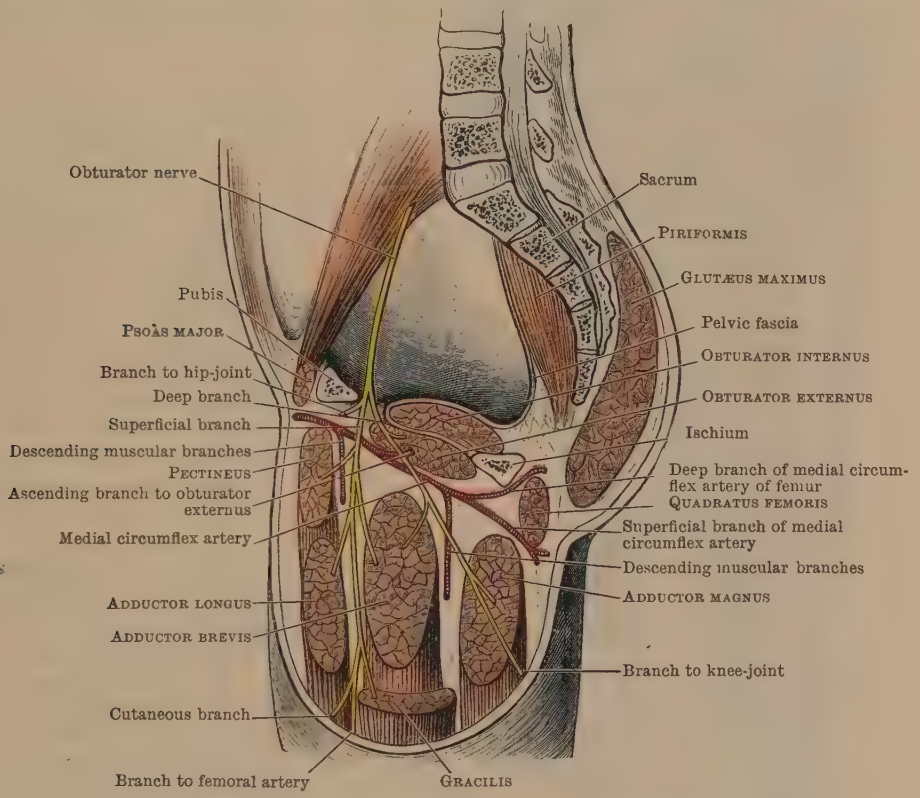

Fig. 341.—Scheme of the Course and Distribution of the Right Obturator Nerve.

while the femoral vessels are in contact with it in the distal part of the adductor canal. The posterior surface of the muscle is in relation with the hamstring muscles and the sciatic nerve.

Nerve-Supply.—The adductor magnus is a double muscle, and has a double nerve-supply. The medial part of the muscle extending between the tuber ischiadicum and the medial condyle of the femur, associated with the hamstring group of muscles, is supplied by the nerve to that group, viz. :—the tibial nerve (L. 4. 5. S. 1.). This enters the muscle on its posterior surface.

The adductor portion of the muscle is supplied on its anterior surface by the deep branch of the obturator nerve (L. 3. 4.).

Actions.—The proximal part of the muscle produces adduction, and assists in flexion and lateral rotation. The distal fibres extend the femur and may assist in medial rotation.

M. Obturator Externus.—The **obturator externus** is placed deeply, under cover of the previous muscles. It is a fan-shaped muscle lying horizontally in the angle between the hip bone and the neck of the femur.

It arises from the surfaces of the pubic bone and ischium which form the inferior half of the margin of the obturator foramen, and from the corresponding portion of the superficial surface of the obturator membrane (Figs. 340, p. 414, and 343, p. 417).

Its fibres converge towards the greater trochanter, and end in a stout tendon which, after passing distal to and posterior to the hip-joint, is **inserted** into the trochanteric fossa of the greater trochanter of the femur (Figs. 339, p. 412, and 344, p. 418).

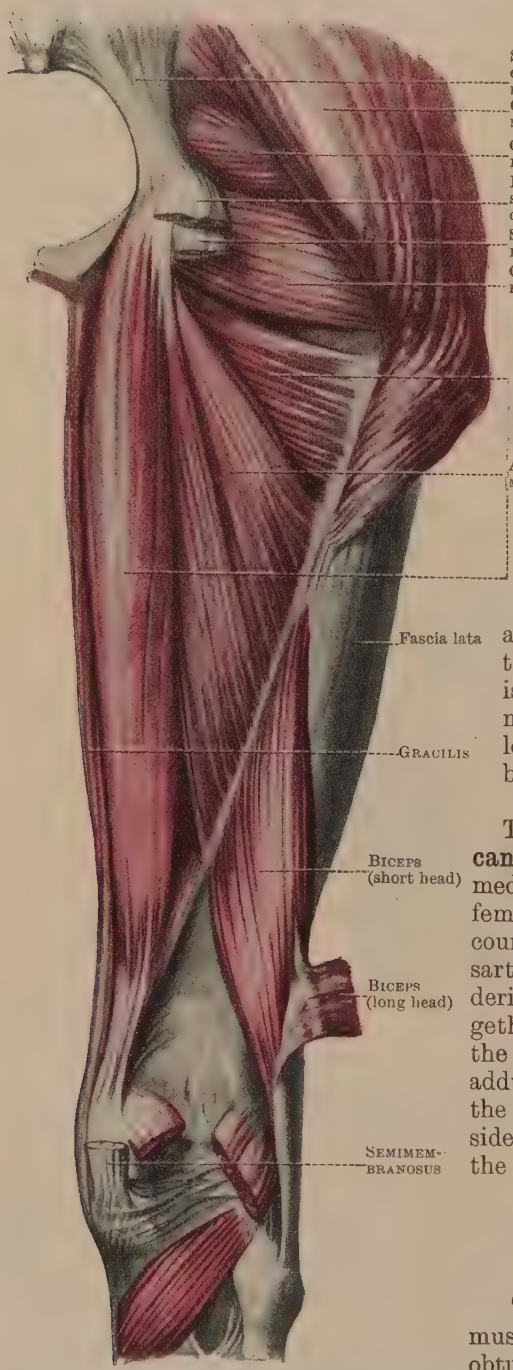

Fig. 342.—Deep Muscles on the Posterior Aspect of the Right Thigh.

Nerve-Supply.—The deep part of the obturator nerve (L. 3. 4.).

Actions.—This muscle is mainly a lateral rotator of the thigh; it also flexes and adducts it.

Trigonum Femorale.—The **femoral triangle** (O.T. **Scarpa's triangle**) is a large triangular space on the front of the thigh in its proximal third, which contains the femoral vessels in the proximal part of their course and the femoral nerve. It is bounded above by the inguinal ligament, laterally by the sartorius, and medially by the medial border of the adductor longus muscle. Its floor is formed laterally by the ilio-psoas, and medially by the pectineus, adductor longus, and a small part of the adductor brevis.

Canalis Adductorius Hunteri.—The **adductor canal** (O.T. **Hunter's canal**) lies in the middle third of the medial side of the thigh, and contains the femoral vessels in the distal part of their course. It is bounded superficially by the sartorius, under which is a dense fascia derived from the fascia lata, binding together the vastus medialis, which forms the lateral wall of the canal, and the adductors, longus and magnus, which form the medial wall or floor of the canal. Besides the femoral vessels and their sheath, the canal contains the saphenous nerve.

THE MUSCLES OF THE BUTTOCK.

This group includes the three glutæi muscles, the tensor fasciæ latæ, piriformis, obturator internus and gemelli, and quadratus femoris.

The glutæus maximus and tensor fasciæ latæ muscles are in the same plane, invested by envelopes of the fascia lata. The glutæus medius, partially covered by the glutæus maximus, conceals the glutæus minimus; while the piriformis, obturator internus, gemelli, and quadratus femoris intervene between the glutæus maximus and the posterior surface of the hip-joint.

M. Glutæus Maximus.—The **glutæus maximus** is a large quadrilateral muscle, with a crescentic origin. It arises from (1) a portion of the area on the dorsum

ilii above the posterior gluteal line (Fig. 343); (2) the tendon of the sacro-spinalis muscle; (3) the dorsal surface of the sacrum and coccyx (Fig. 345, p. 418); and (4) the posterior surface of the sacro-tuberous ligament. The fibres forming its superior and lateral border take origin directly from the fascia lata which covers the glutæus medius muscle.

The muscle forms a large fleshy mass, whose fibres are directed obliquely over the buttock, and are **inserted**, by short tendinous fibres, partly into the fascia lata (p. 404) over the greater trochanter of the femur (joining the ilio-tibial tract), and partly into the gluteal tuberosity (Fig. 344, p. 418). The fascia lata receives the insertion of the whole of the superficial fibres of the muscle and the superior half of the deep fibres. The inferior half of the deep portion of the muscle is

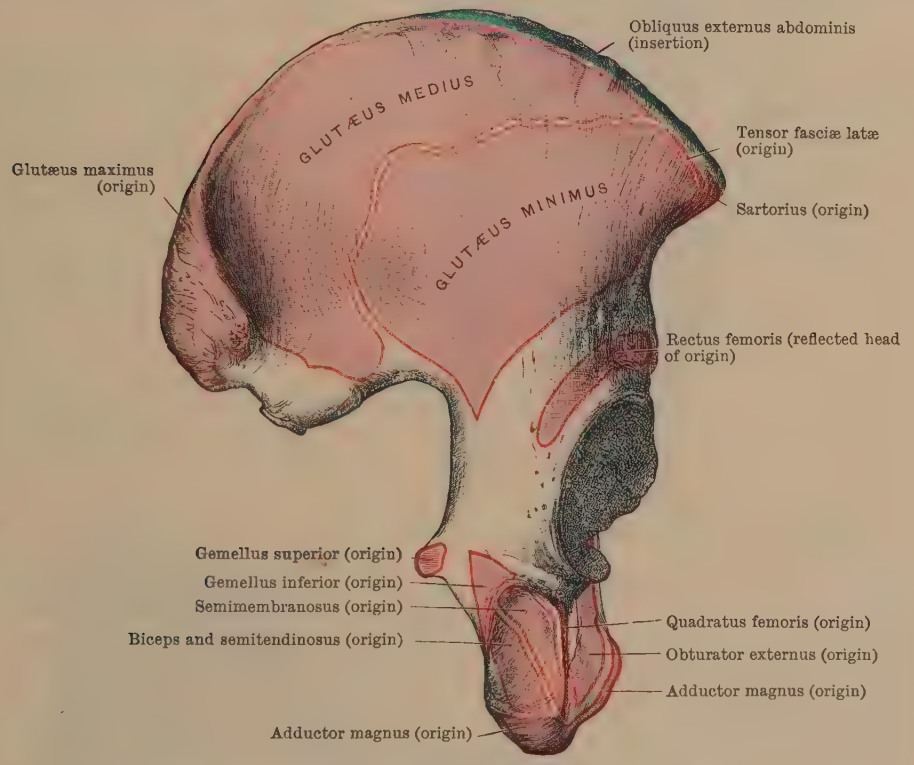

Fig. 343.—Muscle-Attachments to the Right Dorsum Ilii and Tuber Ischiadicum.

inserted, for the most part, into the gluteal tuberosity; but the most inferior fibres of all are inserted into the fascia lata, and are thereby connected with the lateral intermuscular septum and the origin of the short head of the biceps.

The glutæus maximus is the coarsest and heaviest muscle in the body. By its weight it helps to form the fold of the nates. It is superficial in its whole extent. The glutæus medius is visible at its superior border, covered by the fascia lata; at its lower border the hamstring muscles and sciatic nerve appear on their way to the thigh. Three bursæ are deep to it: one (not always present) over the sciatic tuberosity, a second over the lateral side of the greater trochanter, and a third over the vastus lateralis. The fibres of the glutæus maximus arising from the coccyx may form a separate muscle (**agitator caudæ**).

Nerve-Supply.—Inferior gluteal nerve, from the sacral plexus (L. 5. S. 1. 2.).

Actions.—The glutæus maximus is mainly an extensor of the thigh, and has a powerful action in straightening the lower limb, as in climbing or running. Its lower fibres also adduct the thigh and rotate it laterally. Acting from its insertion the muscle is a powerful extensor of the trunk on the lower limbs, and is called into play when the body is raised from the sitting or stooping position.

M. Tensor Fasciæ Latæ.—The **tensor fasciæ latæ** arises from the iliac crest

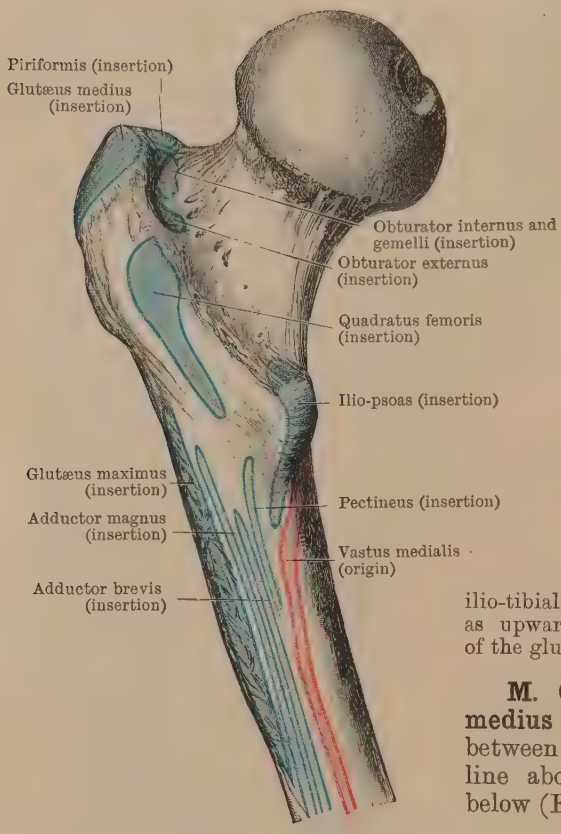

FIG. 344.—MUSCLE-ATTACHMENTS TO THE POSTERIOR ASPECT OF THE PROXIMAL PART OF THE LEFT FEMUR.

fascia lata covering its surface anteriorly.

It is a fan-shaped muscle, its fibres converging to the greater trochanter, to be **inserted** by a strong, short tendon into the postero-superior angle of the greater trochanter, and into a well-marked diagonal line on its lateral surface (Fig. 220, p. 262, and Fig. 344). The most anterior fibres of origin are inserted most distally on the trochanter, and a bursa is situated between the tendon and the bone.

The muscle is partly superficial, partly concealed by the glutæus maximus. It covers the glutæus minimus, and the superior gluteal nerve and the deep branches of the superior gluteal artery.

Nerve-Supply.—The superior gluteal nerve from the sacral plexus (L. 4. 5. S. 1.).

and the dorsum ilii just lateral to the anterior superior spine, and from the fascia covering its lateral surface (Fig. 343, p. 417).

It is **inserted**, distal to the level of the greater trochanter of the femur, into a splitting of the fascia lata (p. 404), and many of its fibres are continued into the **ilio-tibial** tract (p. 406). The muscle obscures the anterior borders of the glutæus medius and glutæus minimus.

Nerve-Supply. — The superior gluteal nerve from the sacral plexus (L. 4. 5. S. 1.) ends in this muscle after passing between the glutæus medius and glutæus minimus.

Actions.—It assists in abduction and medial rotation of the thigh, but its most important action is exerted as an extensor of the knee-joint through the ilio-tibial tract, which it draws forwards as well as upwards, so counteracting the backward pull of the glutæus maximus.

M. Glutæus Medius.—The **glutæus medius** arises from (1) the dorsum ilii, between the iliac crest and posterior gluteal line above and the anterior gluteal line below (Fig. 343, p. 417), and (2) the strong

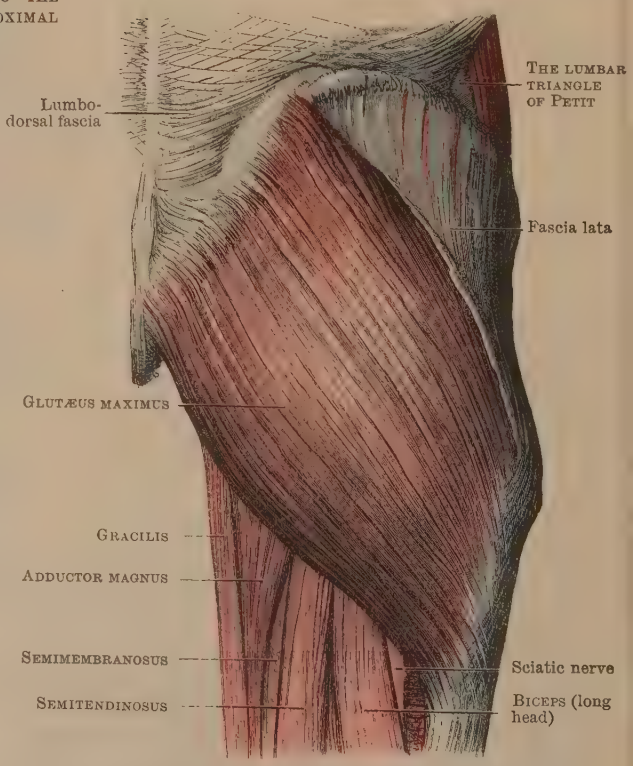

FIG. 345.—THE RIGHT GLUTÆUS MAXIMUS MUSCLE.

Actions.—This muscle is a powerful abductor of the thigh for all positions of the limb and a medial rotator of the extended thigh.

Both the glutæus medius and the glutæus minimus take an active part in the movements of the pelvis associated with walking. When one limb leaves the ground, the centre of gravity of the body no longer falls within the area of support, but the force of gravitation is successfully opposed by the abductors of the opposite side. Further, as one limb advances, the pelvis is rotated to the opposite side by the glutæus medius and minimus muscles of that side.

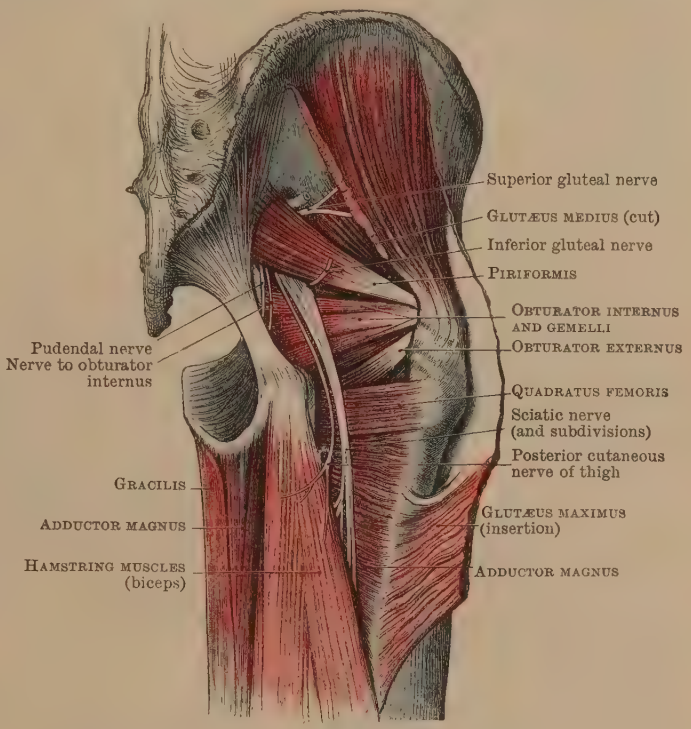

Fig. 346.—The Muscles and Nerves of the Right Buttock.

The glutæus maximus is reflected; and the glutæus medius is cut, in part, to show the glutæus minimus.

M. Glutæus Minimus.—The **glutæus minimus arises**, under cover of the glutæus medius, by fleshy fibres, from the dorsum ilii between the anterior and inferior gluteal lines (Fig. 343, p. 417).

This muscle is fan-shaped and its fibres converge to the antero-superior angle of the greater trochanter, covering the superior aspect of the capsule of the hip-joint. It is **inserted** into the anterior surface of the trochanter (Fig. 219, p. 261, and Fig. 347). A bursa is placed deep to the tendon in front of the medial part of the anterior surface of the greater trochanter.

Nerve-Supply.—The superior gluteal nerve from the sacral plexus (L. 4. 5. S. 1.).

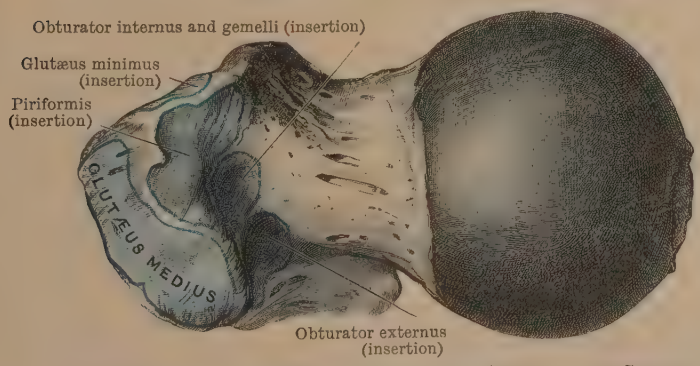

Fig. 347.—Muscle-Attachments to the Proximal Aspect of the Greater Trochanter of the Left Femur.

Actions.—The muscle is primarily an abductor of the thigh. Its anterior fibres in addition produce medial rotation and its posterior fibres lateral rotation of the extended limb. The muscle also takes part in the movements of the pelvis associated with walking.

M. Piriformis.—The **piriformis** is one of the few muscles connecting the lower limb to the axial skeleton. It **arises** (1) within the pelvis from the roots of the vertebral arches of the second, third, and fourth sacral vertebræ, and from the adjacent part of the bone lateral to the anterior sacral foramina. Passing out through the greater sciatic foramen, it receives an origin from (2) the upper margin of the greater sciatic notch of the ilium, and (3) the pelvic surface of the sacro-tuberous ligament.

In the buttock it forms a rounded tendon, which is **inserted**, under cover of the glutæus medius, into a facet on the superior border and medial aspect of the greater trochanter of the femur (Figs. 344, 347, pp. 418, 419).

The piriformis, at its origin, covers part of the inner surface of the posterior wall of the pelvis minor. In the buttock it is covered by the glutæus maximus, and lies behind the capsule of the hip-joint, between the glutæus medius and superior gemellus.

Nerve-Supply.—Branches direct from the anterior rami of the first and second sacral nerves.

Actions.—The muscle is a lateral rotator of the extended thigh and an abductor of the flexed thigh.

M. Obturator Internus.—The **obturator internus arises** on the pelvic aspect of the hip bone, from (1) the whole of the margin of the obturator foramen (except the obturator notch); (2) the surface of the obturator membrane; (3) the whole of the pelvic surface of the hip bone behind and above the obturator foramen; and (4) the parietal pelvic fascia covering it medially.

It is a fan-shaped muscle. Its fibres converge to the lesser sciatic foramen, and end in several tendons, united together, which hook round the margin of the foramen (a bursa intervening), and after passing over the posterior surface of the hip-joint, are **inserted** into a facet on the medial surface of the greater trochanter of the femur above the trochanteric fossa (Figs. 219, p. 261, and 347, p. 419).

In the pelvis minor the muscle occupies the side wall, covered by the parietal pelvic fascia, which separates it from the pelvic cavity above and the ischio-rectal fossa below. In the buttock the tendon is embraced by the gemelli muscles which are attached to its superior and inferior margins.

The **gemelli muscles** form accessory portions of the obturator internus.

M. Gemellus Superior.—The **superior gemellus arises** from the gluteal surface of the ischial spine (Fig. 348, p. 421).

It is **inserted** into the upper margin and superficial surface of the tendon of the obturator internus muscle.

M. Gemellus Inferior.—The **gemellus inferior arises** from the superior part of the ischial tuberosity (Fig. 348, p. 421).

It is **inserted** into the inferior margin and superficial aspect of the tendon of the obturator internus.

Nerve-Supply.—The obturator internus and superior gemellus receive branches from a special nerve, the *nerve to the obturator internus* from the anterior aspect of the sacral plexus (S. 1. 2.). The inferior gemellus is supplied by the nerve to the quadratus femoris, a branch derived also from the anterior aspect of the sacral plexus (L. 4. 5. S. 1.).

Actions.—The obturator internus and gemelli are lateral rotators of the extended thigh, and abductors, when the limb is flexed.

M. Quadratus Femoris.—The **quadratus femoris arises** from the lateral margin of the tuber ischiadicum (Figs. 348, p. 421, and 214, p. 250). It is **inserted** into the quadrate tubercle and quadrate line of the femur (Fig. 344, p. 418).

The muscle is concealed by the glutæus maximus and the hamstring muscles. Its anterior surface is in contact with the obturator externus muscle and the lesser trochanter of the femur, a bursa intervening. The muscle is not infrequently fused with the adductor magnus.

Nerve-Supply.—A special nerve from the sacral plexus (L. 4. 5. S. 1.) which enters its deep (anterior) surface.

Actions.—The muscle is an adductor and lateral rotator of the thigh.

THE MUSCLES ON THE POSTERIOR ASPECT OF THE THIGH.

The Hamstring Muscles.

The muscles comprised in this series include the biceps, semitendinosus, and semimembranosus. A part of the adductor magnus, already described, also belongs, morphologically, to this group. They lie in the buttock and posterior aspect of the thigh, and diverge at the knee to bound the popliteal fossa. The origins of

the muscles are concealed by the glutæus maximus. In the back of the thigh, enveloped by the fascia lata, they are placed behind the adductor magnus—the semitendinosus and semimembranosus medially, the biceps laterally. The former two muscles help to form the medial boundary of the popliteal fossa, of which the biceps is a lateral boundary.

M. Biceps Femoris.—The **biceps femoris** has a double **origin.** (1) *Its long head* arises, by means of a tendon, in common with the semitendinosus, from the inferior and medial facet upon the sciatic tuberosity (Fig. 214, p. 250, and Fig. 348) and from the sacro-tuberous ligament. This head, united for a distance of two or three inches with the semitendinosus, forms a separate fleshy mass, which extends to the distal third of the thigh, to end in a tendon joined by

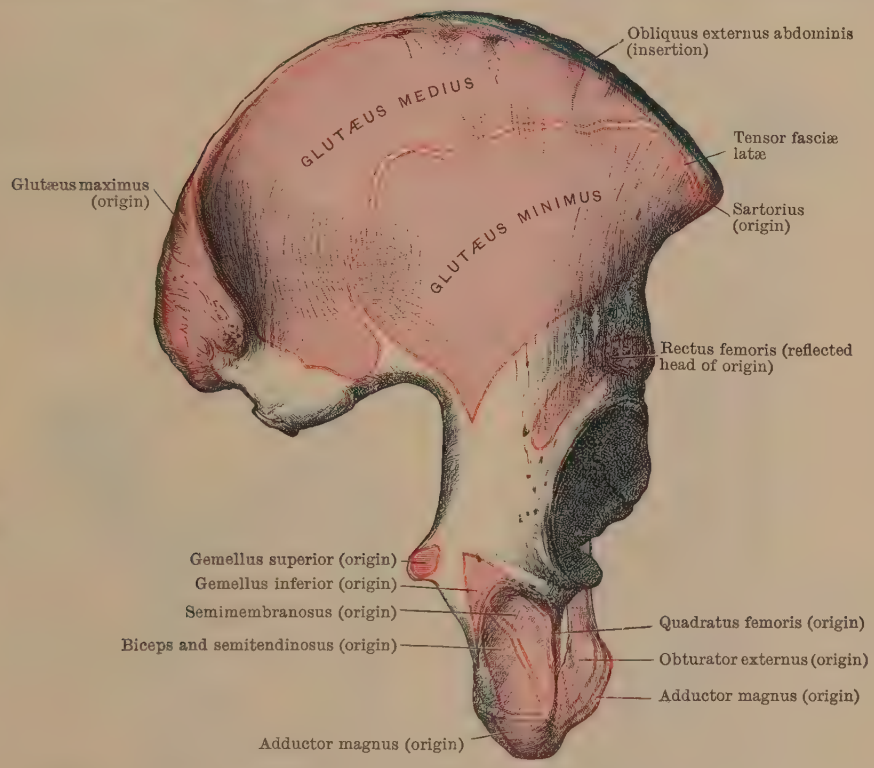

FIG. 348.—MUSCLE-ATTACHMENTS TO THE RIGHT DORSUM ILII AND TUBER ISCHIADICUM.

the short head of the muscle. (2) *The short head* arises separately from, (1) the whole length of the lateral lip of the linea aspera and the proximal two-thirds of the lateral epicondylic line of the femur, and (2) the lateral intermuscular septum. The proximal limit of its origin is sometimes blended with the insertion of the lowest fibres of the glutæus maximus.

The fibres of the short head, directed distally, join the tendon of the long head, and the muscle is **inserted** (1) into the head of the fibula by a strong tendon, which is split into two parts by the *fibular collateral* ligament of the knee-joint; (2) by a slip attached to the lateral condyle of the tibia; and (3) along its posterior border by an expansion to the deep fascia on the lateral aspect of the leg.

There is a bursa between the tendon and the fibular collateral ligament of the knee-joint.

The short head may be absent: there may be an additional origin from the ischium or femur; and the long head may send a slip to the gastrocnemius or tendo calcaneus (Achillis) (**tensor fasciæ suralis**).

Nerve-Supply.—The long head is supplied by the sciatic (tibial part, L. 5. S. 1. and 2.) and the short head by the common peroneal nerve (L. 5. S. 1. 2.).

Actions.—The muscle is a powerful flexor of the knee-joint, and through its long head,

assists in extension of the thigh. When the knee is flexed, the biceps is a lateral rotator of the leg.

M. Semitendinosus.—The **semitendinosus** arises, in common with the long head of the biceps, from the inferior and medial facet upon the ischial tuberosity (Fig. 348, p. 421). Separating from the common tendon, two or three inches from its origin, the muscle forms a long, narrow band which becomes tendinous in the middle third of the thigh lying on the surface of the semimembranosus.

Passing over the medial side of the knee it spreads out and becomes membranous, and is **inserted** (1) into the medial side of the body of the tibia just distal to the medial condyle, distal to the gracilis and behind the sartorius (Fig. 350), and (2) into the deep fascia of the leg. A bursa separates it from the sartorius superficially, and another, common to it and the gracilis, lies deep to its

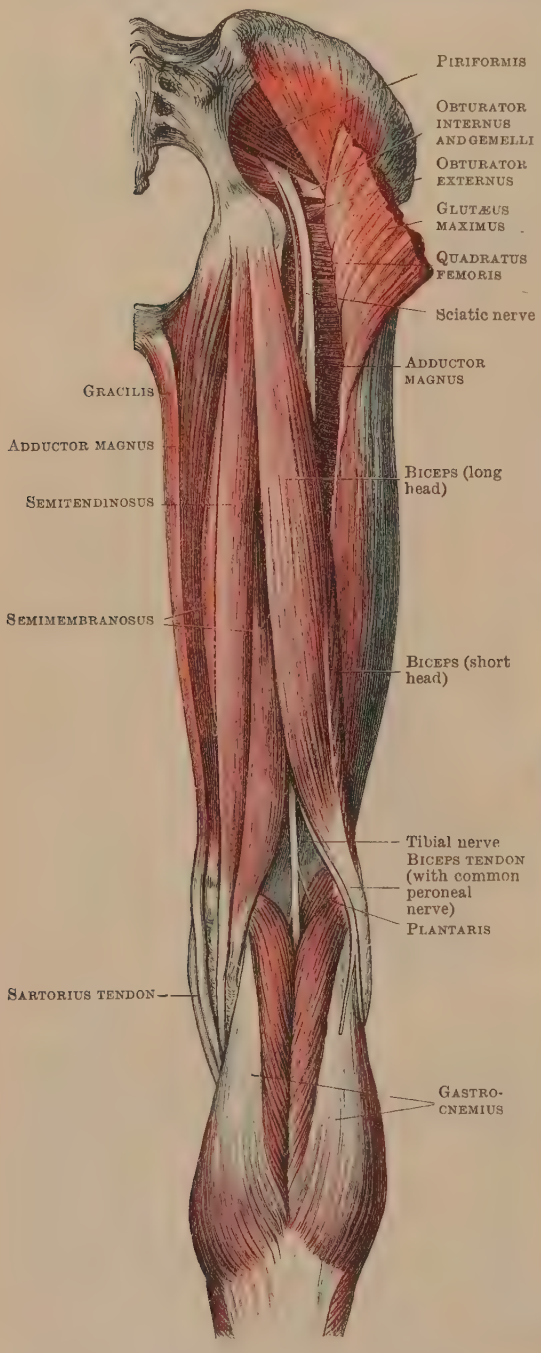

Fig. 349.—The Muscles on the Posterior Aspect of the Right Thigh.

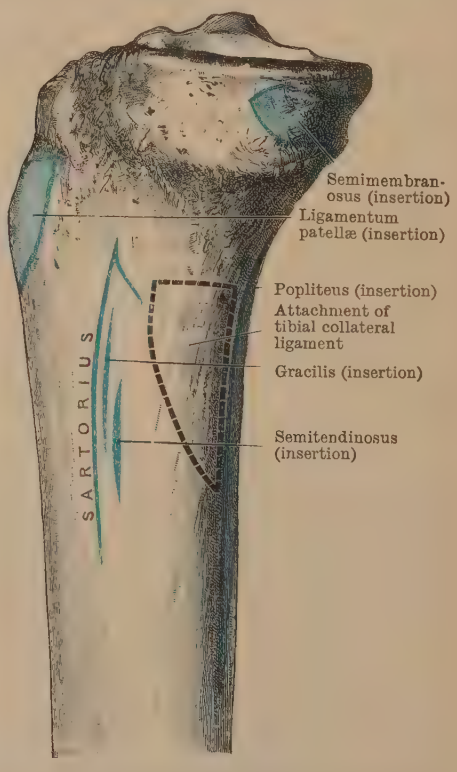

Fig. 350.—Muscle-Attachments to the Medial Surface of the Proximal Part of the Right Tibia.

insertion. The belly of the muscle is marked by an oblique septal tendinous intersection about its middle.

Nerve-Supply.—The semitendinosus is supplied by two branches from the sciatic nerve, tibial part (L. 5. S. 1. 2.).

Actions.—A flexor of the knee, a medial rotator of the flexed tibia, and an extensor of the hip.

M. Semimembranosus.—The **semimembranosus** arises by a tendon from the superior and lateral facet on the ischial tuberosity (Figs. 214, p. 250, and 349, p. 422). In the proximal third of the thigh the tendon gives place to a rounded fleshy belly, which lies anterior to the ischial portions of the biceps and semitendinosus muscles.

Becoming tendinous, at the back of the knee, it is **inserted** into the horizontal groove on the postero-medial aspect of the medial condyle of the tibia (Figs. 227, p. 270, and 350, p. 422). A bursa lies deep to the tendon at its insertion. It has three *additional membranous insertions*: (1) a fascial band extends distally and medially to join the posterior border of the *tibial collateral* ligament of the knee-joint; (2) another fascial band extends distally and laterally, forms the fascia covering the popliteus muscle (*popliteus fascia*), and is attached to the oblique line of the tibia; and (3) a third strong band extends proximally and laterally to the back of the lateral condyle of the femur, forming the oblique popliteal ligament of the knee-joint.

The membranous origin of the muscle is concealed by the proximal parts of the semitendinosus and long head of the biceps. The tendon of insertion covers the origin of the medial head of the gastrocnemius.

Nerve-Supply.—It is innervated by the sciatic nerve, tibial part (L. 5. S. 1. 2.).

Actions.—A flexor of the knee, a medial rotator of the flexed tibia, and an extensor of the hip.

THE FASCIÆ AND MUSCLES OF THE LEG AND FOOT.

FASCIÆ.

The **superficial fascia** of the leg and foot presents no special features except in the sole, where it is greatly thickened by pads of fat, particularly under the tuberosity of the calcaneus, and under the balls of the toes.

The **deep fascia** has numerous important attachments about the knee. Posteriorly it forms the *popliteal fascia,* and is joined by expansions from the tendons of the sartorius, gracilis, semitendinosus, and biceps femoris muscles. In front of the knee it is attached to the patella, the ligamentum patellæ, and the tubercle of the tibia; medially and laterally it is connected to the condyles of the tibia and the head of the fibula, and helps to form the **collateral patellar ligaments**—broad fascial bands which pass obliquely from the sides of the patella to the condyles of the tibia, and are joined by fibres of the vasti muscles. Passing into the leg, the fascia blends, over the medial surface of the tibia, with the periosteum of the bone. It extends round the lateral side of the leg from the anterior crest to the medial border of the tibia, binding together and giving origin to the muscles, and gaining an attachment to the distal part of the body of the fibula. **Two septa** pass from its deep surface; one septum (anterior peroneal septum), attached to the anterior crest of the fibula, encloses the superficial peroneal nerve, and separates the extensor from the peronæi muscles. The other septum (posterior peroneal septum) is attached to the lateral crest of the fibula, and separates the peronæi from the flexor muscles. From the last-named septum another extends across the back of the leg; it forms a partition between the superficial and deep flexor muscles, and encloses the posterior tibial vessels and the tibial nerve. It gives rise to subordinate septa attached to the vertical line of the tibia and the medial crest of the fibula, which separate the tibialis posterior from the flexors of the toes on either side.

At the ankle the deep fascia is strengthened by additional transverse fibres, which give rise to thickened bands named the ligamentum laciniatum, lig. transversum cruris, lig. cruciatum cruris and the retinacula of the peroneal muscles. They were formerly known as the annular ligaments.

The **ligamentum laciniatum** stretches between the medial malleolus and the tuberosity of the calcaneus. While it is continuous, at its proximal border, with the general investment of the deep fascia, it is chiefly formed by the septal layer

covering the deep muscles on the back of the leg. It sometimes gives insertion to the plantaris muscle. It is continuous, distally, with the plantar aponeurosis, and gives origin to the abductor hallucis muscle. It is pierced by the calcanean vessels and nerve. Along with the posterior tibial vessels and the tibial nerve, the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus, pass beneath it, each enclosed in a separate mucous sheath.

The **superior peroneal retinaculum** is a thickened band of the deep fascia stretching between the lateral malleolus and the calcaneus. It binds down the tendons of the peronæi, as they pass behind the lateral malleolus, invested by a single mucous sheath while the **inferior peroneal retinaculum** is attached proximally to the apex of the lateral malleolus, and crosses the peroneus brevis tendon to reach the trochlear process (O.T. peroneal tubercle). From this attachment its fibres are continued over the peroneus longus tendon to the lateral surface of the calcaneus.

The **ligamentum transversum cruris**, broad and undefined at its proximal and distal borders, stretches across the front of the ankle between the two malleoli. This band binds down, to the distal end of the tibia, the tendons of the tibialis interior and extensor muscles of the toes. One mucous sheath is found deep to it, surrounding the tendon of the tibialis anterior.

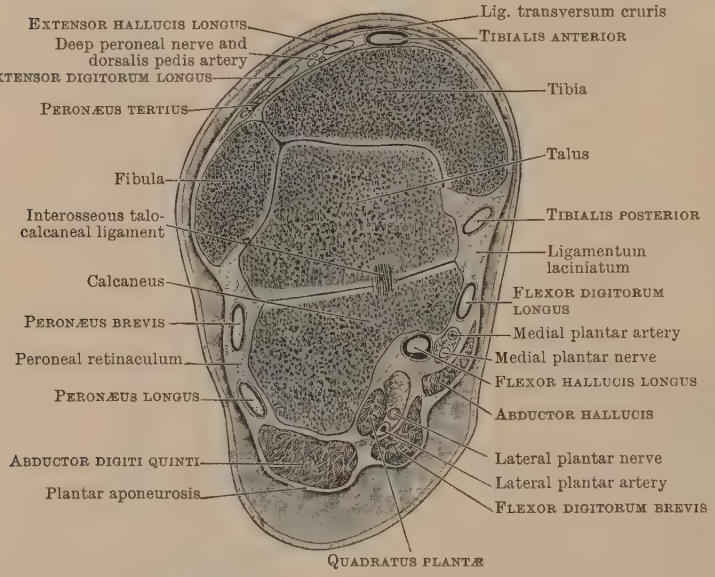

Fig. 351.—Frontal Section through the Left Ankle-Joint, Talus, and Calcaneus.

Ligamentum Cruciatum Cruris.—On the dorsum of the foot, where the general covering of deep fascia is much thinner, a special well-defined band, named the **ligamentum cruciatum cruris**, stretches over the extensor tendons. It has an attachment laterally to the lateral border of the dorsal surface of the calcaneus. It divides into two bands as it passes medially over the dorsum of the foot—a *proximal part*, which joins the lig. transversum cruris and is attached to the medial malleolus, and a *distal part*, which passes across the dorsum of the foot, and joins the fascia of the sole at its medial border. Deep to this ligament are three special compartments with separate mucous sheaths, one for the tibialis anterior tendon, a second for that of the extensor hallucis longus, and a third for the extensor digitorum longus and peronæus tertius tendons. Occasionally the ligament is joined by an additional band, which is attached proximally to the lateral malleolus.

The **plantar aponeurosis** is of great importance. In the centre of the sole it forms a thick triangular band, attached posteriorly to the tuberosity of the calcaneus. It spreads out anteriorly and separates into *five slips*, which are directed forwards to the bases of the toes. These slips as they separate are joined together by ill-defined bands of transverse fibres, which constitute the **fasciculi transversi aponeurosis plantæ**. The slip for each toe straddles the flexor tendons and is attached on each side to the deep transverse metatarsal ligament and the base of the first phalanx. Distally it is continuous with the fibrous layer of the digital sheath.

This central portion of the plantar aponeurosis assists in preserving the arch of the foot, by drawing the toes and the calcaneus together.

On each side it is continuous with a much thinner layer, which covers the lateral and medial muscles of the sole and joins the fascia of the dorsum of the foot at each border. It also gives rise to intermuscular septa, which pass deeply on each side of the flexor digitorum brevis, enclosing that muscle in a separate sheath, and giving investments on either side to the abductor muscles of the great and little toes. At the lateral border of the foot the **calcaneo-metatarsal ligament**, a thickened band of the fascia, connects the tuberosity of the calcaneus with the base of the fifth metatarsal bone.

The **digital sheaths**, though smaller, are the same in arrangement as those of the fingers (p. 387). **Vaginal ligaments** are present in relation to the first and second phalanges.

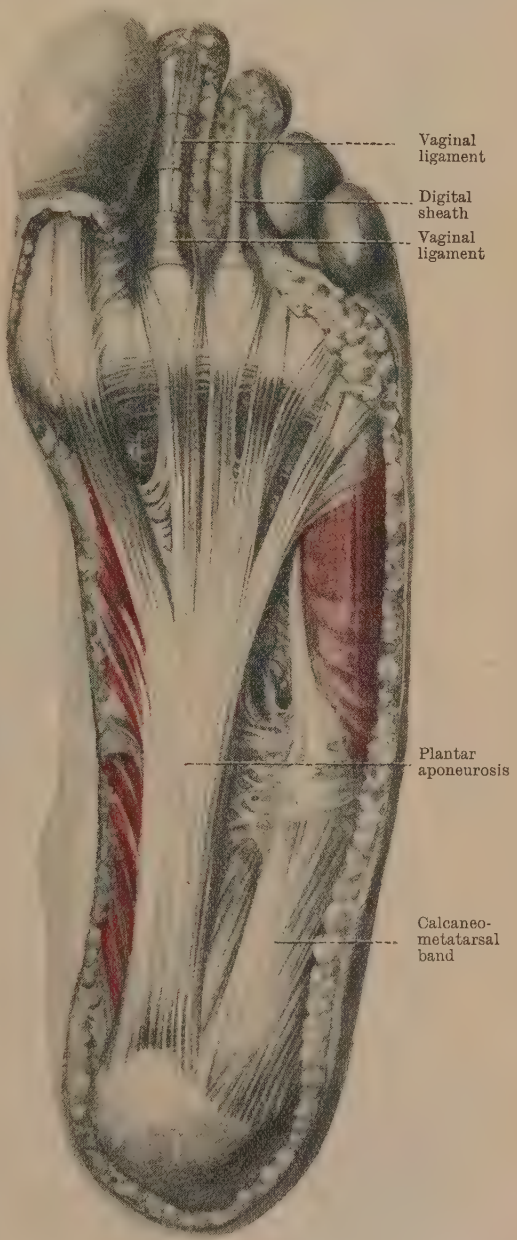

Fig. 352.—The Left Plantar Fascia.

THE MUSCLES OF THE LEG AND FOOT.

The muscles of the leg and foot are divisible into three series: (1) the extensor muscles on the front of the leg and dorsum of the foot; (2) the peronæi on the lateral aspect of the leg; and (3) the flexor muscles on the back of the leg and in the sole of the foot.

The Muscles on the Front of the Leg and Dorsum of the Foot.

The muscles on the front of the leg and dorsum of the foot include two groups: (1) on the front of the leg, the tibialis anterior, long extensors of the toes and peronæus tertius; and (2) on the dorsum of the foot, the extensor digitorum brevis.

On the front of the leg the tibialis anterior and the extensor digitorum longus and peronæus tertius are superficially placed, and conceal the extensor hallucis longus muscle. On the dorsum of the foot the extensor digitorum brevis muscle lies beneath the tendons of the long extensor of the toes.

M. Tibialis Anterior. — The **tibialis anterior** arises from the lateral condyle and the proximal two-thirds of the lateral surface of the body of the tibia, from the interosseous membrane, from the fascia over it, and from an intermuscular septum laterally. The muscle ends in a strong tendon which becomes free in the distal third of the leg. It passes distally and medially over the front of the distal end of the tibia, the ankle-joint and the dorsum of the foot to be inserted into a facet on the medial surface

of the first cuneiform and the medial side of the base of the first metatarsal bone (Fig. 226, p. 269). Special compartments, lined by a separate mucous sheath, are provided for the tendon under both the transverse and the cruciate ligaments.

The **tibio-fascialis anterior** is a separated portion of the muscle occasionally present, inserted into the fascia on the dorsum of the foot.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).

Actions.—The muscle is a dorsi-flexor of the ankle, and (in combination with the tibialis posterior) it inverts the foot.

M. Extensor Digitorum Longus.—The **extensor digitorum longus arises**, by fleshy fibres, from the lateral side of the lateral condyle of the tibia, from the

FIG. 353.—MUSCLE-ATTACHMENTS TO LEFT TARSUS AND METATARSUS (Plantar Aspect).

proximal two-thirds or more of the anterior part of the medial surface of the body of the fibula, from the fascia over it, from intermuscular septa on either side, and from the anterior aspect of the interosseous membrane in its proximal part.

It gives rise to a tendon which, passing deep to the ligamentum transversum, subdivides in front of the ankle into four smaller tendons. These, with the tendon of the peronæus tertius, are provided with a mucous sheath as they lie in the most lateral compartment under the ligamentum cruciatum cruris. They are **inserted** into the four lateral toes, exactly in the same way as the corresponding tendons in the hand (see p. 400). They form membranous expansions on the dorsum of the first phalanx, joined by the tendons of the extensor digitorum brevis,

lumbricales, and interossei, and each then separates into one central and two collateral slips, attached respectively to the middle and terminal phalanges.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).
Actions.—A dorsi-flexor of the ankle and an extensor of the four lateral toes.

M. Peronæus Tertius.—The **peronæus tertius** is a separated portion of the extensor digitorum longus. It is an essentially human muscle. It arises (inseparably from the extensor digitorum longus) from the distal part of the medial surface of the fibula, and from the intermuscular septum lateral to it.

The tendon of the muscle is **inserted** into the dorsal aspect of the base of the fifth metatarsal bone.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).
Actions.—The muscle dorsi-flexes the ankle and raises the lateral border of the foot (as in skating or dancing).

M. Extensor Hallucis Longus.—The **extensor hallucis longus arises** from the anterior part of the medial surface of the fibula in its middle three-fifths, deep to the origin of the extensor digitorum longus, and for a corresponding extent from the interosseous membrane. Its tendon passes over the dorsum of the foot, to be **inserted** into the base of the terminal phalanx of the great toe. As it lies under cover of the transverse ligament, this tendon occupies the same compartment as the extensor digitorum longus and the peronæus tertius, but it is provided with a special compartment, lined by a separate mucous sheath, as it lies under the cruciate ligament.

The **extensor primi internodii longus** and **extensor ossis metatarsi hallucis** are occasional separate slips of this muscle inserted into the proximal phalanx and the metatarsal bone.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).
Actions.—This muscle dorsi-flexes the ankle, and extends the great toe.

M. Extensor Digitorum Brevis.—The **extensor digitorum brevis arises**, on the dorsum of the foot, from a special impression on the fore part of the dorsal surface of the calcaneus, and from the deep surface of the ligamentum cruciatum cruris.

It usually gives rise to four fleshy bellies, from which narrow tendons are directed forwards and medially, to be **inserted** into the four medial toes. The three lateral tendons join those of the long extensor muscle to form the membranous expansions on the dorsum of the toes. The *most medial tendon* (**extensor hallucis brevis**), after crossing the dorsalis pedis artery, is inserted separately into the base of the first phalanx of the great toe.

Nerve-Supply.—Deep peroneal nerve (L. 4. 5. S. 1.).
Actions.—Extension of the four medial toes.

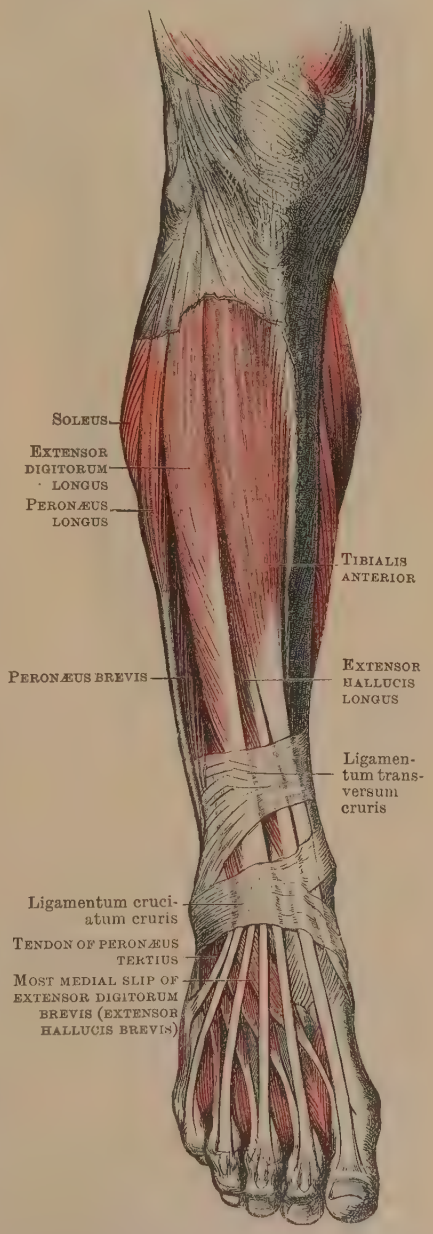

Fig. 354.—Muscles of the Front of the Right Leg and Dorsum of the Right Foot.

The Muscles on the Lateral Side of the Leg.

These muscles comprise the peronæi,—longus and brevis. They are placed on the lateral side of the leg between the extensor digitorum longus in front, and the soleus and flexor hallucis longus behind, enclosed in a special osteo-fascial compartment.

M. Peronæus Longus. — The **peronæus longus arises** from the lateral condyle of the tibia, from the head and the proximal two-thirds of the lateral surface of the body of the fibula, from intermuscular septa on either side, and from the fascia over it.

It forms a stout tendon, which lies

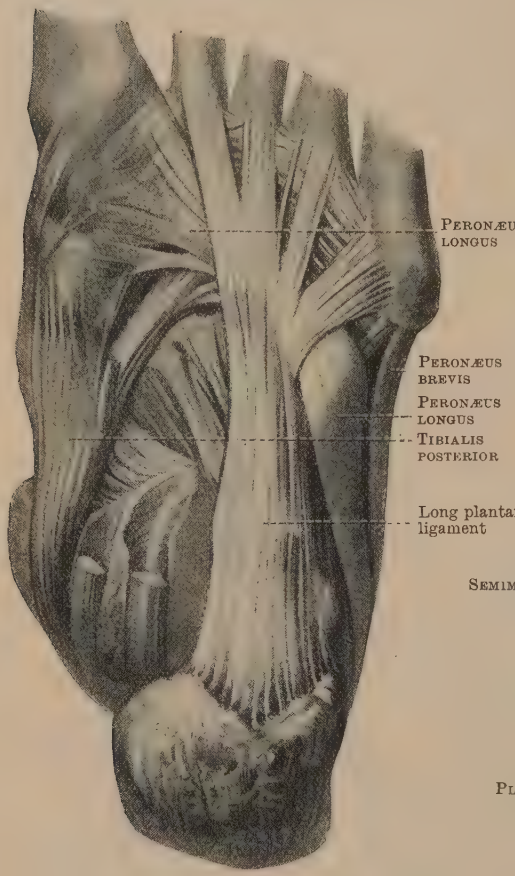

Fig. 355.—The Insertions of the Tibialis Posterior and Peronæus Longus in the Sole of the Left Foot.

superficial to the peronæus brevis, and hooks round the lateral malleolus deep to the superior peroneal retinaculum. It then crosses the lateral side of the calcaneus, where it diverges from the peronæus brevis tendon, passing below the trochlear process and under the inferior peroneal retinaculum. Finally, traversing the groove on the cuboid bone, it is directed across the sole of the foot to be **inserted** into the lateral sides of the first cuneiform and the base of the first metatarsal bones (Fig. 353, p. 426). As it enters the sole of the foot a *fibro-cartilage* is formed in the tendon, which plays over a smooth tubercle on the cuboid bone, a bursa intervening. In its passage across the foot the tendon is enclosed in a sheath derived from the long plantar (long calcaneo-cuboid) ligament and

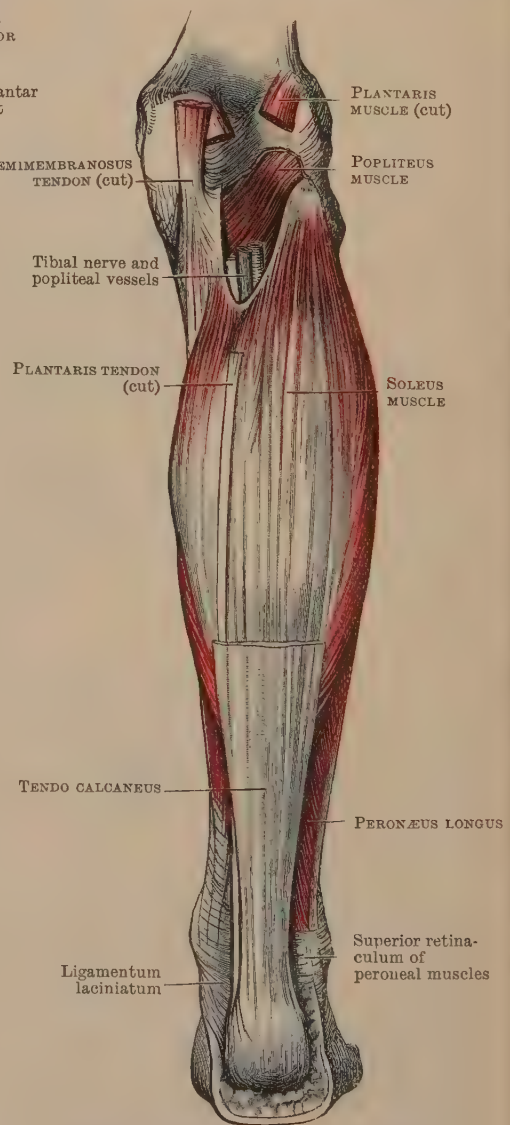

Fig. 356.—The Right Soleus Muscle.

the tibialis posterior tendon. A second mucous sheath invests this part of the tendon.

Nerve-Supply.—Superficial peroneal nerve (L. 4. 5. S. 1.).
Actions.—This muscle is an evertor and a plantar flexor of the foot. It supports the transverse arch of the foot by its passage across the sole to its insertion.

M. Peronæus Brevis.—The **peronæus brevis arises** by fleshy fibres from the distal two-thirds of the lateral surface of the body of the fibula, and from an intermuscular septum along its anterior border.

Its tendon grooves the back of the lateral malleolus and the lateral side of the calcaneus, invested by a mucous sheath common to it and the peronæus longus, and is **inserted** into the tuberosity and dorsal surface of the base of the fifth metatarsal bone.

The peronæus longus and brevis may be fused together, or additional slips may be present, as **peronæus accessorius, peronæus digiti quinti, peronæocalcaneus externus,** and **peronæocuboideus.**
Nerve-Supply.—Superficial peroneal nerve (L. 4. 5. S. 1.).
Actions.—An evertor and plantar flexor of the foot.

The Muscles on the Posterior Aspect of the Leg.

The muscles on the back of the leg are divisible into two groups, superficial and deep.

The superficial group comprises the gastrocnemius and soleus (constituting together the **triceps suræ**) and the plantaris. They form the prominence of the calf of the leg. The gastrocnemius is superficial except at its origin, where the two bellies, forming the boundaries of the popliteal fossa, are overlapped by the tendons of the hamstring muscles. The soleus muscle is partially concealed by the gastrocnemius and plantaris, and becomes superficial in the distal part of the leg on each side of the common tendon (tendo calcaneus).

M. Gastrocnemius.—The **gastrocnemius arises** by *two heads*, medial and lateral, by means of strong tendons which are prolonged over the surface of the muscle. The **lateral head** arises from an impression on the proximal and posterior part of the lateral surface of the lateral condyle of the femur, and from the distal end of the lateral epicondylic line; while the **medial head** arises from a prominent rough mark on the popliteal surface of the femur, proximal to the medial epicondyle. Each head has an additional origin from the back of the capsule of the knee-joint. A bursa lies deep to each tendon of origin; in the case of the medial head it frequently communicates with the synovial cavity of the articulation, but such a communication is comparatively rare in the case of the lateral head.

The two fleshy bellies, of which the medial is the larger, remain separate and are inserted into the posterior surface of a broad, membranous tendon, which narrows distally and constitutes the **tendo calcaneus.**

Becoming thicker in the distal part of the leg, where it receives, on its anterior surface, the insertion of the soleus, the tendo calcaneus is inserted into the middle part of the posterior surface of the calcaneus. A bursa intervenes between the tendon and the bone, immediately proximal to its insertion.

Nerve-Supply.—Each head of the muscle is innervated by a branch from the tibial nerve (S. 1. 2.).
Actions.—The muscle is a powerful flexor of the knee and extensor of the ankle.

M. Plantaris.—The **plantaris arises** by fleshy fibres from the lateral epicondylic line of the femur for about an inch at its distal end, from the adjacent part of the popliteal surface of the femur, and from the oblique ligament of the knee-joint.

It forms a narrow fleshy slip ending in a tendon which runs distally in the back of the leg, to be **inserted** into the medial side of the tuberosity of the calcaneus or the tendo calcaneus, or the ligamentum laciniatum. The tendon of the muscle, although apparently a rounded bundle, can be drawn out into a fine, aponeurotic sheet, two or three inches in width.

The plantaris lies between the lateral head of the gastrocnemius and the soleus.

In the distal half of the leg its tendon lies along the medial border of the tendo calcaneus. The muscle is not always present.

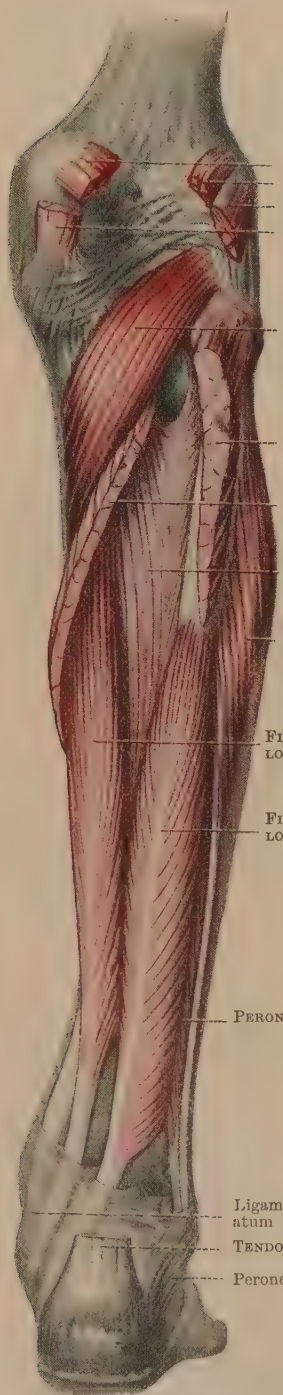

Fig. 357.—The Deep Muscles on the Back of the Right Leg.

Nerve-Supply.—Tibial nerve (L. 4. 5. S. 1.).

Actions.—The muscle is an accessory flexor of the knee and extensor of the ankle.

M. Soleus. — The **soleus** has a triple **origin** from (1) the posterior surfaces of the head and the proximal third of the body of the fibula; (2) a fibrous arch (**arcus tendineus m. solei**) stretching, over the popliteal vessels and tibial nerve, between the tibia and fibula; and (3) the oblique line, and the middle third of the medial border of the tibia (Fig. 358).

From their origin the proximal muscular fibres are directed distally to join a tendon, placed on the superficial aspect of the muscle, which is **inserted** into the tendo calcaneus; the more distal fibres are inserted directly into the tendo calcaneus to within one or two inches of the calcaneus.

Nerve-Supply.—Two nerves supply this muscle. One from the tibial nerve in the popliteal space enters its superficial surface (S. 1. 2.); the other from the tibial nerve in the back of the leg supplies the deep surface of the muscle (L. 5. S. 1. 2.).

Actions.—The soleus is a powerful extensor of the ankle.

The **deep muscles** of the back of the leg comprise the popliteus, flexor digitorum longus, flexor hallucis longus, and tibialis posterior.

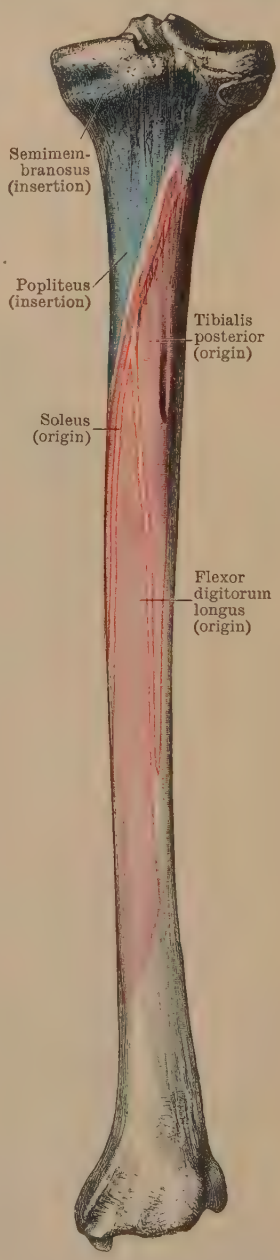

Fig. 358.—Muscle-Attachments to the Posterior Surface of the Right Tibia.

The popliteus muscle is deeply placed in the distal part of the floor of the popliteal fossa, and is covered by the popliteal vessels and tibial nerve. The flexor digitorum longus lies on the tibia, the flexor hallucis longus on the fibula, and the tibialis posterior, lying between them, is related to the interosseous membrane

and both bones of the leg. All these muscles are concealed by the superficial group, and are bound down to the bones of the leg by layers of the deep fascia.

M. Popliteus.—The **popliteus arises**, by a stout tendon, from a rough impression in front of a groove on the lateral aspect of the lateral epicondyle of the femur. The tendon passes between the lateral meniscus and the capsule of the knee-joint, and pierces the posterior ligament, from which it takes an additional fleshy origin.

The muscle is **inserted**, by fleshy fibres, (1) into a triangular surface on the back of the tibia above the oblique line (Fig. 358, p. 430), and (2) into the fascia over it (the popliteus fascia, derived from the tendon of the semimembranosus muscle).

Intracapsular at its origin, the tendon is partially invested by the synovial stratum of the joint, which protrudes along it for a short distance after it has pierced the posterior ligament.

Nerve-Supply. — The popliteus is supplied by a branch of the tibial nerve (L. 4. 5. S. 1.), which winds round the distal border of the muscle and enters it in its deep surface.

Actions.—A medial rotator of the tibia, and a flexor of the knee. It is believed that this muscle is responsible for the unlocking movement of medial rotation of the tibia which occurs immediately prior to, or synchronous with the initial stages of flexion of the fully extended knee-joint.

M. Flexor Digitorum Longus.—The **flexor digitorum longus** lies in both the back of the leg and the sole of the foot. Its **origin** is, by fleshy fibres, from the posterior surface of the body of the tibia in its middle three-fifths, distal to the oblique line, and medial to the vertical line and the origin of the tibialis posterior, from the fascia over it, and from an intermuscular septum on each side (Fig. 357, p. 430).

Its tendon, after crossing obliquely over the tendon of the tibialis posterior, passes deep to the ligamentum laciniatum, invested in a special mucous sheath, and enters the sole of the foot. There it crosses superficial to the tendon of the flexor hallucis longus, by which it is separated from the plantar calcaneo-navicular ligament. Finally, it divides into four subordinate tendons, which are **inserted** into the four lateral toes in precisely the same manner as the flexor digitorum profundus is inserted in the hand (p. 391). Each tendon enters the digital sheath of the toe, perforates the tendon of the flexor digitorum brevis, and is inserted into the base of the terminal phalanx. **Vincula accessoria** (**longa** and **brevia**) are present as in the hand.

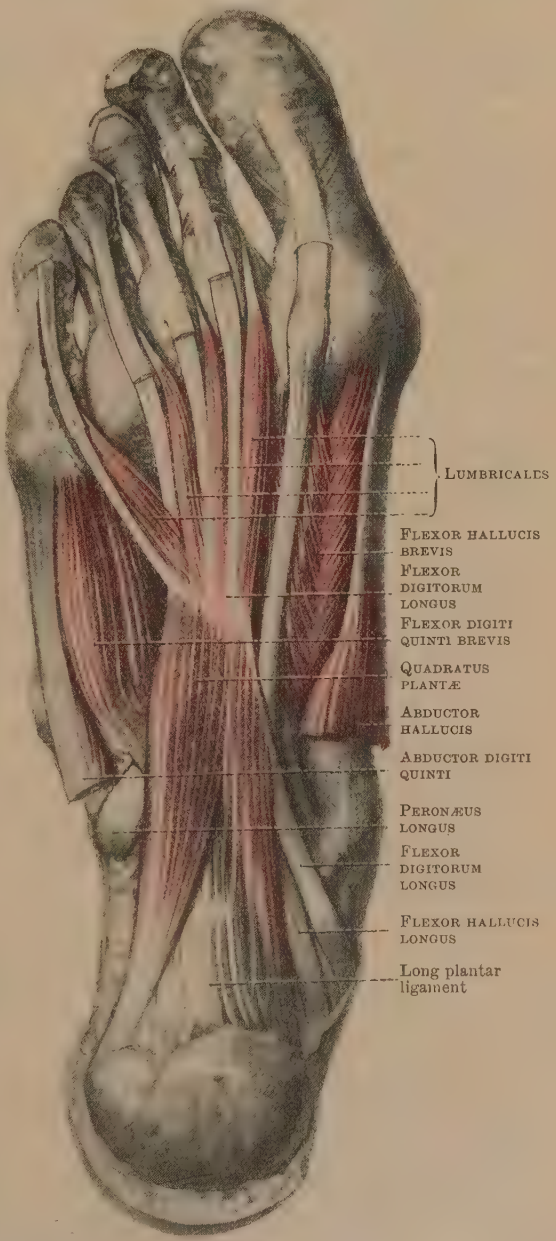

Fig. 359.—The Muscles of the Right Foot (Second Layer).

The tendon of the flexor hallucis longus sends a fibrous band to the tendon of the flexor digitorum longus as it crosses it in the sole of the foot; the band usually passes to the tendons destined for the second and third toes. Associated with this muscle in the sole of the foot are the lumbricales and quadratus plantæ muscles.

Mm. Lumbricales.—The **lumbricales** are four small muscles which **arise** in association with the tendons of the flexor digitorum longus in the sole. The *first muscle* arises by a single origin from the tibial side of the tendon of the flexor digitorum longus for the second toe; each of the *other three* arises by two heads from the adjacent sides of two tendons.

Each muscle is **inserted** into the dorsal expansion of the extensor tendon, the metatarso-phalangeal capsule, and the base of the first phalanx, precisely as in the case of the lumbrical muscles of the hand. Each muscle passes forwards on the tibial side of the corresponding toe, superficial to the transverse metatarsal ligament.

Nerve-Supply.—The flexor digitorum longus is supplied by the tibial nerve (L. 5. S. 1.). The first lumbrical is supplied by the medial plantar nerve (L. 4. 5. S. 1.); the other three, by the lateral plantar nerve (S. 1. 2.).

Actions.—The flexor digitorum longus flexes the four lateral toes and is a plantar flexor of the ankle. The lumbrical muscles have a similar action to those of the hand; they flex the metatarso-phalangeal, and extend the interphalangeal joints of the four lateral toes.

M. Quadratus Plantæ.—The **quadratus plantæ** (O.T. **accessorius**) **arises** by two heads: (1) the lateral tendinous head, which may be absent, springs from the lateral border of the plantar surface of the calcaneus and from the lateral border of the long plantar ligament; (2) the medial head, which is fleshy, arises from the concave medial surface of the calcaneus in its whole extent, and from the medial border of the long plantar ligament (Fig. 353, p. 426). The long plantar ligament separates the two origins.

The two heads unite to form a flattened band, which is **inserted** into the dorsal aspects of the tendons of the flexor digitorum longus, and usually into those destined for the second, third, and fourth toes.

In the sole of the foot the tendons of the flexor digitorum longus, along with the lumbricales and quadratus plantæ, and the flexor hallucis longus muscles, constitute the second layer of muscles, lying between the abductors of the great and little toes and the flexor digitorum brevis superficially, and the flexor brevis and adductor of the great toe more deeply.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).

Actions.—The muscle is an accessory flexor of the toes, assisting the long flexor of the toes. It tends to draw the tendons into which it is inserted into the middle of the sole of the foot.

M. Flexor Hallucis Longus.—The **flexor hallucis longus arises** between the tibialis posterior and the peronæi muscles, from the distal two-thirds of the posterior surface of the body of the fibula, from the fascia over it, and from intermuscular septa on either side.

Its tendon passes deep to the ligamentum laciniatum, enclosed in a special mucous sheath, and after grooving the posterior surface of the distal end of the tibia, the talus, and the plantar surface of the sustentaculum tali of the calcaneus, it is directed forwards in the sole of the foot, to be **inserted** into the base of the terminal phalanx of the great toe.

In the foot it crosses over the deep aspect of the tendon of the flexor digitorum longus, and gives to it a strong fibrous slip, which is prolonged into the tendons for the second and third toes.

Nerve-Supply.—Tibial nerve (L. 5. S. 1. 2.).

Actions.—The muscle is one of the most important in the leg and foot. It is primarily a flexor of the great toe, but it also assists in plantar flexion of the foot. By its position in relation to the tarsus and inferior calcaneo-navicular ligament, it has an important share in maintaining and supporting the arch of the foot.

M. Tibialis Posterior.—The **tibialis posterior** has a fourfold fleshy **origin** in the leg. It arises (1) from the proximal four-fifths of the medial surface of the

body of the fibula between the medial crest and the interosseous crest; (2) from the distal part of the lateral condyle, and from the proximal two-thirds of the body of the tibia, distal to the oblique line and between the vertical line and the interosseous border (Fig. 358, p. 430); (3) from the interosseous membrane; and (4) from the fascia over it and the septa on either side. The muscle gives rise to a strong tendon which passes deep to the ligamentum laciniatum, invested by a special mucous sheath, and grooves the back of the medial malleolus, on its way to the medial border of the foot.

After crossing over the plantar calcaneo-navicular ligament between the sustentaculum tali and the navicular bone, the tendon spreads out and is **inserted** by three bands into (1) the tubercle of the navicular bone and the plantar surfaces of the first and second cuneiform bones, (2) the plantar aspects of the bases of the second, third, fourth, and sometimes the fifth metatarsal bones, the second and third cuneiform bones, and the groove on the cuboid, and (3) into the medial border of the sustentaculum tali of the calcaneus (Fig. 353, p. 426).

The **peronæo-calcaneus** muscle, when present, **arises** from the fibula, and is **inserted** into the calcaneus.

Nerve-Supply.—Tibial nerve (L. 5. S. 1.).

Actions.—The muscle is an invertor and a plantar flexor of the foot. In addition, through its numerous accessory insertions, it assists in the maintenance of the arches of the foot.

The Muscles in the Sole of the Foot.

The muscles in the sole of the foot are divisible into four layers placed deep to the plantar aponeurosis.

The *first layer* includes the abductor hallucis, flexor digitorum brevis, and abductor digiti quinti. The *second layer* consists of the lumbricales and quadratus plantæ, together with the tendons of the flexor hallucis longus and flexor digitorum longus. The *third layer* comprises the flexor hallucis brevis, adductor hallucis, and flexor digiti quinti brevis. The *fourth layer* consists of the interossei (plantar and dorsal), placed between the metatarsal bones: and the tendons of insertion of the tibialis posterior and peronæus longus.

FIRST LAYER.

M. Abductor Hallucis.—The **abductor hallucis** has a double **origin**: (1) by a short tendon from the medial side of the medial process of the tuberosity of the calcaneus (Fig. 360, p. 434), and (2) by fleshy fibres from the ligamentum laciniatum, the plantar aponeurosis which covers it, and the intermuscular septum between it and the flexor digitorum brevis.

The muscle lies superficially, along the medial border of the sole; its tendon is **inserted**, along with part of the flexor hallucis brevis, into the medial side of the base of the first phalanx of the great toe.

Nerve-Supply.—Medial plantar nerve (L. 4. 5. S. 1.).

Actions.—A flexor and abductor of the great toe at the metatarso-phalangeal joint.

M. Flexor Digitorum Brevis.—The **flexor digitorum brevis** has likewise a double **origin**: (1) from the anterior part of the medial process of the tuberosity of the calcaneus (Fig. 353, p. 426), and (2) from the thick central part of the plantar aponeurosis which covers it, and from the intermuscular septa on either side.

It passes forwards, and gives rise to four slender tendons, which are **inserted** into the second phalanges of the four lateral toes, after having been perforated by the long flexor tendons, just as in the case of the tendons of the flexor digitorum sublimis of the hand (p. 390).

Nerve-Supply.—Medial plantar nerve (L. 4. 5. S. 1.).

Actions.—The muscle is a flexor of the toes, acting on the metatarso-phalangeal and first interphalangeal articulations of the four lateral toes.

M. Abductor Digiti Quinti.—The **abductor digiti quinti** also has a double **origin**: (1) by fleshy and tendinous fibres from the anterior part of both processes of the tuberosity of the calcaneus, partly concealed by the flexor digitorum brevis (Fig. 353, p. 426), and (2) by fleshy fibres from the lateral portion of the plantar aponeurosis and the calcaneo-metatarsal ligament, and from the intermuscular septum between it and the flexor digitorum brevis.

Its tendon lies along the fifth metatarsal bone, and is **inserted** into the lateral side of the posterior end of the first phalanx of the little toe. The most lateral

fibres usually obtain an additional insertion into the lateral side of the plantar surface of the fifth metatarsal bone.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).
Actions.—Flexion and abduction of the little toe at the metatarso-phalangeal joint.

SECOND LAYER.

The tendons of the long flexors of the toes, the **lumbricales** and **quadratus plantæ muscles**, constituting the **second layer of muscles**, have already been described (p. 432). They lie deep to the abductor hallucis and the flexor digitorum brevis, and occupy the hollow of the tarsus and the space between the first and fifth

metatarsal bones; their deep surfaces are in contact with the adductor of the great toe and the interossei muscles.

THIRD LAYER.

M. Flexor Hallucis Brevis.—The **flexor hallucis brevis** arises by tendinous fibres from (1) the medial part of the plantar surface of the cuboid bone (Fig. 353, p. 426), and (2) the tendon of the tibialis posterior. Directed forwards, over the first metatarsal bone, the muscle separates into two parts, between which is the tendon of the flexor hallucis longus.

Each portion gives rise to a tendon which is **inserted** into the corresponding side of the base of the first phalanx of the great toe; in each tendon, under the metatarso-phalangeal articulation, a sesamoid bone is developed. The medial tendon is united with the insertion of the abductor, the lateral tendon with the insertions of the adductor muscle of the great toe.

Nerve-Supply.—Medial plantar nerve (L. 4. 5. S. 1.).

Actions.—A flexor of the metatarso-phalangeal joint of the great toe.

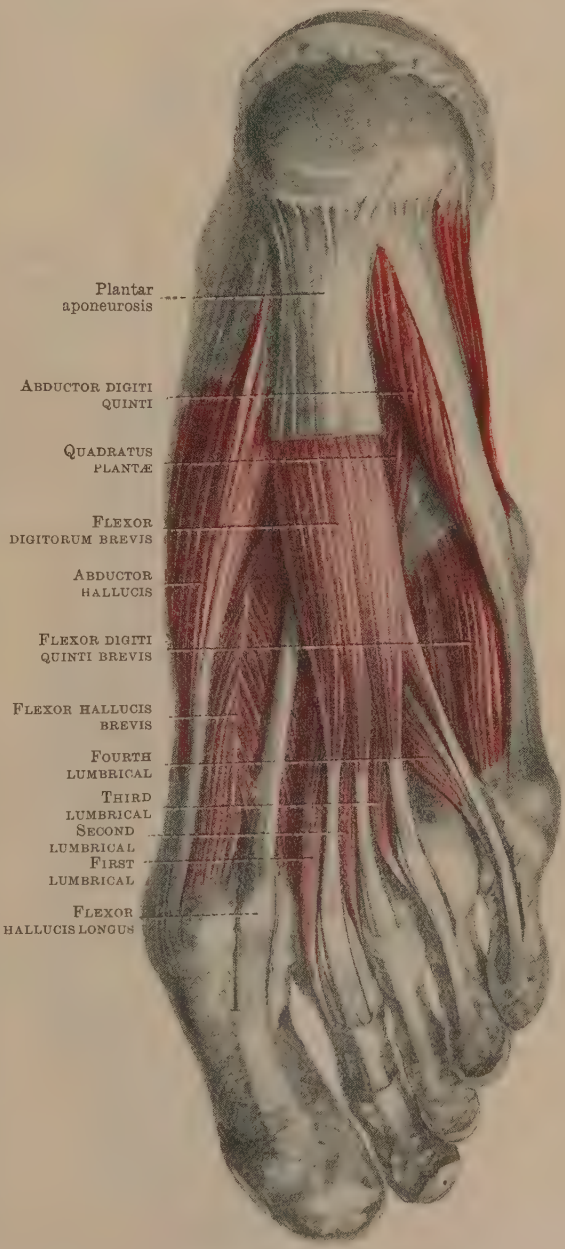

Fig. 361.—Superficial Muscles of the Right Foot.

M. Adductor Hallucis.—The **adductor hallucis** consists of two parts. The **oblique head** of the muscle **arises** (1) from the sheath of the peronæus longus, and (2) from the plantar surfaces of the bases of the second, third, and fourth metatarsal bones (Fig. 360, p. 434). It lies in the hollow of the foot, on a deeper plane than the long flexor tendons and lumbricales, and on the lateral side of the flexor hallucis brevis, and it runs obliquely medially and forwards, to be **inserted** on the lateral side of the base of the first phalanx of the great toe between and along with the flexor brevis and the transverse head of the adductor hallucis.

The **transverse head** arises from (1) the capsules of the lateral four metatarso-phalangeal articulations and (2) the transverse metatarsal ligament.

It runs transversely medially under cover of the flexor tendons and lumbricales, and is **inserted,** along with the oblique head, into the lateral side of the base of the first phalanx of the great toe.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).
Actions.—Flexion and adduction of the great toe towards the middle line of the foot.

M. Flexor Digiti Quinti Brevis.—The **flexor digiti quinti brevis** arises from (1) the sheath of the peronæus longus and (2) the base of the fifth metatarsal bone (Fig. 360, p. 434).

Partially concealed by the abductor digiti quinti, the muscle passes along the fifth metatarsal bone, to be **inserted**, in common with that muscle, into the lateral side of the base of the first phalanx of the little toe.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).
Actions.—Flexion of the little toe.

Fig. 362.—Deep Muscles of the Sole of the Foot.

FOURTH LAYER.

Mm. Interossei.—The **interossei muscles** of the foot resemble those of the hand except in one respect. In the hand the line of reference is the middle line of the middle finger, whereas, in the foot, it is the middle line of the second toe.

There are four dorsal and three plantar muscles, which occupy together the four interosseous spaces, and project into the hollow of the foot.

The **four dorsal muscles**, one in each interosseous space, **arise** by two heads each from the shafts of adjacent metatarsal bones.

Each gives rise to a tendon, which, after passing dorsal to the transverse metatarsal ligament, is **inserted** on the dorsum of the foot, into the side of the first phalanx, the metatarso-phalangeal capsule, and the dorsal expansion of the extensor tendon. The *first* and *second muscles* are inserted respectively into the medial and lateral sides of the proximal end of the first phalanx of the second toe. The *third* and *fourth muscles* are inserted into the lateral sides of the third and fourth toes.

The **three plantar muscles** occupy the three lateral interosseous spaces. Each **arises**, by a single head, from the medial side of the third, fourth, and fifth metatarsal bones respectively.

Each ends in a tendon which passes dorsal to the transverse metatarsal ligament, and is **inserted**, in the same manner as the dorsal muscles, into the medial sides of the third, fourth, and fifth toes.

Nerve-Supply.—Lateral plantar nerve (S. 1. 2.).
Actions.—The muscles are flexors of the metatarso-phalangeal joints, and extensors of the interphalangeal joints of the four lateral toes. The dorsal interossei *abduct* the toes into which

they are inserted from the middle line of the second toe. The plantar interossei *adduct* the three lateral toes towards the second toe.

Movements of the Lower Limb generally.

The characteristic features of the lower limb are stability and strength, and its muscles and joints are both subservient to the functions of transmission of weight and of locomotion. In the standing position the centre of gravity of the trunk falls between the heads of the femora, and is located about the middle of the body of the last lumbar vertebra. It is transmitted from the sacrum through the posterior sacro-iliac ligaments to the hip bone, and through the bones of the lower limb to the arch of the foot, where the talus distributes it backwards through the calcaneus to the heel, and forwards through the tarsus and metatarsus to the balls of the toes.

Locomotion.—The three chief means of progression are walking, running, and leaping. In **walking**, the body and its centre of gravity are inclined forwards, the trunk oscillates from side to side as it is supported alternately by each foot, the arms swing alternately with the corresponding leg, and one foot is always on the ground. The act of progression is performed by the leg, aided in two ways by gravity. The movements of the leg occur in the following way. At the beginning of a step, one leg, so to speak, "shoves off"; the heel is raised and the limb is extended. By the action of the muscles flexing the hip and knee-joints, and extending the ankle-joint and toes, this limb is raised from the ground sufficiently to clear it, and passes forwards by the action of gravity, aided by the force given to the movement by the extensor muscles. After passing the line of the centre of gravity the flexion of the joints ceases, the muscles relax, and the limb gradually returns to the ground. The other limb then passes through the same cycle, the weight of the body now resting on the limb which is in contact with the ground. As the foot reaches the ground it, as it were, rolls over it; the heel touches it first, then the sole, and lastly, as the foot leaves the ground again, only the toes. In **running**, the previous events are all exaggerated. The time of the event is diminished, while the force and distance are increased. Both feet are off the ground at one time; the action of flexors and extensors alternately is much more powerful, so that on the one hand the knees are drawn upwards to a greater extent in the forward movement, and not the whole foot, but only the toes reach the ground in the extension of the limb. The attempt is made to bring the foot to the ground in front of the line of the centre of gravity. At the same time the trunk is sloped forwards much more than in walking. In **leaping**, the actions of the limbs are still more exaggerated. The movements of flexion of the limb are still more marked, and the foot reaches the ground still farther in front of the line of the centre of gravity.

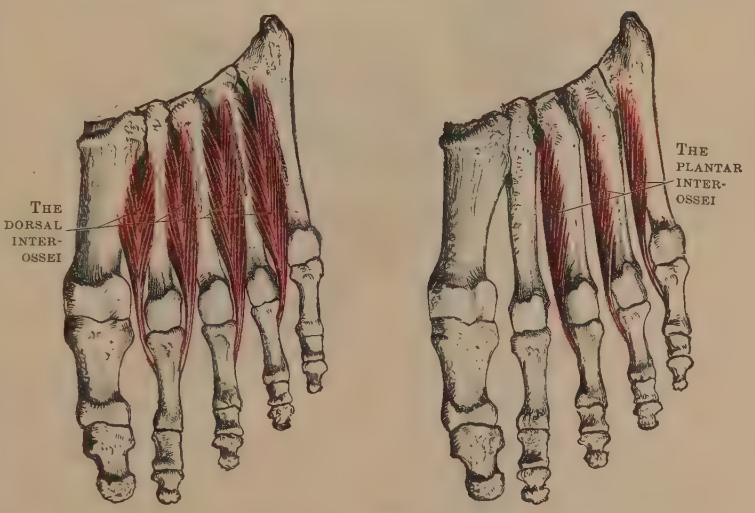

FIG. 363.—INTEROSSEOUS MUSCLES OF THE RIGHT FOOT.

AXIAL MUSCLES.

THE FASCIÆ AND MUSCLES OF THE BACK.

THE FASCIÆ OF THE BACK.

The general fascial investments of the back have been described along with the superficial muscles associated with the shoulder-girdle (p. 368). The latissimus dorsi muscle has been described as arising in large part from the **posterior layer of the lumbo-dorsal fascia.** This is a strong fibrous lamina which conceals the sacro-

spinalis muscle. In the loin it extends from the spines of the lumbar vertebræ, laterally, to the interval between the last rib and the iliac crest, where it joins the middle layer. Below the loin the posterior layer of the lumbo-dorsal fascia is attached to the iliac crest, and more medially blends with the subjacent tendinous origin of the sacrospinalis. The layer can be followed upwards over the sacrospinalis in the region of the thorax, where it is attached laterally to the ribs and is continuous with the intercostal aponeuroses. In the lower part of the thorax it is replaced by the muscular slips of the serratus posterior inferior; in the upper part of the thorax it passes beneath the serratus posterior superior and blends with the deep cervical fascia.

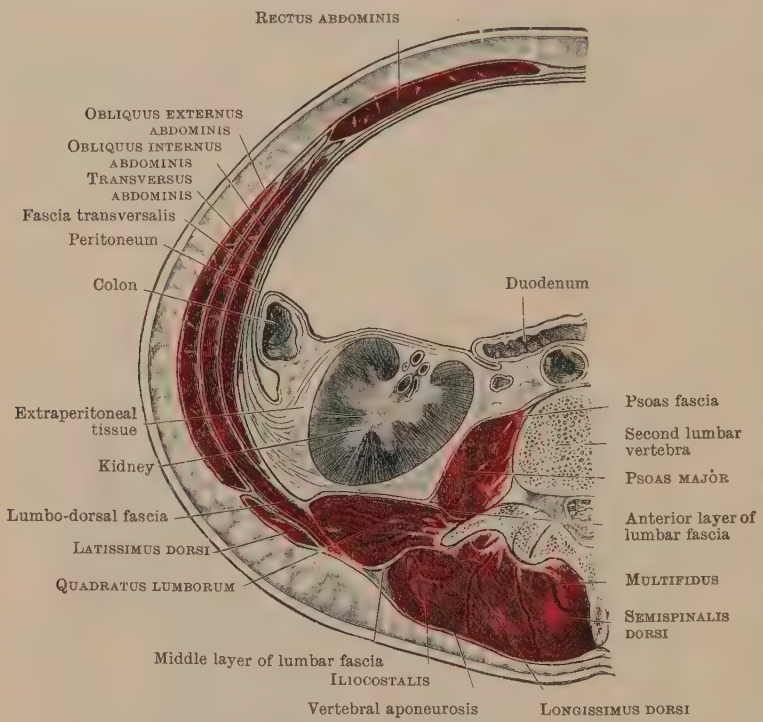

Fig. 364.—Transverse Section through the Abdomen, opposite the Second Lumbar Vertebra.

Fascia Lumbodorsalis.—The **lumbo-dorsal fascia** consists of three fascial strata, called respectively the posterior layer, just described; the middle, and the anterior layers. They unite at the lateral margin of the sacrospinalis muscle to form a narrow ligamentous band which connects the last rib to the iliac crest and gives partial origin to the obliquus internus and the transversus abdominus muscles. The **middle layer** stretches laterally from the ends of the transverse processes of the lumbar vertebræ, between the sacrospinalis behind and the quadratus lumborum muscle in front. The **anterior layer** is attached to the anterior aspects of the transverse processes of the lumbar vertebræ. It covers the anterior surface of the quadratus lumborum muscle, and separates it from the psoas major.

THE MUSCLES OF THE BACK.

The muscles of the back are arranged in four series according to their attachments: (1) vertebro-scapular and vertebro-humeral, (2) vertebro-costal, (3) vertebro-cranial, and (4) vertebral. They are in irregular strata, the most superficial muscles having the most widely spread attachments.

The first series of muscles of the back, connecting the axial skeleton to the upper limb, have already been described. They are arranged in two layers: (1) trapezius and latissimus dorsi superficially; (2) levator scapulæ, and rhomboidei, deep to the trapezius (p. 369).

The remaining muscles are almost entirely axial, and may be divided into four groups: (1) serrati posteriores, superior and inferior; splenius capitis and splenius cervicis; (2) sacrospinalis and semispinalis capitis; (3) semispinalis dorsi and cervicis (transversospinales); and (4) the small deep muscles (rotatores, inter-

spinales, intertransversarii, and suboccipital muscles). They extend from the sacrum to the head, forming a cylindrical column in the loin, filling up the vertebral groove in the thorax, and giving rise to the muscular mass at the back of the neck.

First Group.

M. Serratus Posterior Superior.—The **serratus posterior superior** has a membranous **origin** from the ligamentum nuchæ and the spines of the last cervical and upper three or four thoracic vertebræ. It is directed obliquely downwards and laterally, to be **inserted**, by separate slips, into the second, third, fourth, and fifth ribs. The muscle is concealed by the vertebro-scapular muscles, and crosses obliquely over the splenius, sacrospinalis, and semispinalis capitis. It lies superficial to the lumbo-dorsal fascia.

Nerve-Supply.—Second and third intercostal nerves.

Actions.—It elevates the ribs to which it is attached, thus acting as an accessory muscle of inspiration.

M. Serratus Posterior Inferior.—The **serratus posterior inferior** has a membranous **origin**, through the medium of the lumbo-dorsal fascia, from the last two thoracic and first two lumbar spinous processes.

It forms four muscular bands which pass almost horizontally to an **insertion** into the last four ribs. The muscular slips overlap one another from below upwards. The muscle is on the same plane as the posterior layer of the lumbo-dorsal fascia, and is concealed by the latissimus dorsi.

Nerve-Supply.—Lower, usually tenth and eleventh, intercostal nerves.

Actions.—The principal action of this muscle is to assist the diaphragm, by fixing the lower ribs.

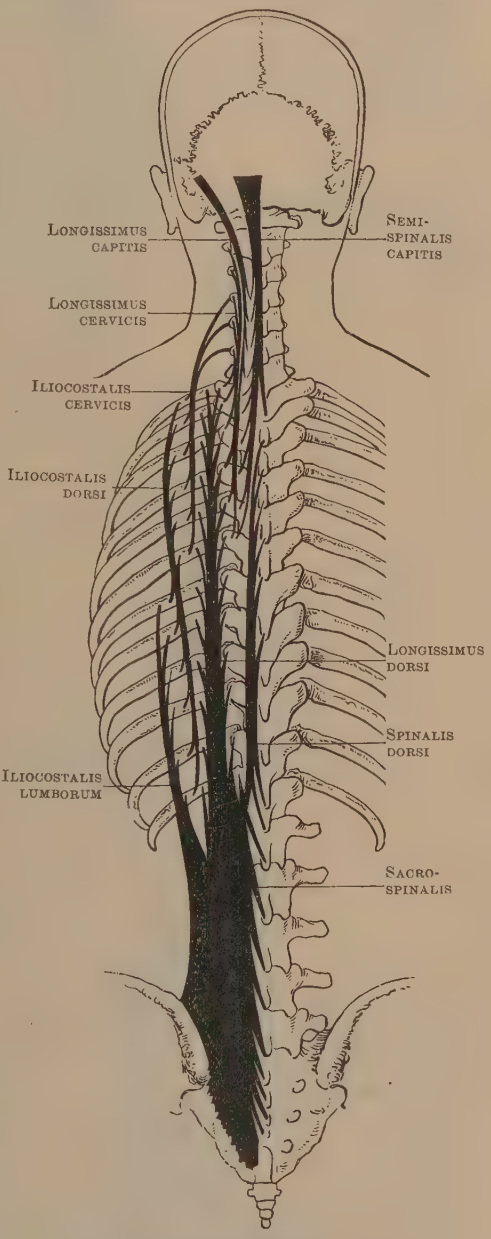

Fig. 365.—Schematic Representation of the Parts of the Left Sacrospinalis Muscle.

M. Splenius.—The **splenius muscle** is a broad, flattened band which occupies the back of the neck and the upper part of the thoracic region. It **arises** from the ligamentum nuchæ (from the level of the fourth cervical vertebra downwards) and from the spinous processes of the last cervical and higher (four to six) thoracic vertebræ.

Its fibres extend upwards and laterally into the neck, separating in their course into an upper and a lower part. The upper part forms the **splenius capitis**, which is **inserted** into the mastoid portion of the temporal bone and the lateral part of the superior nuchal line of the occipital bone (Fig. 370, p. 445). The lower part forms the **splenius cervicis**, which is **inserted** into the posterior tubercles of the transverse processes of the upper three or four cervical vertebræ, under cover of the origin of the levator scapulæ.

The muscle is partially concealed by the trapezius and sterno-mastoid, and appears between them in the floor of the posterior triangle of the neck (splenius capitis). It is covered by the rhomboid muscles, levator scapulæ, and serratus posterior superior.

Nerve-Supply.—Posterior rami of cervical and upper thoracic nerves.

Actions.—The splenius cervicis assists in extension and lateral movement of the spine to the same side. The splenius capitis helps in the movements of raising the head, and also of lateral flexion and rotation to the same side.

Second Group.

M. Sacrospinalis.—The **sacrospinalis** (O.T. **erector spinæ**) possesses vertebral, vertebro-cranial, and vertebro-costal attachments. It consists of an elongated mass composed of separate slips extending from the sacrum to the skull. Simple at its origin, it becomes more and more complex as it is traced upwards towards the head.

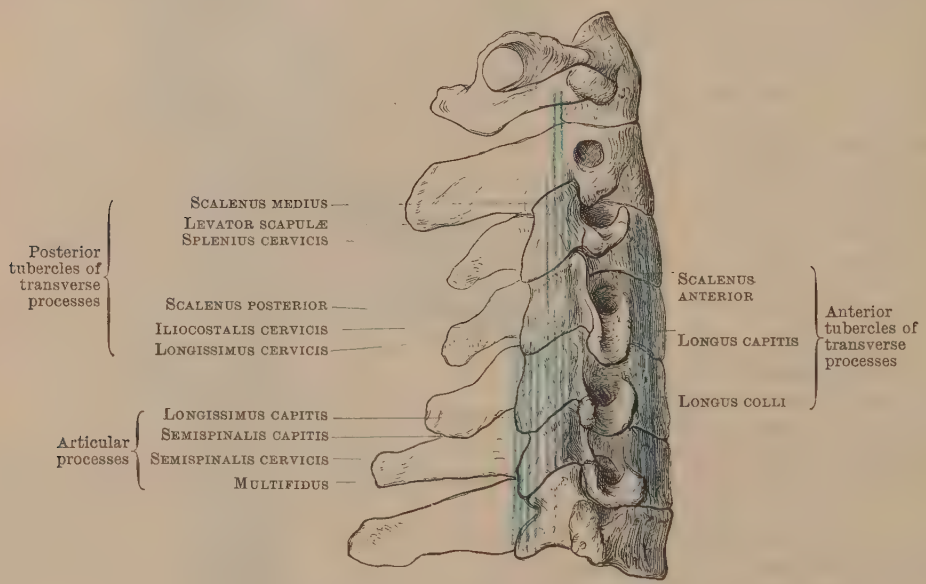

Fig. 366.—Scheme of Muscular-Attachments to the Transverse and Articular Processes of the Cervical Vertebræ.

It **arises** (1) by fleshy fibres from the iliac crest; (2) from the posterior sacro-iliac ligament; and (3) by tendinous fibres continuous with the former from the iliac crest, the dorsum of the sacrum, and the spines of the upper sacral and all the lumbar vertebræ. Its fibres extend upwards through the loin, enclosed between the posterior and middle layers of the lumbo-dorsal fascia, and separate into two columns—a **lateral portion** derived from the lateral fleshy origin, the **iliocostalis**, and a **medial portion** comprising the remaining larger part of the muscle, the **longissimus.**

M. Iliocostalis.—The **iliocostalis lumborum** is **inserted** by six slender slips into the lower six ribs.

Medial to the insertion of each of these slips is the origin of the **iliocostalis dorsi** (O.T. **accessorius**), which, **arising** from the lower six ribs medial to the iliocostalis lumborum, is **inserted** in line with it by similar slips into the upper six ribs.

The **iliocostalis cervicis** (O.T. **cervicalis ascendens**) **arises** in the same way by six slips from the upper six ribs, medial to the insertions of the previous muscle. It forms a narrow band, which, extending into the neck, is **inserted** into the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ, behind the scalenus posterior. *The iliocostales, lumborum, dorsi, and cervicis form together a continuous muscular column, and constitute the most lateral group of the omponent clements of the sacrospinalis.*

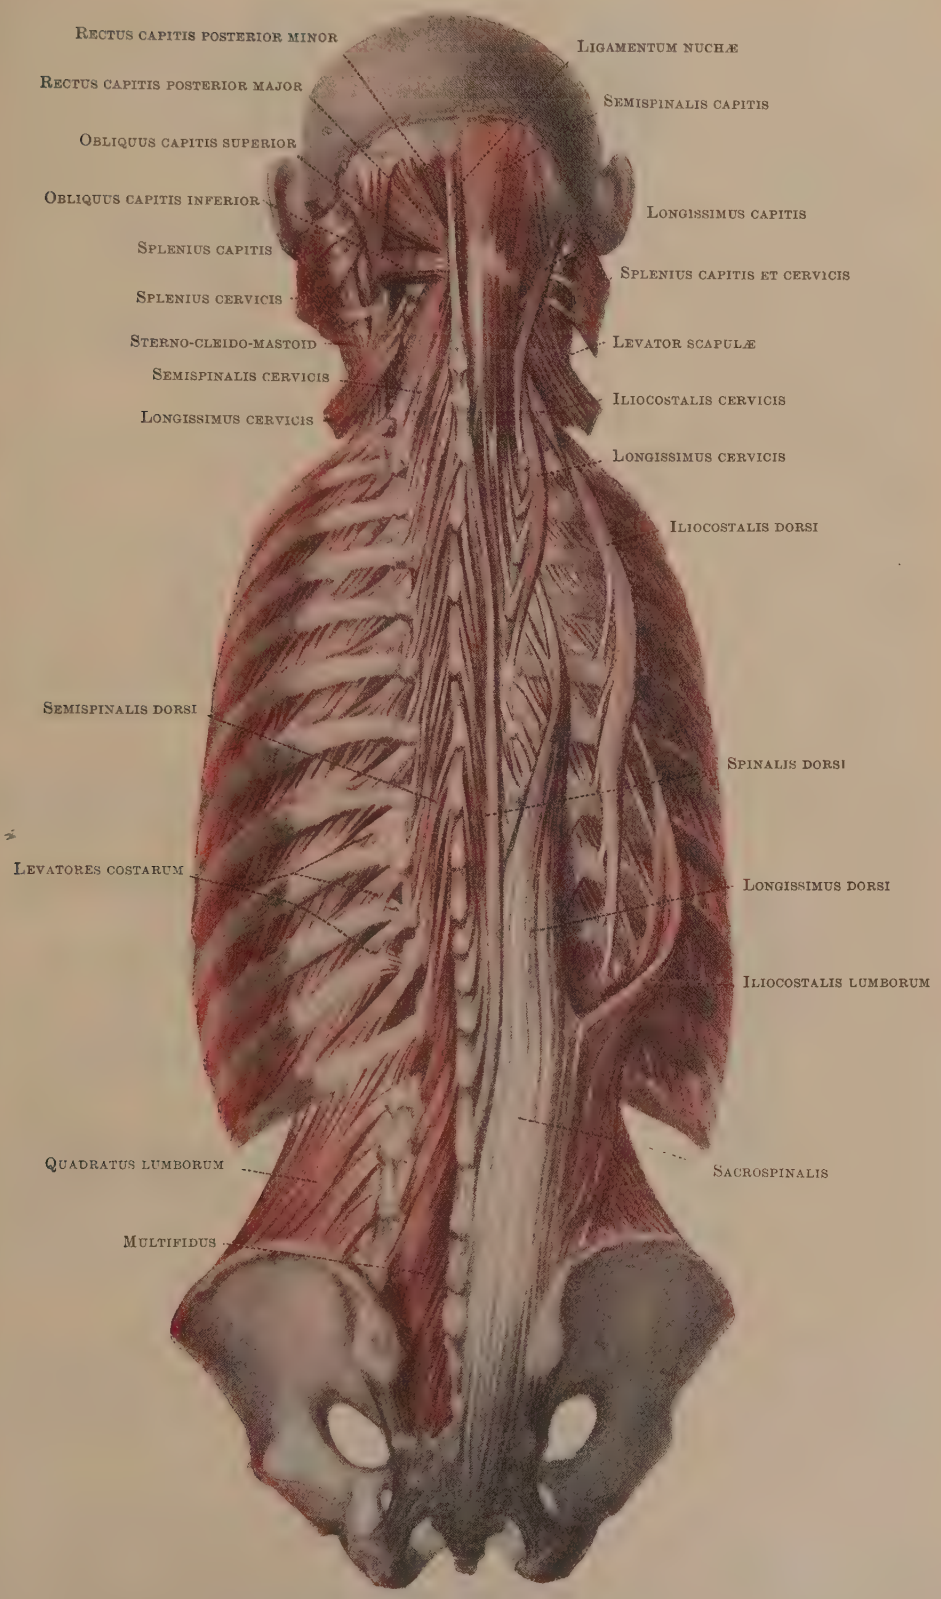

Fig. 367.—The Deep Muscles of the Back.

M. Longissimus.—The **longissimus** is the largest element in the sacrospinalis muscle. The longissimus dorsi forms the middle column of the muscle. It is continued up into the neck as the longissimus cervicis and longissimus capitis. Mostly tendinous, on the surface, at its origin, it becomes fleshy in the upper part of the loin. It is thickest in the loin, and becomes thinner as it passes upwards in the back between the column formed by the iliocostalis and its upward continuations laterally, and the spinalis dorsi medially.

It is **inserted** by two series of slips, medial and lateral, laterally into nearly all the ribs, and medially into the transverse processes of the thoracic and the accessory processes of the upper lumbar vertebræ. It is prolonged upwards into the neck by its association with the common origin of the longissimus cervicis and the longissimus capitis.

The **longissimus cervicis (transversalis cervicis)** has an **origin** from the transverse processes of the upper six thoracic vertebræ, medial to the insertions of the longissimus dorsi.

Extending upwards into the neck, it is **inserted** into the posterior tubercles of the transverse processes of the second, third, fourth, fifth, and sixth cervical vertebræ. It is concealed in the neck by the iliocostalis cervicis and splenius cervicis muscles.

The **longissimus capitis (trachelo-mastoid) arises**, partly by an origin common to it and the previous muscle, from the transverse processes of the upper six thoracic vertebræ, and partly by an additional origin from the articular processes of the lower four cervical vertebræ.

Separating from the longissimus cervicis, the muscle ascends through the neck as a narrow band which is **inserted** into the mastoid portion of the temporal bone, deep to the splenius capitis muscle. In the neck the muscle is placed between the splenius capitis and semispinalis capitis.

M. Spinalis Dorsi.—The **spinalis dorsi** forms the medial column of the sacrospinalis. It lies in the thoracic region, and **arises** by tendinous fibres from the lower two thoracic and upper two lumbar spinous processes, and also directly from the tendon of the longissimus dorsi.

It is a narrow muscle which lies close to the thoracic spinous processes medial to the longissimus dorsi, and is **inserted** into the upper (four to eight) thoracic spines. It is not prolonged into the neck.

The **semispinalis capitis** (O.T. **complexus**) closely resembles in position and attachments the longissimus capitis.

It takes **origin** from the transverse processes of the upper six thoracic and the articular processes of the lower four cervical vertebræ, medial to the longissimus cervicis and longissimus capitis. It has an additional origin also from the spinous process of the last cervical vertebra.

It forms a broad muscular sheet which extends upwards in the neck, to be **inserted** into the medial impression between the superior and inferior nuchal lines of the occipital bone (Fig. 370, p. 445.) The medial portion of the muscle is separate, and forms the **biventer cervicis**, consisting of two fleshy bellies with an intervening tendon, placed vertically in contact with the ligamentum nuchæ. The muscle is covered mainly by the splenius and longissimus capitis muscles. It conceals the semispinalis cervicis and the medial part of the suboccipital triangle.

Nerve-Supply.—Posterior rami of spinal nerves.

Actions.—The several parts of the sacrospinalis muscle have a complex action, on the vertebral column, head, ribs, and pelvis. The muscle serves as an extensor of the vertebral column, and assists in lateral movement and rotation. The longissimus capitis and semispinalis capitis assist in extension, lateral movement and rotation of the head. The whole muscle helps in extension and lateral movement of the pelvis in the act of walking.

Third Group.

This group comprises the semispinales (dorsi and cervicis) and multifidus. They occupy the vertebral furrow, under cover of the sacrospinalis and semispinalis capitis muscles. They are only incompletely separate from one another. The semispinales, dorsi and cervicis, form a superficial stratum, the multifidus being

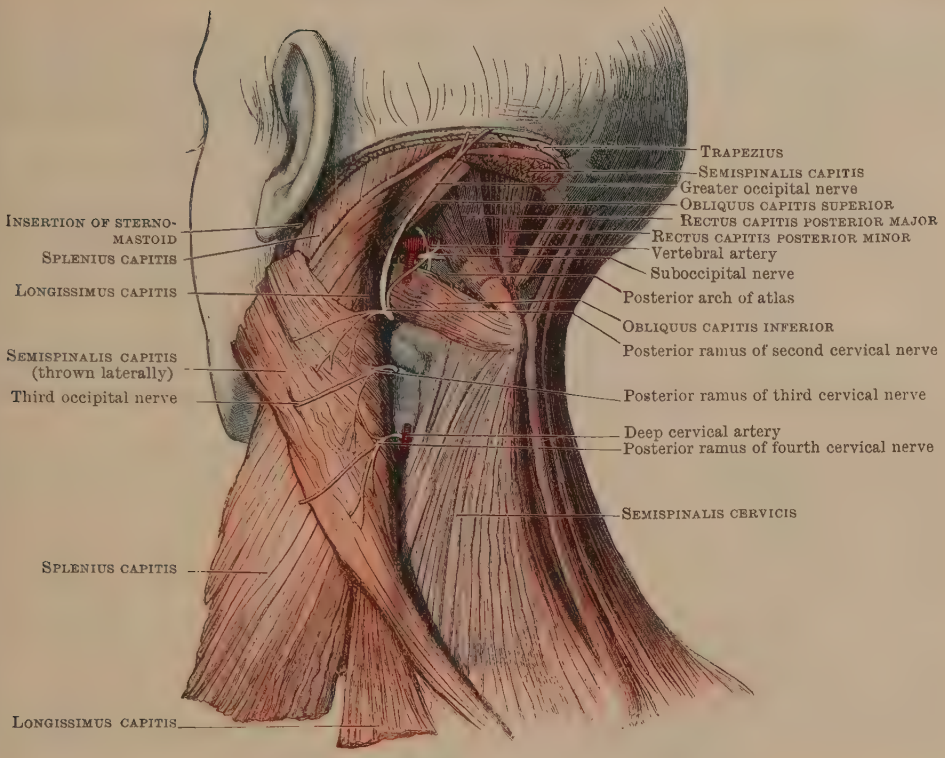

Fig. 368.—The Suboccipital Triangle of the Left Side.

more deeply placed. The more superficial muscles have the longer fibres; the fibres of the multifidus pass over fewer vertebræ. Both muscles extend obliquely upwards from transverse to spinous processes.

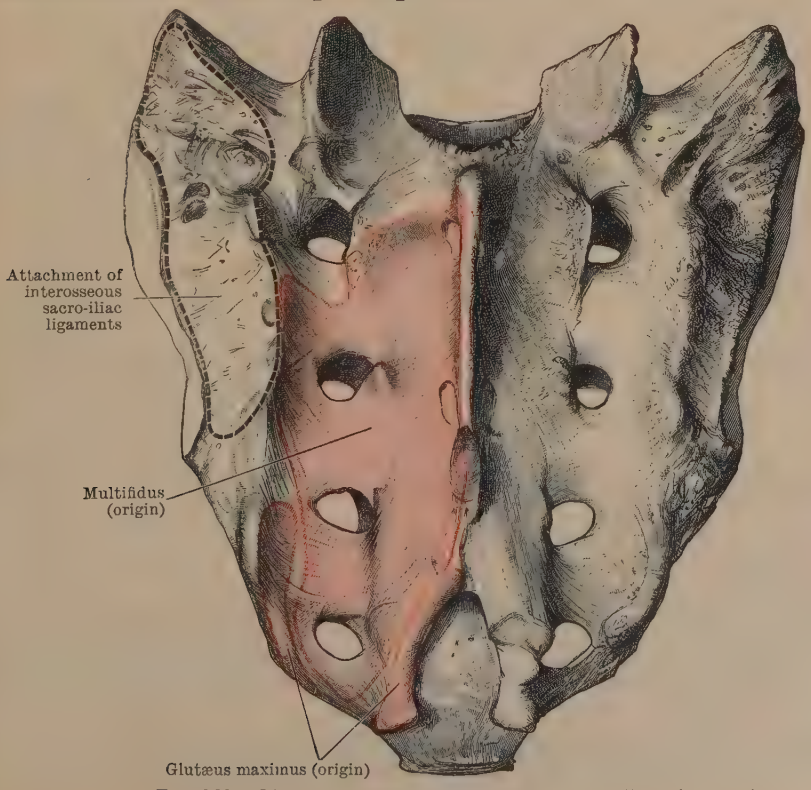

Fig. 369.—Muscle-Attachments to the Sacrum (Dorsal Aspect).

M. Semispinalis.—The **semispinalis muscle** extends from the loin to the second cervical vertebra. Its fibres are artificially separated into an inferior part, the **semispinalis dorsi**, and a superior part, the **semispinalis cervicis.**

The **semispinalis dorsi arises** from the transverse processes of the lower six thoracic vertebræ.

It is **inserted** into the spinous processes of the last two cervical and first four thoracic vertebræ.

The **semispinalis cervicis arises** from the transverse processes of the upper six thoracic, and the articular processes of the lower four cervical vertebræ.

It is **inserted** into the spines of the cervical vertebræ from the second to the fifth.

M. Multifidus.—The **multifidus** (O.T. **multifidus spinæ**) differs from the previous muscle in extending from the sacrum to the second cervical vertebra, and in the shortness of its fasciculi, which pass over fewer vertebræ to reach their insertion.

It **arises** from the sacrum, from the posterior sacro-iliac ligament (Fig. 369, p. 443), from the mamillary processes of the lumbar vertebræ, from the transverse processes of the thoracic vertebræ, and from the articular processes of the lower four cervical vertebræ.

It is **inserted** into the spines of the vertebræ up to and including the second cervical.

Lying in contact with the vertebral laminæ and, in the thoracic region, with the rotatores, the muscle is covered in the neck and back by the semispinalis, and in the loin by the sacrospinalis muscle.

Nerve-Supply.—Posterior rami of the spinal nerves.
Actions.—These muscles are concerned in extension, lateral movement and rotation of the spine.

Fourth Group.

This group includes several sets of small muscles, which are vertebro-cranial or intervertebral in their attachments.

The muscles bounding the **suboccipital triangle** are four in number—obliqui capitis, inferior and superior, and recti capitis posteriores, major and minor.

These muscles are concealed by the semispinalis capitis, longissimus capitis, and splenius capitis; they enclose a triangular space (the suboccipital triangle) in which the vertebral artery, the posterior ramus of the suboccipital nerve, and the posterior arch of the atlas are contained.

The **obliquus capitis inferior arises** from the spine of the epistropheus, and is **inserted** into the transverse process of the atlas.

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.
Actions.—Extension, lateral flexion and rotation of the atlas (and therefore the head) on the epistropheus.

M. Obliquus Capitis Superior.—The **obliquus capitis superior arises** from the transverse process of the atlas, and is **inserted** into the occipital bone deep and lateral to the semispinalis capitis and above the inferior nuchal line (Fig. 370, p. 445).

The upper border of the muscle is closely related to the posterior belly of the digastric at its origin, and the occipital artery runs backwards between them.

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.
Actions.—Elevation, lateral movement and rotation of the head on the atlas. The last-named movement is usually very limited.

M. Rectus Capitis Posterior Major.—The **rectus capitis posterior major arises** from the spine of the epistropheus, and is **inserted** into the occipital bone deep to the obliquus capitis superior and semispinalis capitis and below the inferior nuchal line (Fig. 370).

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.
Actions.—Elevation, lateral movement and rotation of the head.

M. Rectus Capitis Posterior Minor.—The **rectus capitis posterior minor** arises deep to the preceding muscle from the posterior tubercle of the atlas, and is **inserted** into the occipital bone below the inferior nuchal line, medial to and beneath the rectus capitis posterior major (Fig. 370).

Nerve-Supply.—Posterior ramus of the first cervical (suboccipital) nerve.
Actions.—Elevation and lateral movement of the head.

Mm. Rotatores.—The **rotatores** are eleven pairs of small muscles occupying the vertebral groove in the thoracic region, deep to the semispinalis dorsi, of which

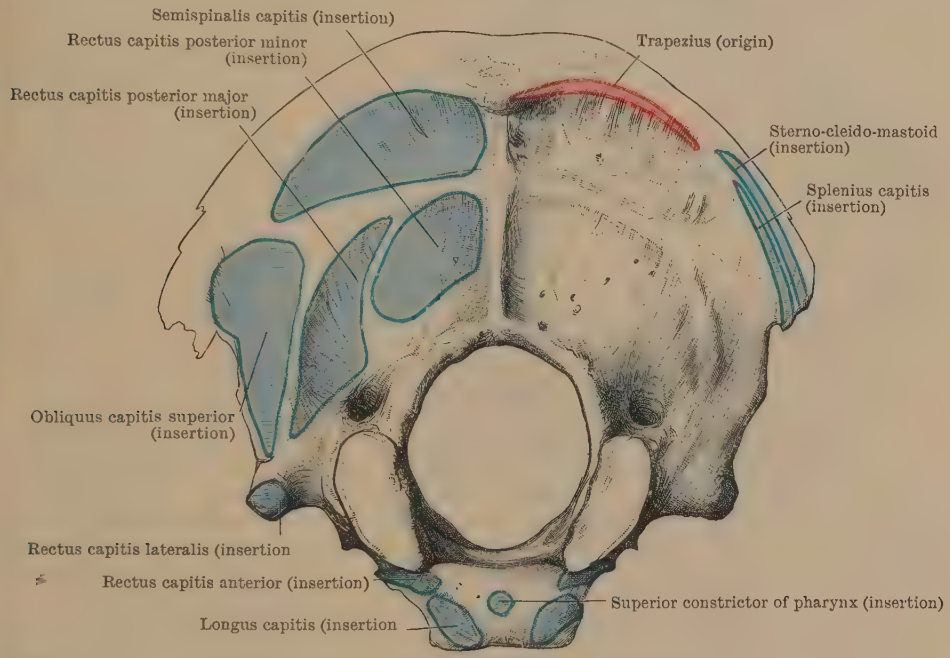

FIG. 370.—MUSCLE-ATTACHMENTS TO THE OCCIPITAL BONE.

they form the deepest fibres. Each consists of a small slip **arising** from the transverse process and **inserted** into the lamina of the vertebra directly above.

Nerve-Supply.—Posterior rami of the thoracic nerves.
Actions.—Extension and rotation of the vertebral column.

Mm. Interspinales.—The **interspinales** are bands of muscular fibres connecting together the spinous processes of the vertebræ from the epistropheus downwards. Well developed in the cervical and lumbar regions, where they lie one on each side of the corresponding interspinous ligament, they are poorly developed and may be absent in the thoracic region.

Nerve-Supply.—Posterior rami of the spinal nerves.
Action.—Extension of the vertebral column.

Mm. Intertransversarii.—The **intertransversarii** are slender slips extending between the transverse processes.

In the cervical region, with certain exceptions, an anterior intertransverse muscle extends from costal element to costal element, in front of the emerging anterior ramus of the corresponding spinal nerve, and a posterior intertransverse muscle extends from transverse element to transverse element, behind the nerve. Above the atlas, the rectus capitis lateralis is in series with the posterior intertransverse muscles, but there is no representative of the anterior group. Between the atlas and the epistropheus, the posterior muscle is well developed and is situated, like the rectus capitis lateralis, lateral to the emerging nerve, but the anterior muscle in this space is frequently absent.

In the thoracic region the intertransverse muscles are absent, except in the lower three or four intervals, where their arrangement corresponds to that found in the lumbar region.

In the lumbar region lateral and medial intertransverse muscles are present. The former are in series with the posterior muscles of the cervical region and pass between the extremities of the transverse processes, while the latter connect the mamillary tubercles to the accessory tubercles of the vertebral above.

Nerve-Supply.—Anterior rami of the spinal nerves.

Actions.—Lateral movement and rotation of the vertebral column.

Mm. Rectus Capitis Lateralis.—The **rectus capitis lateralis**, extending from the transverse process of the atlas to the jugular process of the occipital bone (Fig. 370, p. 445), is homologous with the posterior of the two intertransverse muscles.

Nerve-Supply.—Anterior ramus of the first cervical (suboccipital) nerve.

Action.—Lateral movement of the head.

It should be observed that the muscles of all four groups in the back assist in extension of the vertebral column, and such as are inserted into the skull combine to raise the head. Lateral flexion of the head and of the vertebral column to one side is produced by the muscles of the same side acting alone.

Rotation of the head or of the vertebral column (the latter movement is almost entirely restricted to the thoracic region) is produced by those muscles which run obliquely, inclining either laterally or medially as they pass from origin to insertion. When the insertion is placed lateral to the origin, rotation occurs to the same side; when the insertion is placed medial to the origin, rotation occurs to the opposite side.

THE FASCIÆ AND MUSCLES OF THE HEAD AND NECK.

FASCIÆ.

The **superficial fascia** of the head and neck possesses certain features of special interest. Over the scalp it is closely adherent to the skin and subjacent galea aponeurotica and contains the superficial vessels and nerves. Beneath the skin of the eyelids it is loose and thin and contains no fat. Over the face and at the side of the neck it is separated from the deep fascia by the facial muscles and the platysma. Between the buccinator and the masseter it is continuous with a pad of fat (*corpus adiposum buccæ*) occupying the interval between those muscles.

The **deep fascia** of the head and neck presents many remarkable characters. *Over the scalp* it is represented by the **galea aponeurotica** (O.T. **epicranial aponeurosis**), the tendon of the epicranius muscle. This is a tough membrane, tightly stretched over the calvaria, from which it is separated by loose areolar tissue. It is attached posteriorly, partly through the agency of the occipitalis muscle, to the superior nuchal line of the occipital bone; anteriorly it joins the frontalis muscle and the orbicularis oculi, and has no bony attachment; laterally it extends downwards for a short distance over the temporal fascia, with which it subsequently blends. The **temporal fascia**, a stout layer of fascia attached to the temporal line and zygomatic arch, covers and gives origin to the temporal muscle. This fascia separates into two layers above the zygomatic arch, to enclose a quantity of fat along with branches of the temporal and zygomatico-orbital arteries. *On the face* deep fascia is practically non-existent anteriorly in relation to the facial muscles. Posteriorly it forms the thin **parotideo-masseteric fascia**, and is much thicker in relation to the parotid gland, for which it forms a capsule.

In the neck the deep fascia invests the muscles, and forms fascial coverings for the pharynx, trachea, œsophagus, glands, and large vessels. A superficial, or **investing**, layer encloses the sterno-mastoid muscle, and can be traced backwards over the posterior triangle to the trapezius, which it surrounds; it can be traced forwards over the anterior triangle to the median plane of the neck, where it forms a continuous membrane.

In the upper part of the neck, this layer is bound down to the body and greater cornu of the hyoid bone and blends with the thin fascial sheath of the submaxillary gland. At a higher level it becomes attached to the lower border of the mandible as far back as the angle, behind which it blends with the fascial sheath of the parotid gland. Through this intermediary the investing layer gains attachment to the zygoma, the posterior border of the petro-tympanic fissure, the styloid

process, and the lower border of the tympanic plate. Posterior to the parotid gland the line of attachment of this layer follows the line of attachment to the skull of the sterno-cleido-mastoid and trapezius muscles, so reaching the external occipital protuberance. A specially thickened portion of the parotid sheath extends between the styloid process and the posterior border of the angle of the mandible, separating the lower part of the antero-medial surface of the parotid gland from the posterior part of the submaxillary gland. This is termed the **stylo-mandibular ligament.**

Below the cricoid cartilage, the investing layer separates into anterior and posterior lamellæ, which are continuous on each side with the fascial investments of the sterno-cleido-mastoid muscles. At the jugular notch, the anterior lamella is attached to the anterior surface of the manubrium sterni, but the posterior lamella, which covers the infra-hyoid muscles, is attached to the interclavicular ligament. The **suprasternal space,** which is enclosed between these two lamellæ, contains the lower ends of the anterior jugular veins and the transverse anastomosis between them.

The **prævertebral fascia** covers the prævertebral muscles, extending upwards on the longus capitis to the basilar part of the occipital bone and downwards on the longus colli into the thorax, where it blends with the anterior longitudinal ligament. From the lateral borders of the longus capitis and the scalenus anterior it passes on to the levator scapulæ, the splenius, and the scalenus medius muscles, covering the loops of the cervical plexus and constituting a fascial floor for the posterior triangle of the neck. The subclavian artery and the trunks of the brachial plexus, as they emerge from behind the scalenus anterior, carry a strong prolongation of this fascia downwards behind the clavicle into the axilla, where it forms the axillary sheath.

In the median plane, above, the prævertebral fascia is connected to the fascial covering of the constrictor muscles by some loose areolar tissue, in which are embedded the retro-pharyngeal lymph glands.

As the phrenic nerve descends on the anterior aspect of the scalenus anterior, it is situated between the muscle and the prævertebral fascia which covers it. The dorsal scapular and the long thoracic nerves are also retro-fascial, as they lie in the floor of the posterior triangle of the neck.

The **carotid sheath** is formed by a condensation of connective tissue around and between the common carotid artery, the internal jugular vein, and the vagus nerve, and is usually regarded as a derivative of the deep fascia of the neck. Where it surrounds the artery, the sheath is very thick and the ansa hypoglossi and its constituent nerves are embedded in its anterior aspect, but over the anterior, lateral, and posterior aspects of the vein it is reduced to a very thin layer. Antero-medially, the carotid sheath blends with the sheath of the thyreoid gland (pretracheal fascia) and antero-laterally it is intimately connected to the fascia on the deep surface of the sterno-cleido-mastoid muscle. Posteriorly, it is connected to the prævertebral fascia by some loose areolar tissue in which the sympathetic trunk is embedded.

The **pretracheal fascia** is a very ill-defined layer which constitutes a sheath for the thyreoid gland. Placed deep to the sterno-thyreoid muscle, it is attached to the oblique line on the lamina of the thyreoid cartilage, where it blends with the fascial covering of the inferior constrictor muscle. It is also bound down to the cricoid cartilage, anteriorly, and, on the postero-lateral aspect of the lateral lobe of the thyreoid gland, it blends with the carotid sheath. This layer is carried downwards from the isthmus of the thyreoid gland in front of the trachea and blends with the fascial sheaths of the great vessels in the thorax.

THE MUSCLES OF THE HEAD.

The muscles of the head are divisible into three separate groups: the superficial muscles, muscles of the orbit, and muscles of mastication.

Superficial Muscles.

The superficial muscles comprise a large group, including the muscles of the scalp and face, and the platysma in the neck.

The **platysma** is a thin quadrilateral sheet extending from chest to face over the side of the neck, between the superficial and deep fasciæ. It **arises** from the deep fascia of the pectoral region.

It is directed upwards and forwards, and is partly **inserted** (by its intermediate fibres) into the inferior border of the mandible, becoming connected with the quadratus labii inferioris and triangularis muscles (Fig. 372, p. 449). The more anterior fibres pass across the median plane of the neck and decussate for a variable distance below the chin with those of the opposite side. The posterior fibres sweep over the angle of the jaw and become continuous with the risorius muscle. The platysma is the rudiment of the cervical portion of the **panniculus carnosus** of lower animals, in which it has a much more intimate connexion with the muscles of the face than is usually the case in man.

Nerve-Supply.—Cervical branch of the facial nerve.

Actions.—It depresses the mandible and laterally flexes the head. It also throws into folds the skin of the side of the neck.

The Muscles of the Scalp.

The muscles of the scalp comprise the epicranius muscle and the muscles of the auricle.

M. Epicranius.—The **epicranius** (O.T. **occipitofrontalis**) is a muscle with four bellies, two posterior and two anterior, and an intervening tendon (the galea aponeurotica) which stretches uninterruptedly across the median plane of the cranium. Each **posterior belly (occipitalis) arises** as a broad flat band from the

lateral two-thirds of the superior nuchal line of the occipital bone. Each **anterior belly (frontalis)** has no bony attachments; **arising** from the galea aponeurotica about the level of the coronal suture, it passes downwards to the supra-orbital arch, where it blends with the orbicularis oculi and corrugator supercilii muscles. It extends across the full width of the forehead, and blends in the median plane with the muscle of the opposite side.

The **galea aponeurotica** (O.T. **epicranial aponeurosis**), extending between the two anterior and the two posterior fleshy bellies, has been described on p. 446.

Nerve-Supply.—The occipitalis is supplied by the posterior auricular branch of the facial nerve. The frontalis is supplied by the temporal branches of the same nerve.

Actions.—When the frontalis muscle contracts, acting from behind, the eyebrows are

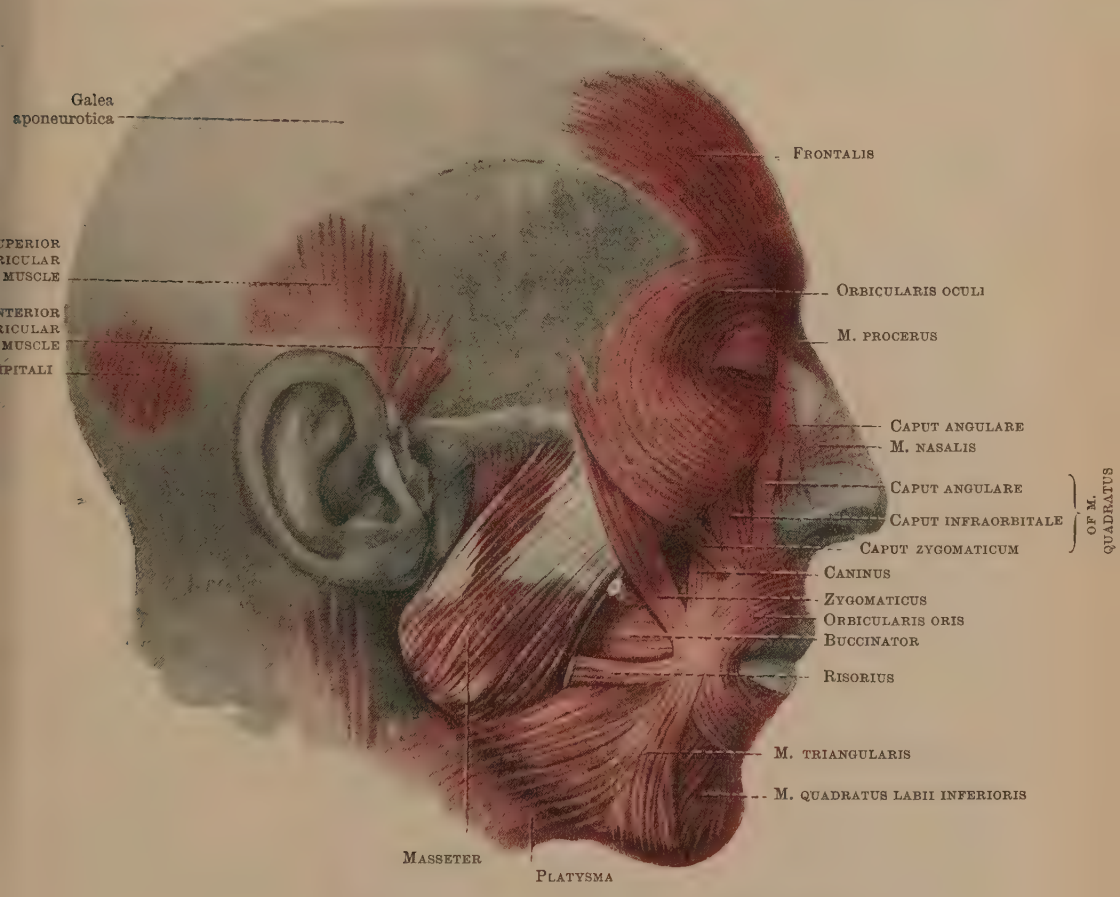

FIG. 372.—THE MUSCLES OF THE FACE AND SCALP (Muscles of Expression).

elevated and the skin of the forehead is thrown into horizontal folds. Acting from in front, the frontales draw the scalp forwards, and it can then be drawn backwards by the occipitales. Relatively few individuals have complete control over the movements of the scalp.

The **extrinsic muscles of the ear** are three in number: posterior, superior, and anterior. They are rudimentary and usually functionless.

The **m. auricularis posterior** is a narrow fleshy slip which **arises** from the surface of the mastoid process and is **inserted** into the cranial surface of the auricle. It bridges across the groove between the mastoid process and the auricle, and conceals the posterior auricular vessels and nerve.

The **m. auricularis superior** is a small fan-shaped muscle which **arises** from the galea aponeurotica, and descends to be **inserted** into the convex medial surface of the fossa of the antihelix.

The m. **auricularis anterior** is a similar small muscle, placed in front of the auricularis superior, and stretching obliquely between the galea aponeurotica and the anterior part of the medial surface of the helix.

The Muscles of the Face.

The facial muscles are divided into three groups, associated with the apertures of the eyes, nose, and mouth.

1. The **muscles of the eyelids** include four muscles: the levator palpebræ superioris (described with the orbital muscles (p. 453)), orbicularis oculi, lacrimal part of the orbicularis, and corrugator supercilii.

M. Orbicularis Oculi.—The **orbicularis oculi** is a transversely oval sphincter muscle surrounding and occupying the eyelids. It is divisible into an *orbital portion*

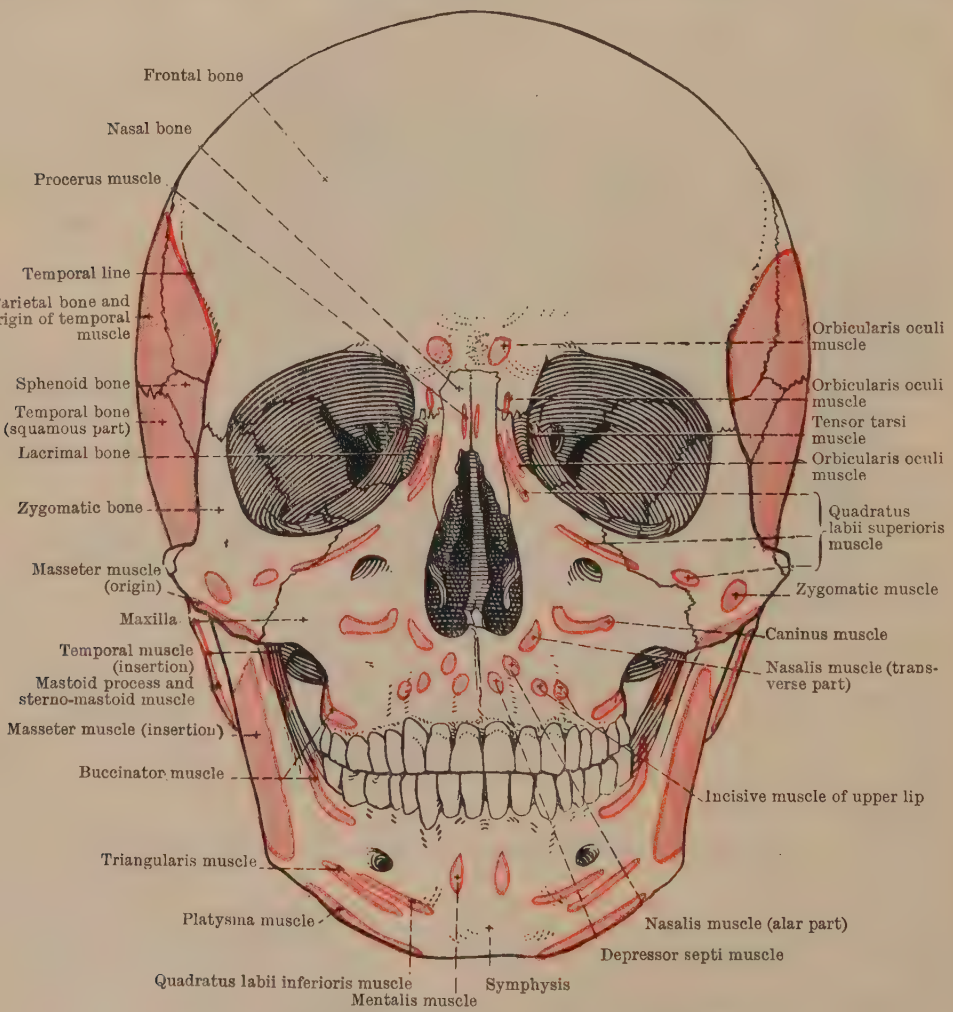

FIG. 373.—ANTERIOR VIEW OF THE SKULL (Norma frontalis), showing the bones and the muscular attachments.

(*pars orbitalis*), composed of coarse fibres, spreading on to the forehead, temple, and cheek, and a *palpebral portion* (*pars palpebralis*), composed of finer fibres, situated beneath the skin of the eyelids. At the medial commissure of the eye the muscle (by its palpebral fibres) gains an **attachment** to the medial palpebral ligament and the borders of the naso-lacrimal groove. Its fibres enclose the

lacrimal sac and the canaliculi. The posterior fibres, extending between the posterior edge of the naso-lacrimal groove and the tarsal ligaments behind the lacrimal sac, constitute the **pars lacrimalis** (O.T. **tensor tarsi muscle**). A collection of very fine fibres extends along the margins of the lids and constitutes a separate **ciliary bundle.**

Laterally the orbicularis oculi has no bony attachment; so that when it contracts and closes the eyelids, both lids at the same time tend to be drawn towards the medial commissure of the eye.

M. Corrugator Supercilii.—The **corrugator supercilii arises** from the medial part of the superciliary arch, and passing laterally, its fibres intermingle with the upper fibres of the orbicularis oculi on its deep surface, but many of them reach the skin of the forehead. The contraction of this muscle throws the skin of the central part of the forehead into vertical folds, as in frowning.

2. The **muscles of the nose** comprise five small muscles proper to the nose, and one common to the nose and upper lip: the m. procerus, nasalis, dilatores naris (anterior and posterior), depressor alæ nasi, and angular head of the quadratus labii superioris. They are all small and feeble muscles.

The **m. procerus** (O.T. **pyramidalis nasi**) **arises** from a membrane stretching over the nose, which gives attachment to the musculus nasalis also; it is **inserted** into the skin over the glabella. This muscle draws down the skin of the central part of the forehead and produces transverse wrinkles at the root of the nose.

The **m. nasalis** (O.T. **compressor naris**) **arises** by a narrow origin from the maxilla, under cover of the quadratus. It passes forwards over the bridge of the nose, and ends in a membranous **insertion** common to it and the preceding muscle.

The **mm. dilatores naris** are feeble muscular slips placed on the lateral surface of the margin of the nostril, one anteriorly, the other posteriorly.

The **m. depressor alæ nasi** is a small muscle **arising** from the upper part of the incisor fossa of the maxilla; it divides into two parts as it passes upwards and medially, and is **inserted** into the ala and the septum of the nose (**depressor septi**).

The **caput angulare** (O.T. **levator labii superioris alæque nasi**) is a portion of the quadrate muscle of the upper lip, and is a narrow band **arising** from the root of the frontal process of the maxilla. It descends alongside the nose, and is **inserted**, partly into the ala of the nose and partly into the orbicularis oris muscle.

3. The **muscles of the mouth** comprise a number of muscles, of which all but one, the orbicularis oris, are bilaterally placed. The muscles are: (1) quadratus labii superioris, which includes the angular head just described, the infra-orbital head, and the zygomatic head; (2) the canine muscle; (3) zygomaticus; (4) risorius; (5) orbicularis oris; (6) triangularis; (7) quadratus labii inferioris; (8) mentalis; and (9) buccinator.

M. Orbicularis Oris.—The **orbicularis oris** is the sphincter muscle surrounding the lips. It is continuous with the other muscles converging to the mouth. It lies between the skin and mucous membrane of the lips, and is limited superiorly by the nose, inferiorly by the junction of the lower lip and chin. The deeper fibres in the upper lip are derived from the buccinator muscle, reinforced by the naso-labial and superior incisive bundles. These two little bands arise, the one from the nasal septum and the other from the incisive fossa of the maxilla, and pass laterally to the angle of the mouth. The more superficial fibres are continued upwards from the triangularis and are inserted into the skin of the central part of the lip. A similar arrangement is found in the orbicularis oris in the lower lip. The deeper fibres are derived from the buccinator, but they are reinforced by an inferior incisive bundle, which runs laterally from the incisive fossa of the mandible. The more superficial fibres are continued downwards from the caninus and are inserted into the skin of the central part of the lip.

M. Quadratus Labii Superioris.—The **quadratus labii superioris** comprises three muscles.

(1) The **caput angulare** has already been described.

(2) The **caput infra orbitale arises** from the maxilla just above the infra-orbital foramen. It passes almost vertically downwards to be inserted into the skin of the upper lip between the attachments of the caput angulare and the

caninus, but some of its fibres blend with the orbicularis oris. It conceals the infra-orbital vessels and nerve.

(3) The **caput zygomaticum arises** from the zygomatic bone, and is often continuous with the most peripheral fibres of the orbicularis oculi. It is directed obliquely downwards and forwards over the caninus, to be **inserted** along with the caput infra-orbitale into the skin of the upper lip.

M. Caninus.—The **caninus arises** from the canine fossa of the maxilla below the infra-orbital foramen and under cover of the caput zygomaticum. It is directed laterally and downwards, to be **inserted** into the orbicularis oris and the skin at the angle of the mouth.

M. Zygomaticus.—The **zygomaticus** is a narrow muscular band which **arises** from the zygomatic portion of the zygomatic arch. It passes to the angle of the mouth, to be **inserted** partly into the skin, partly into the orbicularis oris.

M. Risorius.—The **risorius** is a thin flat muscle which forms in part a continuation of the platysma on the face, in part a separate muscle, with an **origin** from the parotideo-masseteric fascia. It passes transversely forwards, to be **inserted** into the skin at the angle of the mouth.

M. Triangularis.—The **triangularis arises** from the oblique line of the mandible and is continuous with the platysma (Fig. 378, p. 456). It is triangular in form, its fibres converging to the angle of the mouth, where they are **inserted** into the orbicularis oris and the skin. Some of the fibres reach the upper lip through the orbicularis muscle.

M. Quadratus Labii Inferioris.—The **quadratus labii inferioris arises** from the lateral surface of the mandible deep and medial to the preceding muscle (Fig. 373, p. 450). It is quadrilateral in form, and is directed upwards, to be **inserted** into the orbicularis oris and the skin of the lower lip. Its lateral fibres are overlapped by the triangularis. Its medial fibres join with those of the opposite muscle.

M. Mentalis.—The **mentalis** is a small muscle which **arises** from the incisor fossa of the mandible and is **inserted** into the skin of the chin.

M. Buccinator.—The **buccinator muscle** forms the lateral wall of the mouth, and is in series posteriorly with the constrictor muscles of the pharynx. It **arises** (1) from the outer alveolar border of the maxilla in the region of the molar teeth (Fig. 373, p. 450); (2) from the pterygo-mandibular raphe; and (3) from the outer alveolar border of the mandible in the region of the molar teeth. Its fibres are directed forwards to the angle of the mouth, where they blend with the corresponding (upper and lower) portions of the orbicularis oris muscle. The *middle fibres* of the muscle decussate at the angle of the mouth, so as to pass, the lower set to the upper lip, the upper set to the lower lip. The buccinator is covered on its deep surface by the mucous membrane of the mouth. Superficially it is concealed by the muscles above mentioned, which converge to the angle of the mouth; it is separated from the masseter by the *corpus adiposum buccæ*; it is pierced by the duct of the parotid gland, and by branches of the buccinator nerve. A small gap is present in the upper and posterior part of the muscle, between the fibres arising from the tuberosity of the maxilla and those arising from the upper end of the pterygo-mandibular raphe. It is through this gap that the tendon of the tensor veli palatini passes, as it twists round the hamulus to gain the soft palate.

Nerve-Supply.—The facial and scalp muscles are all innervated by the **facial nerve.** The *posterior auricular branch* supplies the posterior auricular muscle and occipitalis; the branches into which it breaks up in the parotid gland supply the frontalis, superior and anterior auricular muscles, the several muscles associated with the apertures of the eye, nose, and mouth (including the buccinator), and the platysma.

Actions.—The almost infinite variety of facial expression is produced partly by the action of these muscles, partly by their inactivity, or by the action of antagonising muscles (antithesis). On the one hand joy, for example, is betrayed by the action of one set of muscles, while grief is accompanied by the contraction of another (opposing) set. Determination or eagerness is accompanied by a fixed expression due to a combination of muscles acting together; despair, on the other hand, is expressed by a relaxation of muscular action. For a philosophical account of the action of the facial muscles, the student should consult Darwin's *Expression of the Emotions in Man and Animals*, and Duchenne's *Mécanisme de la Physiologie humaine.*

The **platysma** retracts and depresses the angle of the mouth, and depresses the mandibler The **epicranius,** by its anterior belly, raises the eyebrows; both bellies acting togethe. tighten the skin of the scalp; acting along with the orbicularis oculi, it shifts the scalp backwards and forwards. The **corrugator supercilii** draws the eyebrow medially and wrinkles the skin of the forehead vertically. The **procerus** draws downwards the skin between the eyebrows as in frowning. The upper eyelid is raised by the **levator palpebræ superioris.** The closure of the lids is effected by the **orbicularis oculi,** whose fibres also assist in the lowering of the eyebrows, in the protection of the eyeball, and, by pressure on the lacrimal gland, in the secretion of tears. The **tarsal part,** acting along with the orbicularis oculi, keeps the tarsal plate in contact with the globe of the eye. The **muscles of the ear** and **nose** have quite rudimentary actions. Of the muscles of the mouth, the **orbicularis oris** has a complex action, depending on the degree of contraction of its component parts. It causes compression and closure of the lips in various ways, tightening the lips over the teeth, contracting them as in osculation, or causing pouting or protrusion of one or the other. The **accessory muscles** of the **lips** draw them upwards (zygomaticus, quadratus labii superioris), laterally (zygomaticus, risorius, platysma, triangularis, buccinator), and downwards (triangularis, quadratus labii inferioris, platysma). The **mentalis** muscle elevates the skin of the chin and protrudes the lower lip. The **buccinator** retracts the angles of the mouth, flattens the cheeks, and brings them in contact with the teeth.

The Fasciæ and Muscles of the Orbit.

The eyeball, with its muscles, vessels, and nerves, is lodged in a mass of soft and yielding fat which entirely fills up the cavity of the orbit. Surrounding the posterior part of the eyeball is the **fascia bulbi** (O.T. **capsule of Tenon**), which constitutes a large lymph space or synovial bursa in relation to the posterior part of the eyeball. Anteriorly the capsule is in contact with the conjunctiva, and intervenes between the latter and the eyeball; posteriorly it is pierced by and prolonged along the optic nerve. It is a smooth membrane connected to the globe of the eye by loose areolar tissue. It is pierced by the tendons of the ocular muscles, along which it sends prolongations continuous with the muscular sheaths.

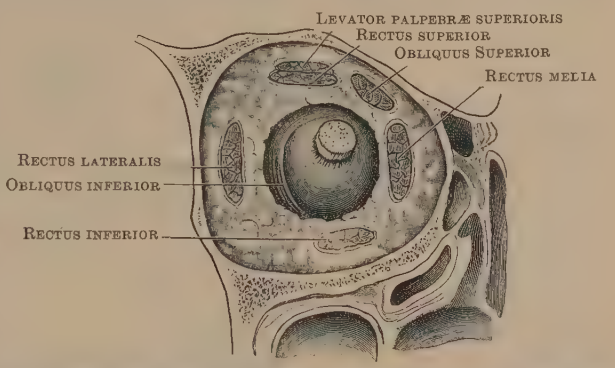

Fig. 374.—Transverse Vertical Section through the Left Orbit behind the Eyeball to show the Arrangement of Muscles.

The **muscles of the orbit** are seven in number: one, the levator palpebræ superioris, belongs to the upper eyelid; the other six are muscles of the eyeball.

M. Levator Palpebræ Superioris.—The **levator palpebræ superioris** lies immediately beneath the orbital periosteum and covers the superior rectus muscle. It has a narrow **origin** above that muscle from the roof of the orbit in front of the optic foramen.

It expands as it passes forwards, to end, in relation to the upper lid, in a membranous expansion which is **inserted** in a fourfold manner; (1) into the orbicularis oculi and skin of the upper lid, (2) mainly into the superior border of the superior tarsus, and (3) by its edges into the upper border of the margin of the orbital opening.

In addition the muscle is connected to the superior fornix conjunctivæ through the medium of its fascial sheath, which becomes considerably thickened in the forepart of the orbit and blends with the sheath of the superior rectus and the conjunctiva.

Nerve-Supply.—The muscle is supplied by the superior division of the oculo-motor nerve.

Actions.—It elevates the upper eyelid and antagonises the action of the palpebral part of the orbicularis oculi muscle.

Mm. Recti.—The **recti muscles** are four in number—**superior, inferior, medial,** and **lateral.** They all **arise** from a membranous ring surrounding the optic foramen, which is separable into two parts—a *superior common tendon,* giving origin to the superior and medial recti and the superior head of the lateral rectus; and an *inferior common tendon,* giving origin to the medial and inferior recti and the inferior head of the lateral rectus. The two origins of the lateral rectus muscle are separated by the passage into the orbit of the oculo-motor, naso-ciliary, and abducent nerves. Forming flattened bands which lie in the fat of the orbit around the optic nerve and eyeball, the four muscles end in tendons which pierce the fascia bulbi, and are **inserted** into the sclera about eight millimetres (three to four lines) behind the margin of the cornea.

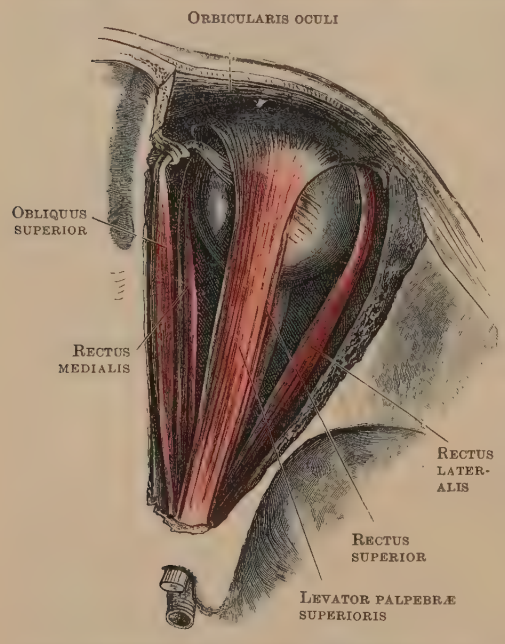

Fig. 375.—Muscles of the Right Orbit (from above).

The **superior** and **inferior recti** are inserted in the vertical plane slightly medial to the axis of the eyeball; the **lateral** and **medial recti** in the transverse plane of the eyeball; and all are attached in front of the equator of the eyeball.

M. Obliquus Superior.—The **obliquus superior arises** from the margin of the optic foramen between the rectus superior and rectus medialis. It passes forwards, as a narrow muscular band, medial to the rectus superior, and at the anterior margin of the orbit forms a narrow tendon which passes through a special fibrous pulley (trochlea) attached to the roof of the orbit.

Its direction is then altered, and passing laterally, between the tendon of the superior rectus and the eyeball, it is **inserted** into the sclera between the superior and lateral recti, midway between the margin of the cornea and the entrance of the optic nerve.

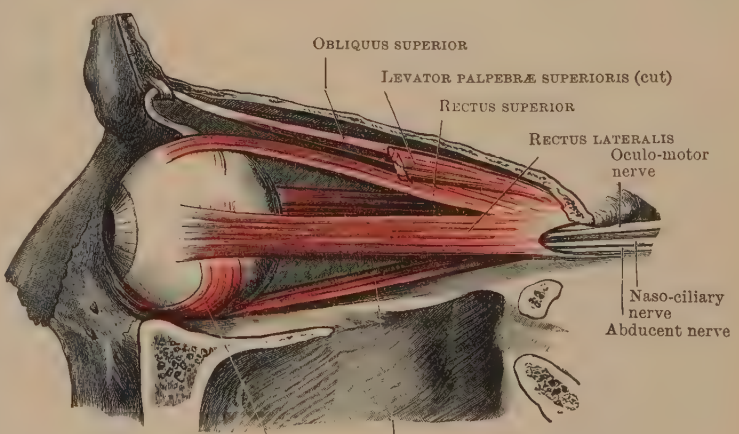

Fig. 376.—Muscles of the Left Orbit (from lateral aspect).

M. Obliquus Inferior.—The **obliquus inferior arises** from the medial side of the floor of the orbit just behind its anterior margin, and lateral to the naso-lacrimal groove.

It forms a slender rounded slip, which curls round the inferior rectus tendon, and passes between the lateral rectus and the eyeball, to be **inserted** into the sclera between the superior and lateral recti, and farther back than the superior oblique muscle.

M. Orbitalis is a rudimentary bundle of non-striated muscular fibres bridging across the inferior orbital fissure and infra-orbital groove. It is supplied by fibres from the sympathetic, and may have a slight influence in the protrusion of the eyeball.

Nerve-Supply.—The muscles of the eyeball are supplied by the third, fourth, and sixth cerebral nerves. The trochlear **(fourth nerve)** supplies the obliquus superior; the abducent **(sixth)** supplies the rectus lateralis; the oculo-motor **(third nerve)** supplies the others—recti, superior, inferior, and medialis, and obliquus inferior.

Actions.—The lateral and medial recti, by virtue of their insertions in front of the coronal equator, rotate the eyeball so as to make the pupil look laterally or medially, respectively. As their insertions extend equally on to the upper and lower quadrants of the sclera, they produce no rotation around the transverse axis of the eyeball.

The superior and inferior recti rotate the eyeball so as to make the pupil look upwards and downwards, respectively, but as the line of pull of each muscle passes to the medial side of the vertical axis of the eyeball, a slight degree of medial rotation accompanies the primary movement.

The superior and inferior oblique muscles, by virtue of their insertion behind the coronal equator of the eyeball and because their pull is exerted from the forepart of the orbit, rotate the eyeball so as to make the pupil look downwards and upwards, respectively. As in the case of the superior and inferior recti, the lines of pull pass to the medial side of the vertical axis of

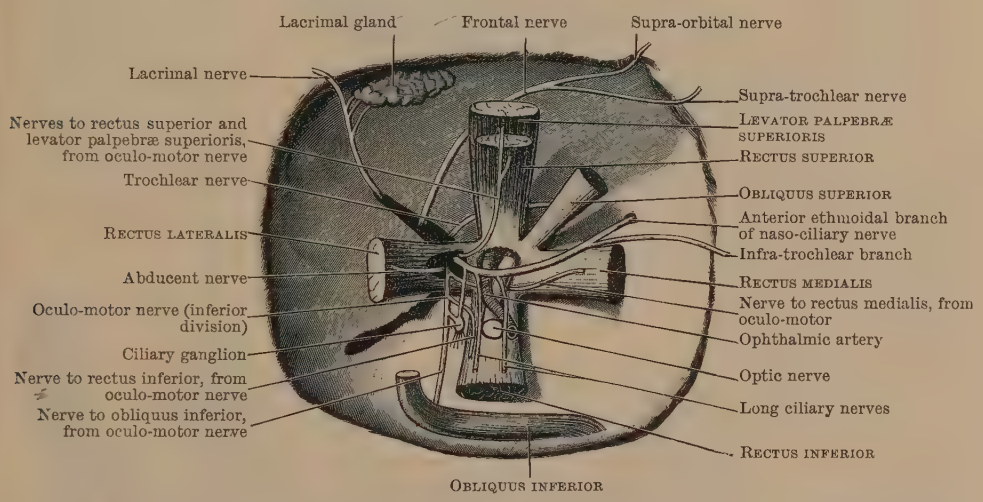

Fig. 377.—Schematic Representation of the Nerves which traverse the Cavity of the Right Orbit.

the eyeball, but, as the pull is exerted from in front instead of from behind, the opposite effect, viz.:—lateral rotation, is added to the primary movement.

When the eyeball is rotated so as to make the pupil look directly downwards, the superior oblique and the inferior rectus act together and the lateral rotation of the former is counteracted by the medial rotation of the latter. In a similar way the inferior oblique and the superior rectus act together to produce a pure upward direction of the pupils.

Combinations of rotation around the vertical and transverse axes of the eyeball are brought about by the combined actions of the superior oblique with the inferior and medial, or with the inferior and lateral recti, or by the combined actions of the inferior oblique with the superior and medial, or superior and lateral recti.

Muscles of Mastication.

The muscles of mastication comprise the masseter, temporal, external and internal pterygoids, and buccinator (described above).

M. Masseter.—The **masseter** is the most superficial. Covered by the parotid gland on the side of the face, it has an **origin** which is partly tendinous and partly fleshy. It arises in two parts: (1) superficially from the inferior border of the zygomatic arch in its anterior two-thirds, and (2) more deeply from the deep surface of the zygomatic arch in its whole length. The superficial fibres are directed downwards and backwards towards the angle of the mandible; the deeper fibres are directed vertically downwards.

The muscle is **inserted** by fleshy and tendinous fibres into the lateral surface

of the ramus and angle of the mandible and the coronoid process (Fig. 378). The deepest fibres blend with the fibres of the subjacent temporal muscle.

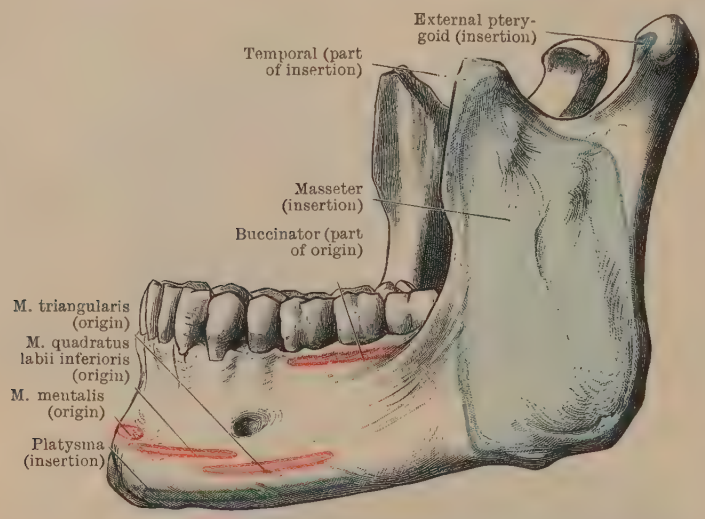

FIG. 378.—MUSCLE-ATTACHMENTS TO THE LATERAL ASPECT OF THE MANDIBLE.

The muscle is partially concealed on the face by the parotid gland, accessory parotid gland, and parotid duct; by the anterior facial vein; the branches of the facial nerve; and by the zygomatic and platysma muscles. It conceals the ramus of the mandible, and, at its anterior border, is separated from the buccinator muscle by the *corpus adiposum buccæ*.

M. Temporalis.—The **temporal muscle** is a fan-shaped muscle **arising** from the whole area of the temporal fossa, as well as from the temporal fascia which covers it. Its converging fibres pass medial to the zygomatic arch.

The muscle is **inserted** into the deep surface and apex of the coronoid process, and into the anterior border of the ramus of the mandible (Figs. 378 and 379).

The origin of the muscle is concealed by the temporal fascia. As it passes to its insertion the muscle is concealed by the zygomatic arch, the masseter muscle, and the coronoid process of the mandible. It is separated from the external pterygoid in a majority of cases by the internal maxillary artery. The masseteric nerve and vessels appear at its posterior border; the buccinator nerve and vessels at its anterior border.

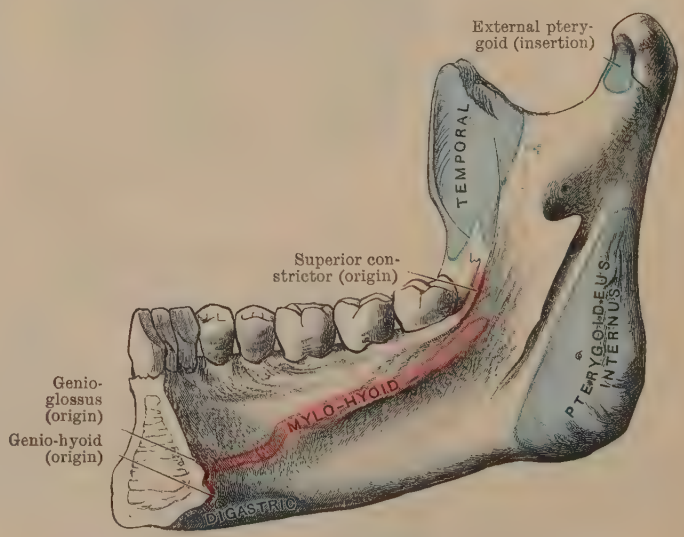

FIG. 379.—MUSCLE-ATTACHMENTS ON THE MEDIAL SIDE OF THE MANDIBLE.

M. Pterygoideus Externus.—The **external pterygoid muscle** is deeply placed under cover of the temporal muscle, in the infra-temporal fossa. It **arises** by two heads, superior and inferior. The *superior* head is attached to the infra-temporal surface of the great wing of the sphenoid; the *inferior* head takes origin from the lateral surface of the lateral pterygoid lamina of the pterygoid process.

The muscle is directed laterally and backwards, to be **inserted** into (1) the fovea pterygoidea on the anterior aspect of the neck of the mandible (Figs. 378 and 379), and (2) the articular disc and capsule of the mandibular articulation.

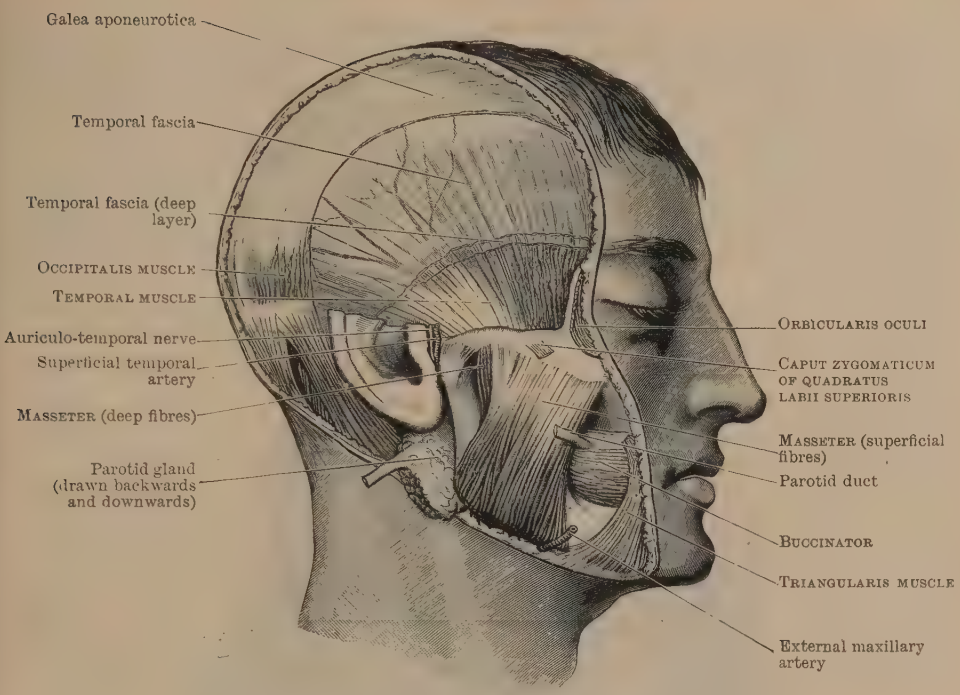

Fig. 380.—Muscles of Mastication (superficial view).

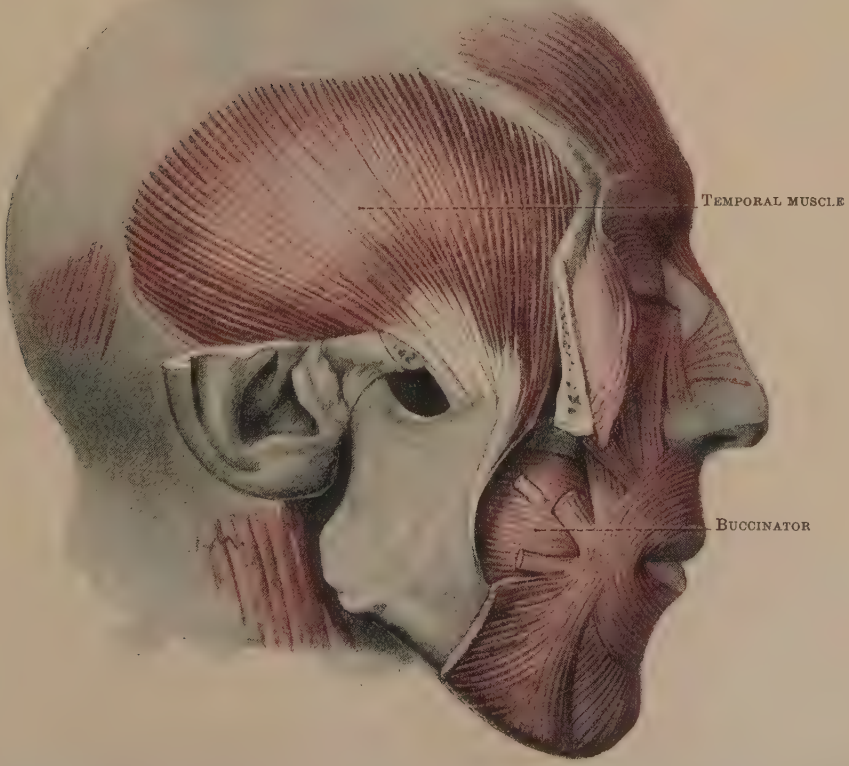

Fig. 381.—The Right Temporal Muscle. (The Zygomatic Arch and the Masseter Muscle have been removed.)

This muscle is covered by the insertion of the temporal muscle and the coronoid process of the mandible, and its inferior head is usually crossed by the internal maxillary artery. It conceals the mandibular branch of the trigeminal nerve, and the pterygoid origin of the internal pterygoid muscle.

M. Pterygoideus Internus.—The **internal pterygoid muscle**, placed beneath the external pterygoid muscle and the ramus of the mandible, has likewise a double **origin**—(1) from the medial surface of the lateral pterygoid lamina and the pyramidal process of the palate bone, and (2) by a stout tendon from the tuberosity of the maxilla. Its two heads of origin embrace the inferior fibres of the external pterygoid muscle.

It is quadrilateral in form, and is directed downwards, laterally, and backwards lateral to the auditory tube and the tensor and levator muscles of the palate,

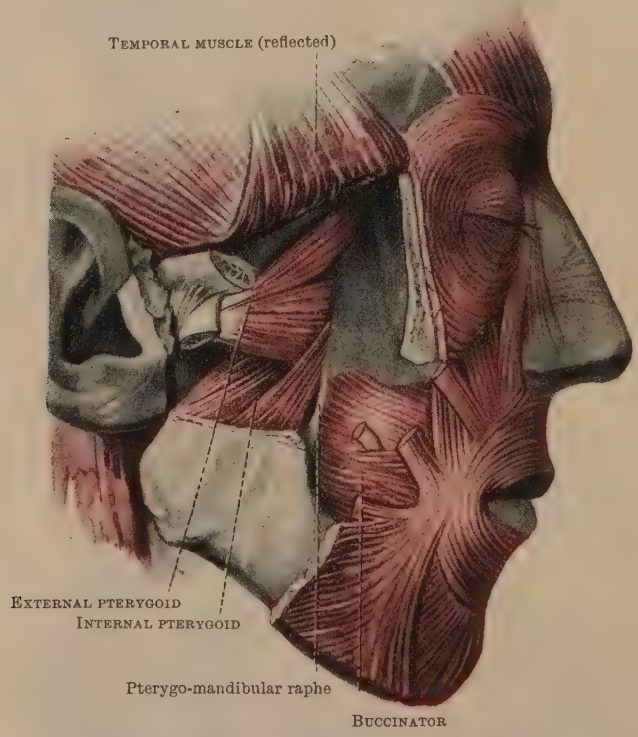

Fig. 382.—The Pterygoid Muscles of the Right Side.

to be **inserted** into a triangular impression on the medial surface of the mandible, between the mylo-hyoid groove and the angle of the bone (Fig. 379, p. 456).

This muscle is covered by the ramus of the mandible and temporal muscle, and partially by the external pterygoid muscle. In contact with its superficial surface are the spheno-mandibular ligament, and the inferior alveolar and lingual nerves and their accompanying vessels. The muscle conceals the tensor veli palatini and the wall of the pharynx (superior constrictor).

Nerve-Supply.—The **mandibular division of the trigeminal nerve** supplies all the muscles of mastication except the buccinator, which is supplied by the **facial nerve.** The internal pterygoid muscle is supplied by the nerve before its division into anterior and posterior parts; the other muscles are innervated by the anterior trunk.

Actions.—The masseter, temporal, and internal pterygoid muscles all take part in the movements of closing the mouth and clenching the teeth, and in this movement the mandible functions as a lever of the third order. It should be observed that when the protruded mandible is elevated, the power of the movement is much reduced and the temporal muscle takes no part in its production.

Protrusion of the mandible results from the combined action of all four pterygoid muscles, and the subsequent retraction of the bone is brought about by the temporal muscles (posterior fibres) and the genio-hyoids.

The side-to-side movement of the mandible, which constitutes the important chewing action, is a combination of unilateral protrusion and the resulting rotation. The external and internal pterygoid muscles of the right side draw the right ramus forwards and medially so that the molar teeth of the mandible pass forwards and to the left across the molar teeth of the maxilla. When the mandible has been twisted over to the left by the right pterygoid muscles, the left pterygoids contract to restore the bone to its resting position and then twist it over to the right. The chewing movement is brought about, therefore, by the right and left pterygoid muscles acting alternately.

Depression of the mandible is usually assisted by gravity and requires little force. The digastric and the mylo-hyoid muscles are the prime movers, and the external pterygoids assist by drawing the condyles forwards.

THE MUSCLES OF THE NECK.

In addition to those included among the muscles of the back (p. 437), the following series of muscles occur in the neck: (1) sterno-cleido-mastoid; (2) the muscles of the hyoid bone (supra-hyoid and infra-hyoid); (3) the muscles of the tongue (extrinsic and intrinsic); (4) the muscles of the pharynx and soft palate; and (5) the prævertebral muscles.

M. Sternocleidomastoideus.—The **sterno-mastoid muscle** is the prominent muscle projecting on the side of the neck, and separating the anterior from the posterior triangle. It **arises** by two heads—(1) a narrow, tendinous, *sternal* head, from the anterior surface of the manubrium sterni (Fig. 126, p. 114), and (2) a broader *clavicular* origin, partly tendinous, partly fleshy, from the superior surface of the clavicle in its medial third (Fig. 193, p. 224). The muscle is **inserted** into the lateral surface of the mastoid portion of the temporal bone and into the superior nuchal line of the occipital bone (Fig. 370, p. 445).

The muscle passes obliquely over the side of the neck, separating the anterior from the posterior triangle. It is almost superficial in its whole extent, but is overlapped superiorly by the parotid gland and is covered in its inferior part by the platysma. It is crossed by the external jugular vein, and by superficial branches of the cervical plexus. Its deep surface is in contact with: (*a*) in its lower third, the infra-hyoid muscles, which separate it from the common carotid artery, and the subclavian artery and the internal jugular vein; (*b*) in its middle third, with the internal jugular vein, the external and internal carotid arteries, and the cervical plexus; and (*c*) in its superior third, with the levator scapulæ muscle, and the accessory nerve, which there pierces the deep surface of the muscle. Near its insertion the muscle is related to the splenius capitis, longissimus capitis, the posterior belly of the digastric, and the occipital artery.

The sterno-cleido-mastoid muscle is properly divisible into three parts: (1) **sterno-mastoid,** placed superficially, and passing obliquely from the sternum to the mastoid process; (2) **cleido-mastoid,** placed more deeply, and directed vertically upwards from the clavicle to the mastoid process; and (3) **cleido-occipitalis,** passing obliquely upwards and backwards behind the cleido-mastoid to the superior nuchal line of the occipital bone.

Nerve-Supply.—The sterno-mastoid muscle is innervated by the accessory nerve, joined by a branch from the cervical plexus (C. 2.).

Actions.—When one muscle acts alone, it flexes the head laterally, and rotates it to the opposite side. The two muscles acting together (1) flex the head in a forward direction, and (2) act as extraordinary muscles of inspiration, by raising the sternum and clavicles.

The Muscles of the Hyoid Bone.

The muscles attached to the hyoid bone are in three series: (1) infra-hyoid muscles, connecting the hyoid bone to the scapula, the wall of the thorax, and thyreoid cartilage; (2) supra-hyoid muscles, connecting it to the mandible, cranium, and tongue; and (3) the middle constrictor muscle of the pharynx.

The **infra-hyoid muscles** comprise the omo-hyoid, sterno-hyoid, sterno-thyreoid, and thyreo-hyoid muscles.

M. Omohyoideus.—The **omo-hyoid** is a muscle with two bellies, anterior and posterior. The *posterior* belly **arises** from the superior margin of the scapula and the superior transverse scapular ligament (Fig. 190, p. 220). It forms a narrow

muscular band, which passes obliquely forwards and upwards, and ends in an intermediate tendon beneath the sterno-mastoid muscle.

From this tendon the anterior belly proceeds upwards, to be **inserted** into the lateral part of the inferior border of the body of the hyoid bone.

The posterior belly of the muscle separates the posterior triangle into occipital and subclavian parts; the anterior belly crosses the carotid sheath at the level of the cricoid cartilage, and in the anterior triangle lies on the lateral side of the sterno-hyoid. A process of the deep cervical fascia binds down the tendon and the posterior belly to the clavicle and the first rib.

M. Sternohyoideus.—The **sterno-hyoid muscle arises** from the posterior surface of the manubrium and from the posterior sterno-clavicular ligament, or

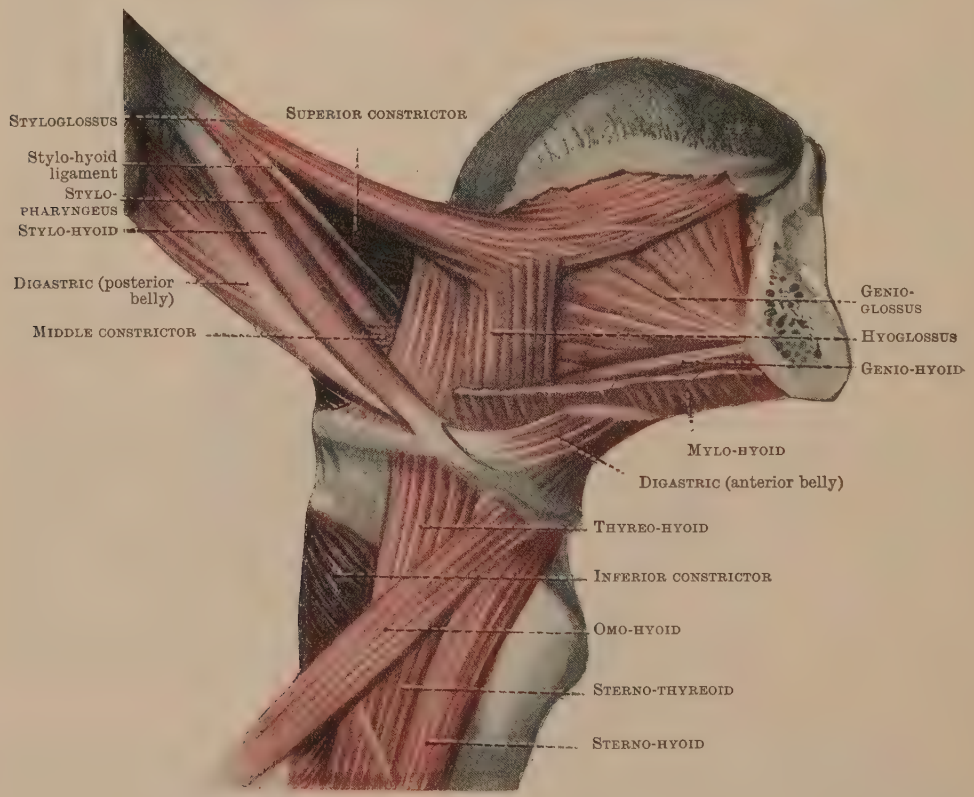

Fig. 383.—The Muscles of the Tongue and Hyoid Bone (right side).

from the latter and the adjoining part of the clavicle. Sometimes it obtains partial origin from the first costal cartilage.

It passes vertically upwards in the neck, medial to the omo-hyoid and anterior to the sterno-thyreoid muscle, to be **inserted** into the medial part of the body of the hyoid bone. Except near its origin, which is covered by the sternum, clavicle, and sternal head of the sterno-mastoid, the muscle is superficially placed.

M. Sternothyreoideus.—The **sterno-thyreoid muscle arises** beneath the sterno-hyoid from the back of the manubrium and first costal cartilage.

Broader than the preceding muscle, it passes upwards, and slightly in a lateral direction in the neck, in front of the trachea and thyreoid gland, and deep to the sterno-mastoid, omo-hyoid, and sterno-hyoid muscles. It is **inserted** into the oblique line of the thyreoid cartilage. The muscle is marked by an oblique tendinous intersection in the middle of its length.

M. Thyreohyoideus.—The **thyreo-hyoid muscle** continues the line of the preceding muscle to the hyoid bone. Short and quadrilateral, it **arises** from the oblique line of the thyreoid cartilage.

Passing over the thyreo-hyoid membrane, deep to the omo-hyoid and sterno-hyoid, it is **inserted** into the body and great cornu of the hyoid bone.

The **levator glandulæ thyreoideæ** is an occasional slip stretching between the hyoid bone and the isthmus or pyramid of the thyreoid gland.

Nerve-Supply.—The sterno-hyoid, sterno-thyreoid, and omo-hyoid are supplied by the *ansa hypoglossi*; the thyreo-hyoid, by a special branch from the hypoglossal nerve. Through the ansa hypoglossi the muscles are innervated by nerves which are ultimately derived from the first three cervical nerves. The descendens hypoglossi is derived from the loop between the first two cervical nerves, and the descendens cervicis springs from the second and third. These two

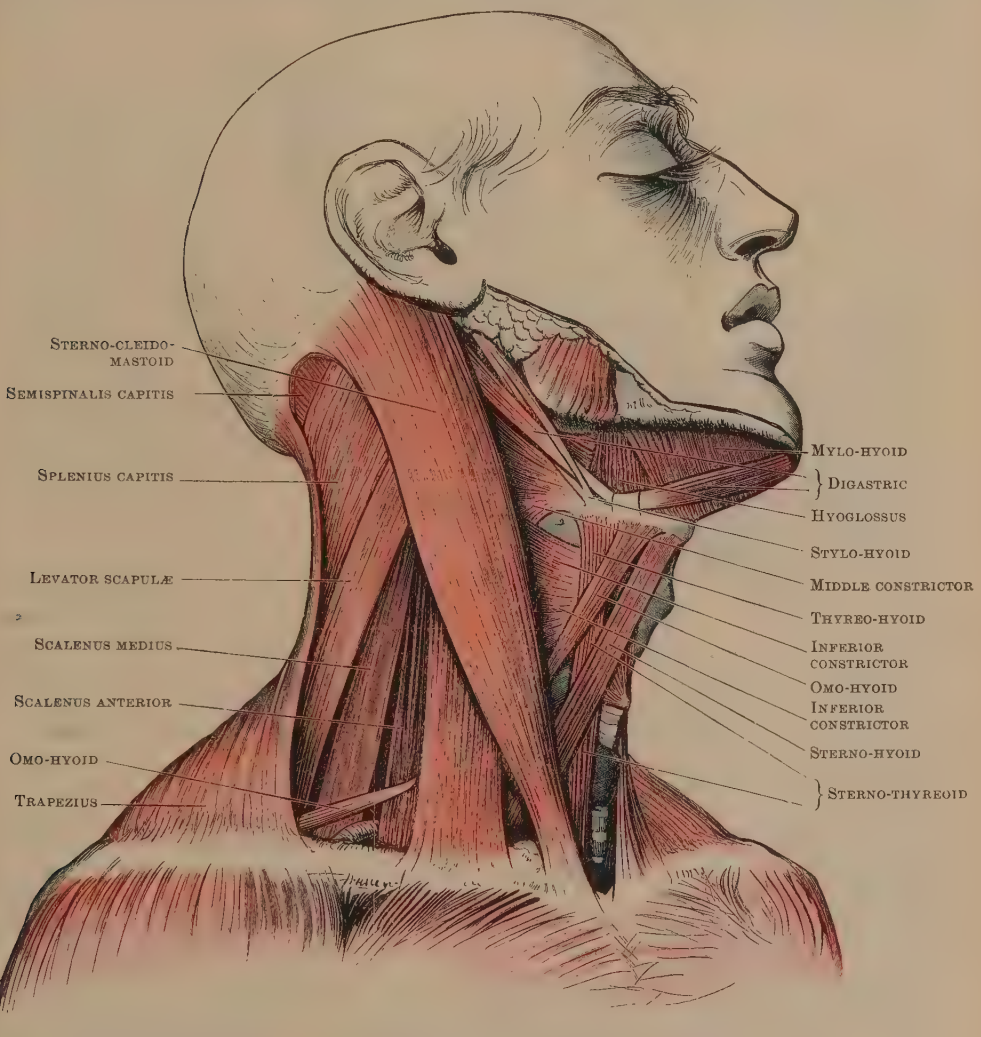

Fig. 384.—The Muscles of the Side of the Neck (anterior and posterior triangles).

trunks combine to form the ansa. The thyreo-hyoid muscle is innervated (through the hypoglossal) from the loop between the first and second cervical nerves.

Actions.—The sterno-hyoid, sterno-thyreoid, and omo-hyoid are depressors of the hyoid bone. The omo-hyoid is a feeble elevator of the scapula. The thyreo-hyoid is, on the one hand, an elevator of the thyreoid cartilage, and acting with the previous muscles, on the other hand, it is a depressor of the hyoid bone.

The **supra-hyoid muscles** comprise the digastric, stylo-hyoid, mylo-hyoid, and genio-hyoid muscles; and also two muscles, the genioglossus and hyoglossus, which will be described along with the extrinsic muscles of the tongue.

M. Digastricus.—The **digastric muscle**, as its name implies, possesses two bellies—anterior and posterior.

The *posterior belly* **arises**, under cover of the sterno-mastoid muscle, from the

mastoid notch medial to the mastoid process. It is directed forwards and downwards, in company with the stylo-hyoid muscle, to end in an intermediate tendon, which is connected by a pulley-like band of cervical fascia to the body of the hyoid bone.

The *anterior belly* of the muscle is directed forwards and slightly upwards, over the mylo-hyoid muscle, to the chin, and is **inserted** into the oval digastric fossa on the inferior border of the mandible close to the symphysis (Fig. 385).

The muscle forms the inferior boundary of the submaxillary division of the anterior triangle, containing the submaxillary gland. The posterior belly in company with the stylo-hyoid crosses the carotid arteries and internal jugular vein. The occipital artery extends posteriorly along its inferior margin, and the parotid gland covers its superior border. The hypoglossal nerve emerges from under cover of the muscle. The anterior belly, as it passes to its insertion, lies upon the mylo-hyoid muscle.

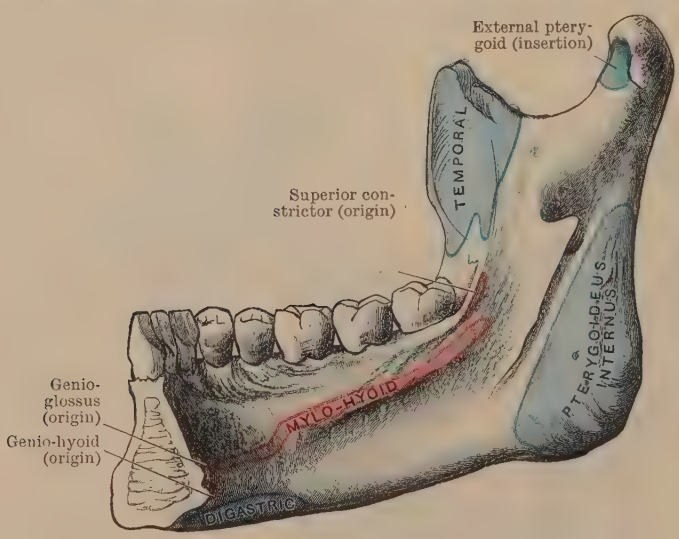

FIG. 385.—MUSCLE-ATTACHMENTS ON THE MEDIAL SIDE OF THE MANDIBLE.

Nerve - Supply. — The posterior belly is supplied by the facial nerve; the anterior belly by the nerve to the mylo-hyoid, a branch of the inferior alveolar nerve.

M. Stylohyoideus. —The **stylo-hyoid muscle arises** from the posterior border of the styloid process of the temporal bone.

Crossing the anterior triangle obliquely, along with the posterior belly of the digastric muscle, it is **inserted** into the body of the hyoid bone, by two slips which enclose the tendon of the digastric muscle.

Nerve-Supply.—Facial nerve.

M. Mylohyoideus.—The **mylo-hyoid muscle** forms with its fellow a diaphragm in the floor of the mouth. It **arises** from the mylo-hyoid ridge of the mandible (Fig. 385).

It is directed downwards and medially, to be **inserted** into (1) the superior border of the body of the hyoid bone, and more anteriorly (along with the opposite muscle) into (2) a median raphe extending from the hyoid bone nearly to the chin.

The muscle is in contact, on its superficial or lateral surface, with the digastric muscle, the submaxillary gland, and the mandible. Its deep or medial surface is partially covered by the mucous membrane of the floor of the mouth, and is separated from the muscles of the tongue by the deep part of the submaxillary gland, the sublingual gland, the submaxillary duct, and the lingual and hypoglossal nerves.

Nerve-Supply.—The muscle is supplied by the nerve to the mylo-hyoid, a branch of the inferior alveolar nerve.

M. Geniohyoideus.—The **genio-hyoid muscle arises** from the inferior of the two mental spines on the posterior surface of the symphysis of the mandible (Fig. 385).

It is directed backwards and slightly downwards, along the inferior border of the genioglossus, to be **inserted** into the anterior surface of the body of the hyoid bone. The muscles of opposite sides are often fused together.

The muscle is placed deep to the mylo-hyoid, and is in contact with the inferior border of the genioglossus muscle.

Nerve-Supply.—It is supplied by the hypoglossal nerve, but its nerve can be traced back to an origin from the communication between that nerve and the first and second cervical nerves.

Actions.—The digastric, stylo-hyoid, mylo-hyoid, and genio-hyoid muscles are all elevators of the hyoid bone. The posterior belly of the digastric and stylo-hyoid draw it upwards and backwards, while the anterior belly of the digastric and the genio-hyoid draw it upwards and forwards. The anterior belly of the digastric, mylo-hyoid, and genio-hyoid also assist in opening the mouth.

The Muscles of the Tongue.

The muscular substance of the tongue consists of two symmetrical series of muscles placed on either side of a membranous raphe in the median plane. The series comprise (1) **extrinsic muscles** arising from the soft palate, styloid process, hyoid bone and mandible, and (2) **intrinsic muscles** proper to the tongue itself. Each set consists of four series of muscles.

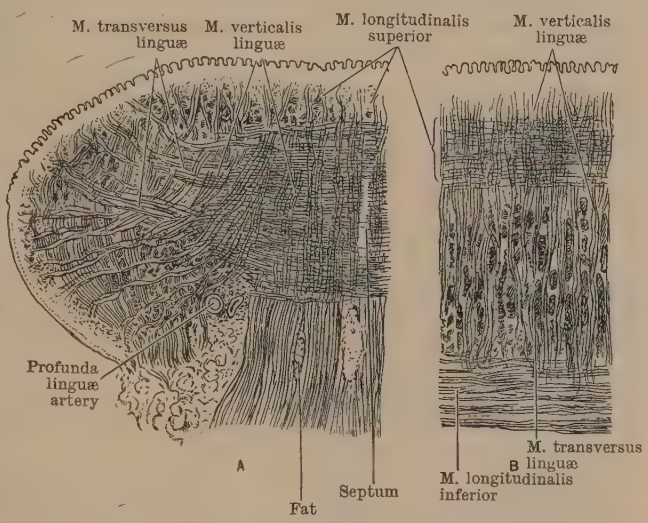

Fig. 386.—A, Transverse, and B, Longitudinal Vertical Sections through the Tongue (Krause).

A. The **extrinsic muscles** are four in number: (1) genioglossus, (2) hyoglossus, (3) styloglossus, and (4) glossopalatinus.

M. Genioglossus.—The **genioglossus muscle** (O.T. **geniohyoglossus**) (Fig. 383, p. 460) is an extrinsic muscle of the tongue as well as a supra-hyoid muscle.

It is a fan-shaped muscle **arising** by its apex from the superior of the two mental spines, behind the symphysis of the mandible (Fig. 385, p. 462).

From that origin the muscular fibres diverge; the lowest fibres are directed downwards and backwards, to be **inserted** into the body of the hyoid bone; the highest fibres curve forwards, to be attached to the tip of the tongue; the intermediate fibres are attached to the substance of the tongue in its whole length between the base and tip.

The muscles of opposite sides are separated by the median raphe of the tongue. On the lateral aspect, of each, are the hyoglossus, the lingual artery, and the sublingual gland.

M. Hyoglossus.—The **hyoglossus muscle** is also an extrinsic muscle of the tongue as well as a supra-hyoid muscle.

It **arises** from the body and greater cornu of the hyoid bone.

It is directed upwards and forwards, to be **inserted** into the side of the tongue, its fibres interlacing with the fibres of the styloglossus (Fig. 383, p. 460).

The muscle is quadrilateral in shape, and, with the exception of its lower and posterior portion, it is entirely hidden by the mylo-hyoid. Numerous structures intervene between the two muscles. A little above the greater cornu of the hyoid bone the hypoglossal nerve and its accompanying vein are found in this intermuscular interval, and, at a higher level, the deep part of the submaxillary gland, the submaxillary duct, the lingual nerve, the submaxillary ganglion, and the posterior part of the sublingual gland separate the two muscles from one another. The insertion of the hyoglossus is separated from the origin of the mylo-hyoid by

the mucous membrane of the floor of the mouth. The postero-inferior part of the muscle is in contact with the hypoglossal nerve and the common tendon of the digastric muscle.

The deep surface of the hyoglossus is in contact with the genioglossus in front, and the middle constrictor of the pharynx behind, but the lingual artery intervenes between them.

The **chondroglossus** is a small separated slip of the hyoglossus, not always present. It arises from the lesser cornu of the hyoid bone.

M. Styloglossus.—The **styloglossus muscle arises** from the anterior border of the styloid process near its tip, and from the stylo-hyoid ligament.

It sweeps forwards and medially, at first, on the stylo-pharyngeus, and subsequently on the lower and anterior part of the superior constrictor muscle of the pharynx, by which it is separated from the palatine tonsil. It is **inserted** into the side and inferior surface of the tongue, its fibres spreading out to decussate with those of the glossopalatinus and hyoglossus muscles beneath the submaxillary gland and the mucous membrane of the tongue.

M. Glossopalatinus.—The **glossopalatinus** is a thin sheet of muscular fibres **arising** from the inferior surface of the soft palate, where it is continuous with fibres of the opposite muscle.

It passes downwards, in the glosso-palatine arch, and spreads out, to be **inserted** into the sides of the tongue, blending with the styloglossus and the deep transverse fibres of the tongue.

The muscle is placed directly beneath the mucous membrane of the soft palate and tongue.

B. **Intrinsic Muscles of the Tongue.**—Besides receiving the fibres of insertion of the extrinsic muscles, the substance of the tongue is composed of four intrinsic muscles on either side—two in the sagittal plane, the superior and inferior longitudinal muscles; two in the frontal plane, the transverse and vertical muscles.

M. Longitudinalis Superior.—The **superior longitudinal muscle** extends from base to tip of the tongue. It is placed on its dorsum immediately under the mucous membrane, into which many of its fibres are inserted.

M. Longitudinalis Inferior.—The **inferior longitudinal muscle** is a cylindrical band of muscular fibres occupying the inferior part of the organ on each side, in the interval between the genioglossus and the hyoglossus muscles. Posteriorly some of its fibres extend to the hyoid bone.

M. Transversus Linguæ.—The **transversus linguæ** arises from the median raphe, and radiates outwards to the dorsum and sides of the tongue, intermingling with the extrinsic muscles and the fibres of the vertical muscle. It occupies the substance of the tongue between the superior and inferior longitudinal muscles.

M. Verticalis Linguæ.—The **verticalis linguæ** arises from the dorsal surface of the tongue, and sweeps downwards and laterally to its sides, intermingled with the fibres of the preceding muscle and the insertions of the extrinsic muscles. The transverse and vertical muscles form a very considerable part of the total muscular substance of the organ.

Nerve-Supply.—All these muscles except the glossopalatinus are supplied by the hypoglossal nerve. The glossopalatinus is supplied by the accessory nerve through the pharyngeal plexus.

Actions.—For the most part, the extrinsic muscles produce alterations in the position of the tongue, while the intrinsic muscles are responsible for changes in its shape. The tongue is protruded by the action of the posterior fibres of the genioglossus, retracted by the anterior fibres aided by the styloglossus. The styloglossus and glossopalatinus are elevators, while the genioglossus and hyoglossus are depressors of the tongue.

The Muscles of the Pharynx.

The muscular envelope of the pharynx is composed of two strata. The *external* or *circular layer* consists of the three fan-shaped constrictor muscles; the *internal* or *longitudinal layer* consists of the fibres of the stylopharyngeus and pharyngopalatinus muscles.

M. Constrictor Pharyngis Superior. — The **superior constrictor muscle arises** successively from the inferior half of the posterior border of the medial lamina of the pterygoid process **(pterygopharyngeus),** from the pterygo-mandibular raphe **(buccopharyngeus)**, from the mylo-hyoid line of the mandible **(mylopharyngeus)** (Fig. 375, p. 456), and from the side of the tongue **(glosso-pharyngeus).**

The muscular fibres radiate backwards and medially, and are **inserted**, for the most part, into a raphe extending down the posterior wall of the pharynx in the median plane. The highest fibres are attached to the pharyngeal tubercle of the occipital bone (Fig. 370, p. 445), and the lowest fibres are overlapped by the middle constrictor. A crescentic interval occurs above the muscle, below the base of the skull, in which the auditory tube and the levator and tensor veli palatini muscles appear. Its lower border is separated from the middle constrictor by the stylopharyngeus muscle.

M. Constrictor Pharyngis Medius.—The **middle constrictor muscle arises** from the stylo-hyoid ligament and from both cornua of the hyoid bone **(chondro-pharyngeus, ceratopharyngeus).**

From its origin the muscular fibres radiate backwards and medially, to be **inserted** into the median raphe on the posterior aspect of the pharynx.

The superior fibres overlap the inferior part of the superior constrictor; the inferior fibres are concealed from view by the inferior constrictor muscle. In the interval between the middle and inferior constrictors are found the superior laryngeal artery and internal laryngeal nerve.

M. Constrictor Pharyngis Inferior. — The **inferior constrictor muscle arises** from the oblique line of the thyreoid cartilage **(thyreo-pharyngeus)**, and from the side of the cricoid cartilage **(cricopharyngeus).**

Its fibres radiate backwards and medially, to be **inserted** into the median *raphe* on the posterior wall of the pharynx, the superior fibres overlapping the inferior part of the middle constrictor, the inferior fibres blending with the muscular fibres of the œsophagus. Below the inferior border of the muscle the inferior laryngeal artery and nerve enter into relation with the larynx.

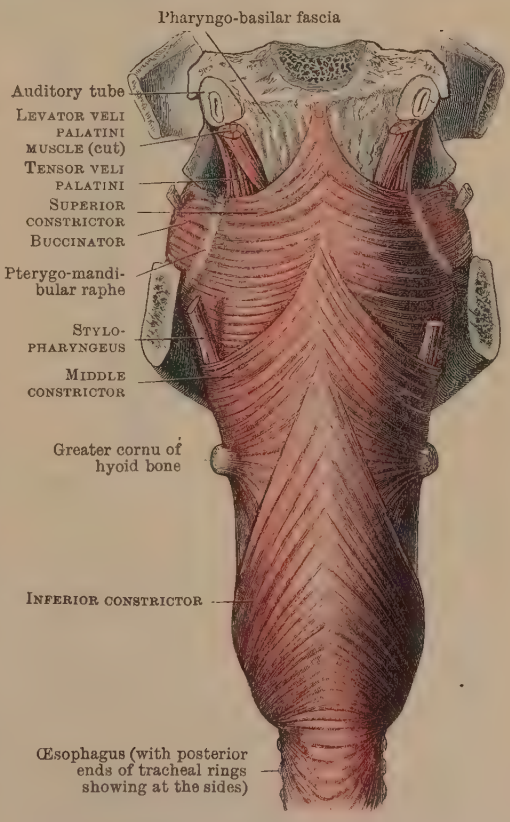

Fig. 387.—Posterior View of the Pharynx and Constrictor Muscles.

Nerve-Supply.—The constrictors of the pharynx receive their nerve-supply through the pharyngeal plexus from the accessory nerve. The inferior constrictor is supplied also by the external laryngeal and recurrent branches of the vagus nerve.

The **deeper longitudinal stratum** of muscles in the pharyngeal wall is composed of the insertions of the stylopharyngeus and pharyngopalatinus muscles.

M. Stylopharyngeus.—The **stylo-pharyngeus arises** from the root of the styloid process on its medial side, and passes downwards between the external and internal carotid arteries. It enters the wall of the pharynx in the interval between the superior and middle constrictor muscles.

Spreading out beneath the middle constrictor muscle, the greater cornu of the

hyoid bone, and the thyreo-hyoid membrane, it is **inserted** into the superior and posterior borders of the thyreoid cartilage and into the wall of the pharynx itself, becoming continuous posteriorly with the palatopharyngeus. In the neck the glossopharyngeal nerve winds round it on its way to the tongue.

Nerve-Supply.—Glossopharyngeal nerve.

M. Pharyngopalatinus.—The **pharyngopalatinus** (O.T. **palatopharyngeus**) occupies the soft palate and the pharyngeal wall. In the substance of the soft palate it consists of *two layers*, a postero-superior layer, thin, and continuous across the median plane with the corresponding layer on the opposite side, and an antero-inferior layer, which is thicker, and is attached to the posterior border of the hard palate. The levator veli palatini and the musculus uvulæ are enclosed between the two layers, which unite at the posterior edge of the palate, receiving at the same time additional fibres arising from the auditory tube **(salpingopharyngeus)**. The muscle descends to the pharynx in the pharyngo-palatine arch.

Its fibres spread out in the form of a thin sheet in the wall of the pharynx, in continuity anteriorly with the stylopharyngeus, and are **inserted** into the posterior border of the thyreoid cartilage, and behind that into the aponeurosis of the pharynx, reaching down as far as the inferior border of the inferior constrictor. The muscle is placed beneath the middle and inferior constrictors, and the fibres of the muscles of opposite sides decussate in the median plane, in the inferior part of the pharyngeal wall.

Nerve-Supply.—The muscle is innervated through the pharyngeal plexus, by the accessory nerve.

The Muscles of the Soft Palate.

The soft palate and uvula form a muscular fold, covered on each surface by mucous membrane, projecting backwards into the pharynx, and forming the posterior parts of the floor of the nasal cavities and the roof of the mouth.

The muscular fold is composed of five pairs of muscles—the pharyngopalatinus, m. uvulæ, levator veli palatini, tensor veli palatini, and glossopalatinus. In its anterior part the fold contains the **palatal aponeurosis**, which is attached in front to the posterior border of the hard palate and on either side to the pharyngeal aponeurosis. Posteriorly it rapidly diminishes in breadth, and the posterior part of the soft palate is entirely muscular. The palatal aponeurosis gives origin to the pharyngopalatinus and the m. uvulæ, and receives fibres of insertion from the levator and the tensor veli palatini.

The **pharyngopalatinus** muscle has been already described (see above).

The **m. uvulæ** consists of two narrow bundles enclosed along with the insertion of the levator veli palatini, between the layers of the pharyngopalatinus. The slips **arise** from the posterior nasal spine and the aponeurosis of the soft palate, and unite as they proceed backwards to end in the uvula.

M. Levator Veli Palatini.—The **levator veli palatini** has a double **origin**: (1) from the inferior surface of the apex of the petrous portion of the temporal bone, and (2) from the inferior part of the cartilaginous part of the auditory tube. It passes obliquely downwards and medially, across the medial aspect of the superior border of the superior constrictor muscle, and enters the soft palate between the two layers of the pharyngopalatinus muscle.

It is **inserted** into the aponeurosis of the soft palate, and some of its fibres become continuous with those of the opposite muscle.

It is separated from the tensor veli palatini muscle (1) by the auditory tube, (2) by the upper fibres of the superior constrictor, and (3) by the deeper layer of the pharyngopalatinus muscle.

M. Tensor Veli Palatini.—The **tensor veli palatini** **arises** (1) from the scaphoid fossa and the angular spine of the sphenoid bone, and (2) from the lateral side of the cartilaginous part of the auditory tube.

It descends, between the internal pterygoid muscle and the medial pterygoid

lamina, and ends in a tendon which hooks round the pterygoid hamulus and passes through a gap in the origin of the buccinator muscle (p. 452) to enter the soft palate. The tendon is **inserted**, beneath the levator veli palatini, into the posterior border of the hard palate, and into the aponeurosis of the soft palate.

M. Glossopalatinus.—The **glossopalatinus**, occupying the inferior surface of the soft palate and the glosso-palatine arch, has already been described with the muscles of the tongue (p. 464).

Nerve-Supply.—The muscles of the soft palate (except the tensor veli palatini, which is innervated through the otic ganglion by the trigeminal nerve) are supplied through the pharyngeal plexus by the accessory nerve.

Actions of the Muscles of the Pharynx and Soft Palate.—The muscles of the pharynx and soft palate are chiefly brought into action in **the act of swallowing.** This act is divided into a *voluntary stage*, in which the bolus lies anterior to the arches of the fauces, and an *involuntary stage*, during which the food passes from the mouth through the pharynx. The movements occurring during the passage of food through the mouth are as follows: the cheeks are compressed by the action of the buccinator muscles; the tongue, hyoid bone, and thyreoid cartilage are successively raised upwards by the action of the muscles which close the mouth and elevate the hyoid bone. By these means the food is pushed backwards between the palatine arches.

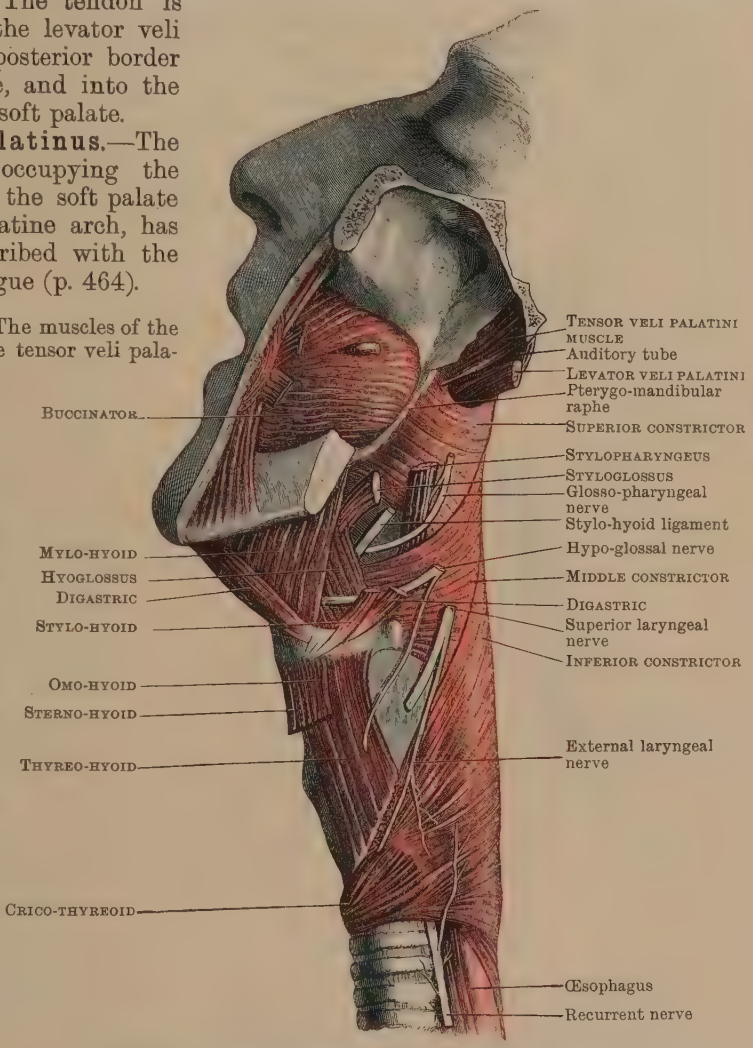

Fig. 388.—Lateral View of the Wall of the Pharynx.

At the same time, by the contraction of the glossopalatinus and pharyngopalatinus, the palatine arches of the fauces are narrowed, while the muscles of the soft palate, contracting, tighten the soft palate, and by bringing it in contact with the posterior wall of the pharynx, shut off the nasal portion of the cavity. The elevation of the tongue, hyoid bone, and larynx simultaneously causes the elevation of the epiglottis and the superior aperture of the larynx, which is closed by the approximation of the arytænoid cartilages and the combined action of laryngeal muscles (arytænoideus, thyreoarytænoideus, and thyreoepiglotticus). The food thus slips over the posterior surface of the epiglottis and the closed superior aperture of the larynx, and between the palatine arches on either side, into the pharynx. It is now clasped by the constrictor muscles, which, by their contractions, force it down into the œsophagus. The contraction of the constrictor muscles results in a flattening of the pharynx and elevation of its anterior attachments.

During the act of swallowing, it is generally thought that the auditory tube is opened by the contraction of the tensor veli palatini muscle, which arises from it. It has been held, on the other hand, that the auditory tube is closed during swallowing by the compression of its wall by the contraction of the levator veli palatini.

Deep Lateral and Prævertebral Muscles of the Neck.

Three series of muscles are comprised in this group: (1) vertebro-costal (scaleni, anterior, medius, and posterior), (2) vertebro-cranial (longus capitis and rectus capitis anterior, and lateralis), and (3) vertebral (longus colli). They clothe the anterior surface of the cervical portion of the vertebral column for the most part, and are in relation anteriorly with the pharynx and œsophagus, and the large vessels and nerves of the neck.

M. Scalenus Anterior.—The **scalenus anterior arises** from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ.

It runs downwards and laterally to be **inserted** into the scalene tubercle and ridge on the first rib (Fig. 389).

The phrenic nerve is formed at the upper part of the lateral border of the scalenus anterior and runs vertically downwards on its anterior surface, leaving its medial border a little above its insertion. The prævertebral fascia covers the muscle and binds down the phrenic nerve to its surface. With the exception of its insertion, which lies behind the clavicle, the muscle is completely covered by the sterno-cleido-mastoid, but the anterior belly of the omo-hyoid, the internal jugular vein, and the subclavian vein intervene between them.

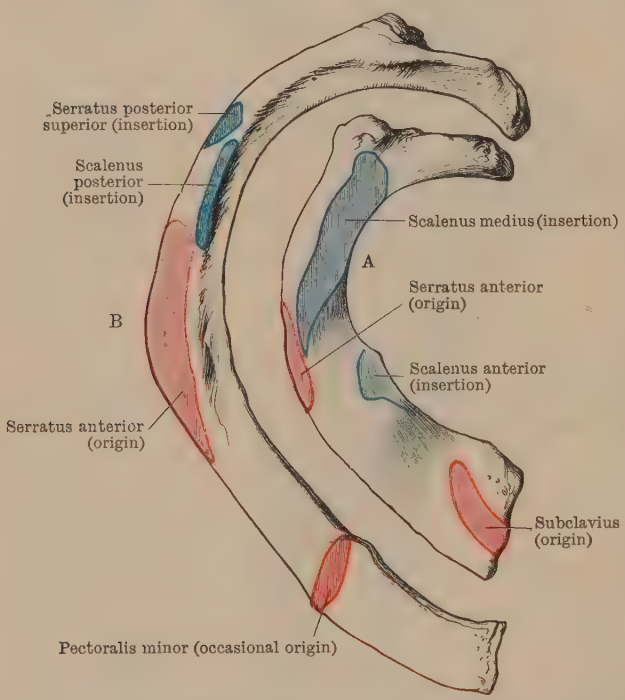

FIG. 389.—MUSCLE-ATTACHMENTS TO THE SUPERIOR SURFACE OF THE FIRST RIB, AND THE EXTERNAL SURFACE OF THE SECOND RIB (RIGHT SIDE).
A, First rib; B, Second rib.

It is separated posteriorly from the scalenus medius by the roots of the brachial plexus, the subclavian artery, and the pleura.

M. Scalenus Medius.—The **scalenus medius arises** from the posterior tubercles of the transverse processes of the cervical vertebræ, from the second to the sixth inclusive.

It descends in the posterior triangle, behind the subclavian artery and the roots of the brachial plexus, to be **inserted** into the rough impression on the first rib behind the subclavian groove (Fig. 389). The muscle is pierced by the dorsal scapular and long thoracic nerves, which descend on its lateral aspect, under cover of the prævertebral fascia.

It is separated from the scalenus anterior by the subclavian artery and the roots of the brachial plexus.

M. Scalenus Posterior.—The **scalenus posterior arises**, behind the scalenus medius, from the posterior tubercles of the fourth, fifth, and sixth cervical transverse processes. It is **inserted** into an impression on the outer side of the second rib.

At first completely hidden by the scalenus medius, the scalenus posterior appears in the lowest part of the floor of the posterior triangle in the angle between the scalenus medius and the levator scapulæ muscles.

Nerve-Supply.—The scalene muscles are supplied by branches which arise directly from the anterior rami of the lowest four or five cervical nerves.

Actions.—The actions of those muscles are twofold. They are lateral flexors of the vertebral column, and are also important muscles of respiration, as elevators of the first and second ribs.

M. Longus Capitis.—The **longus capitis** (O.T. **rectus capitis anticus major**) **arises** from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ.

It forms a flat triangular muscle, which is directed upwards, overlapping the upper oblique part of the longus colli muscle and lying behind the carotid sheath, to be **inserted** into an impression on the inferior surface of the basilar part of the occipital bone, anterior and lateral to the pharyngeal tubercle (Fig. 370, p. 445).

Nerve-Supply. — The muscle receives nerves directly from the anterior rami of the first four cervical nerves.

Action. — Flexion of the head and cervical vertebræ.

M. Rectus Capitis Anterior.—The **rectus capitis anterior** (O.T. **rectus capitis anticus minor**) **arises**, under cover of the preceding muscle, from the lateral mass of the atlas. It is **inserted** into the basilar part of occipital bone between the preceding muscle and the occipital condyle (Fig. 370, p. 445).

Nerve-Supply. — The muscle is innervated by the loop between the first two cervical nerves (anterior rami).

Action. — Flexion of the head on the vertebral column.

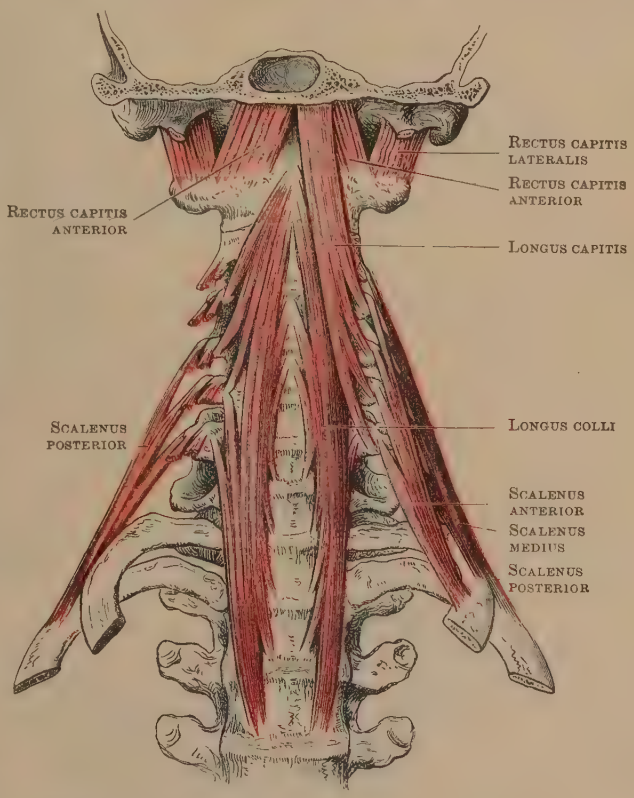

Fig. 390.—The Prævertebral Muscles of the Neck.

M. Longus Colli.—The **longus colli** is a flattened muscular band extending from the third thoracic vertebra to the atlas. It is divisible into three portions—a vertical, an inferior oblique, and a superior oblique portion.

The **vertical portion** of the muscle **arises** from the bodies of the first three thoracic and the last three cervical vertebræ.

Passing vertically upwards, it is **inserted** into the bodies of the second, third, and fourth cervical vertebræ.

The **inferior oblique portion arises** from the bodies of the first three thoracic vertebræ.

It is **inserted** into the anterior tubercles of the fifth and sixth cervical vertebræ.

The **superior oblique portion arises** from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ.

It is directed upwards, to be **inserted** into the anterior tubercle of the atlas.

Nerve-Supply.—It is supplied by the anterior rami of the cervical nerves.

Action.—A flexor of the vertebral column. In addition, the oblique portions act as lateral flexors and the lower oblique part may produce a slight degree of rotation to the opposite side.

M. Rectus Capitis Lateralis.—The **rectus capitis lateralis**, in series with

the posterior inter-transverse muscles in the neck, **arises** from the transverse process of the atlas.

It is **inserted** into the inferior surface of the jugular process of the occipital

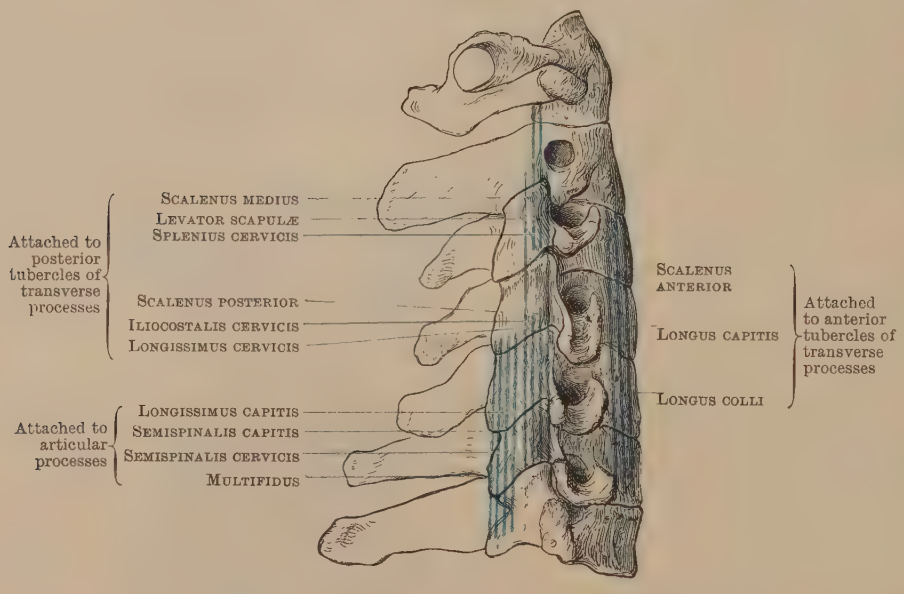

Fig. 391.—Scheme of Muscular Attachments to Cervical Vertebræ.

bone. It is placed alongside the rectus capitis anterior, separated from it by the anterior ramus of the first cervical nerve, and is covered anteriorly by the internal jugular vein.

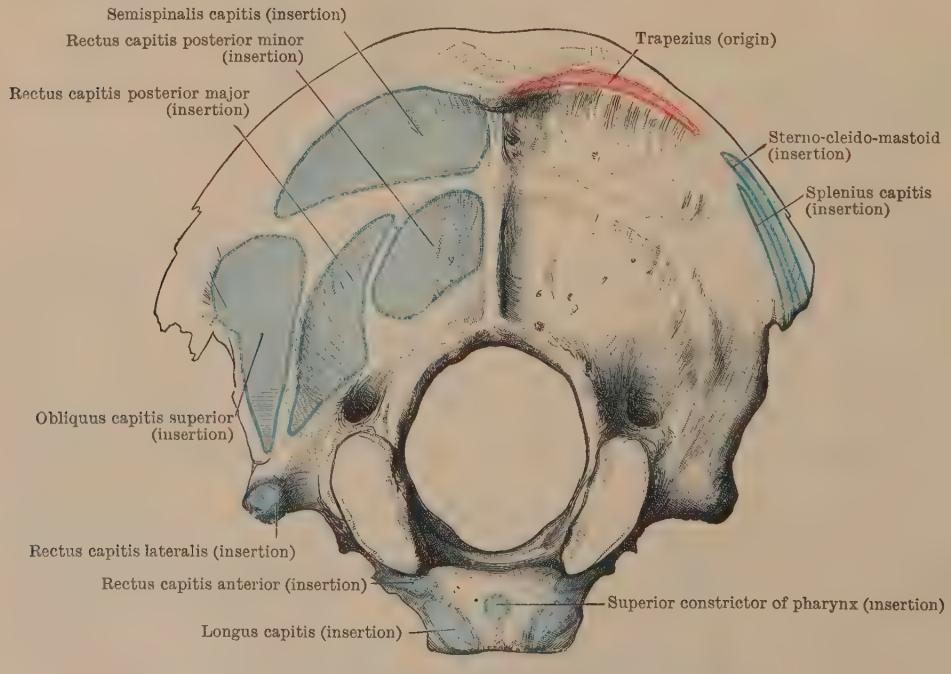

Fig. 392.—Muscle-Attachments to the Occipital Bone.

Nerve-Supply.—The anterior ramus of the first cervical nerve.
Action.—A lateral flexor of the head.

THE MUSCLES OF THE THORAX.

Muscles of Respiration.

The muscles which complete the boundaries of the thorax are the diaphragm and intercostal muscles (external and internal), along with three series of smaller muscles—the transversus thoracis, the levatores costarum, and the subcostal muscles.

Mm. Intercostales.—The **intercostal muscles** are arranged in eleven pairs, which occupy the intercostal spaces.

Each **external muscle arises** from the sharp lower border of a rib, and

Fig. 393.—The Muscles of the Right Side of the Thoracic Wall.

is directed inferiorly and anteriorly, to be **inserted** into the external edge of the superior border of the rib below. It extends from the tubercle of the rib posteriorly nearly to the costal cartilage anteriorly. The *anterior intercostal aponeurosis* is continuous with it anteriorly, and extends forwards to the side of the sternum.

Each **internal muscle arises** from the costal cartilage and the internal or superior edge of the costal groove, and is directed inferiorly and posteriorly, to be **inserted** into the internal edge of the superior border of the rib and costal cartilage below. It extends from the side of the sternum anteriorly to the angle of the rib posteriorly, where it is replaced by the *posterior intercostal aponeurosis* extending to the tubercle of the rib.

The superficial surface of the external muscle is covered by the muscles of the chest, axilla, abdomen, and back. The deep surface of the internal muscle is in contact with the pleura.

Mm. Levatores Costarum.—The **levatores costarum** are in series with the external intercostal muscles. They are twelve small slips **arising** from the transverse processes of the seventh cervical and upper eleven thoracic vertebræ. Each spreads out in a fan-like manner as it descends to the external surface of the rib immediately below, into which it is **inserted** medial to the angle.

Mm. Subcostales.—The **subcostal muscles** are slips of muscles found on the internal surface of the lower ribs near their angles. They are in series with the internal intercostal muscles, but pass over the deep surfaces of several ribs.

M. Transversus Thoracis.—The **transversus thoracis** occupies the posterior aspect of the anterior thoracic wall, and is separated from the costal cartilages by the internal mammary vessels. It **arises** from the posterior surface of the xiphoid process and body of the sternum as high as the level of the third costal cartilage.

From that origin its fibres radiate laterally, the lower horizontally, the upper fibres obliquely upwards, to be **inserted** into the second, third, fourth, fifth, and

sixth costal cartilages. The muscle is continuous below with the transversus abdominis.

Diaphragma.—The **diaphragm** is the great membranous and muscular partition separating the cavities of the thorax and abdomen. It forms a thin lamella arching over the abdominal cavity, and clothed on that surface, for the most part, by peritoneum. It is related, on its inferior concave surface, to the liver, stomach, and spleen, the kidneys and suprarenal glands, and the vena cava inferior. Its superior convex surface projects into the thoracic cavity, rising higher on the right than on the left side, and is related to the pericardium and pleuræ, and along its margin to the chest wall. The œsophagus and thoracic aorta are in contact with this surface posteriorly.

It possesses a peripheral origin from the sternum, ribs, and vertebral column, and an insertion into a central tendon. It **arises** (1) *anteriorly* (**pars sternalis**), from the posterior surface of the xiphoid process by two slender fleshy slips, directed backwards; (2) *laterally* (**pars costalis**), from the deep surface of the lower six costal cartilages on each side by fleshy bands which interdigitate with those of the transversus abdominis; (3) *posteriorly* (**pars lumbalis**), from the lumbar vertebræ, by the crura, and the medial and lateral lumbo-costal arches. The **crura** are two

elongated fibro-muscular bundles which arise, on each side of the aorta, from the anterior surfaces of the bodies of the lumbar vertebræ, on the right side from the first three, on the left side from the first two lumbar vertebræ, as a general rule. They are separated from the vertebral bodies by the upper lumbar arteries, but are firmly attached to their margins and to the invertebral fibro-cartilages. The crura are directed upwards and decussate across the median plane in front of the aorta, the fibres of the right crus passing anterior to those of the left crus. The fibres then encircle the œsophagus, forming an elliptical opening for its passage, and finally join the central tendon, after a second decussation anterior to the gullet.

The medial part of each crus is wholly tendinous and is sometimes called the *crus mediale*; it is connected with its fellow of the opposite side by a tendinous band called the **middle arcuate ligament**, which arches between them, in front of the aorta, and gives origin to fibres which join the crura as they decussate to encircle the gullet. The most outlying part of the crus is sometimes called the *crus laterale*; it arises below from the medial lumbo-costal arch. The intermediate part of the crus is the *crus intermedium*; the splanchnic nerves pierce the diaphragm between it and the medial crus. The sympathetic trunk sometimes pierces the diaphragm between the intermediate and lateral crura.

The **arcus lumbocostalis medialis** is an oblique, linear thickening. Medially, it is attached to the side of the body of the second (sometimes first), laterally to the tip of the transverse process of the first lumbar vertebra. Stretching across the superior end of the psoas muscle, the ligament gives origin to muscular fibres which join the fibres of the crus.

The **arcus lumbocostalis lateralis** is the thickened superior border of the fascia over the quadratus lumborum muscle and is attached medially to the transverse process of the first lumbar vertebra, and laterally to the last rib. It gives origin to a broad band of muscular fibres, which sweep upwards to the central tendon. Not infrequently an interval separates these fibres from those which arise from the medial lumbo-costal arch. In these cases the kidney and the lower limit of the pleura are intimately related.

From this extensive origin the muscular fibres of the diaphragm converge to an **insertion** into a large trilobed **central tendon** called the **centrum tendineum**. Of its lobes the right one is the largest, the middle or anterior is intermediate in size, and the left is the smallest. It does not occupy the centre of the muscle, being placed nearer the front than the back. The fibres of the crura are consequently the longest; those from the xiphoid process are the shortest.

The diaphragm is pierced by numerous structures. The superior epigastric artery enters the sheath of the rectus abdominis between its sternal and costal origins; the musculo-phrenic artery passes between its attachments to the seventh and eighth ribs. The splanchnic nerves pierce the crura and the sympathetic trunk descends behind the medial end of the medial lumbo-costal arch. The last thoracic nerve and the subcostal vessels pass behind the lateral lumbo-costal arch; and the aorta and thoracic duct pass between the crura, underneath the middle arcuate ligament (*hiatus aorticus* or *aortic opening*). The azygos vein is usually described as passing through the aortic opening, but it is placed postero-lateral to the thoracic duct and completely under cover of the right crus, a position which it usually gains by passing under cover of its lateral border. The special foramina are two in number. The *foramen venæ cavæ* in the right lobe of the central tendon transmits the inferior vena cava, and small branches of the right phrenic nerve. The *hiatus œsophageus* (*œsophageal opening*) is in the muscular substance of the diaphragm, posterior to the central tendon, and is surrounded by a sphincter-like arrangement of the crural fibres. Besides the œsophagus, this opening transmits the two vagi nerves.

The comparative morphology of the diaphragm and its derivation from the fourth cervical myotome are summarised on p. 479.

Nerve-Supply.—The intercostal muscles, levatores costarum, subcostal muscles, and transversus thoracis are all supplied by the anterior rami of the **thoracic nerves**. The diaphragm receives its chief, if not its entire, motor supply from the **phrenic nerves** (C. 3. 4. 5.). It is innervated also by the diaphragmatic plexus of the sympathetic, and is sometimes said to receive fibres from the lower thoracic nerves.

Actions.—The act of respiration consists of two opposite movements—inspiration and expiration.

The **movement of inspiration** results in an increase in the capacity of the thorax which is partly brought about by muscles acting on the ribs, sternum, and vertebral column, and partly by the diaphragm. The transverse diameter of the thorax is increased by elevation and eversion of the ribs, and these movements are produced, during quiet respiration, by the

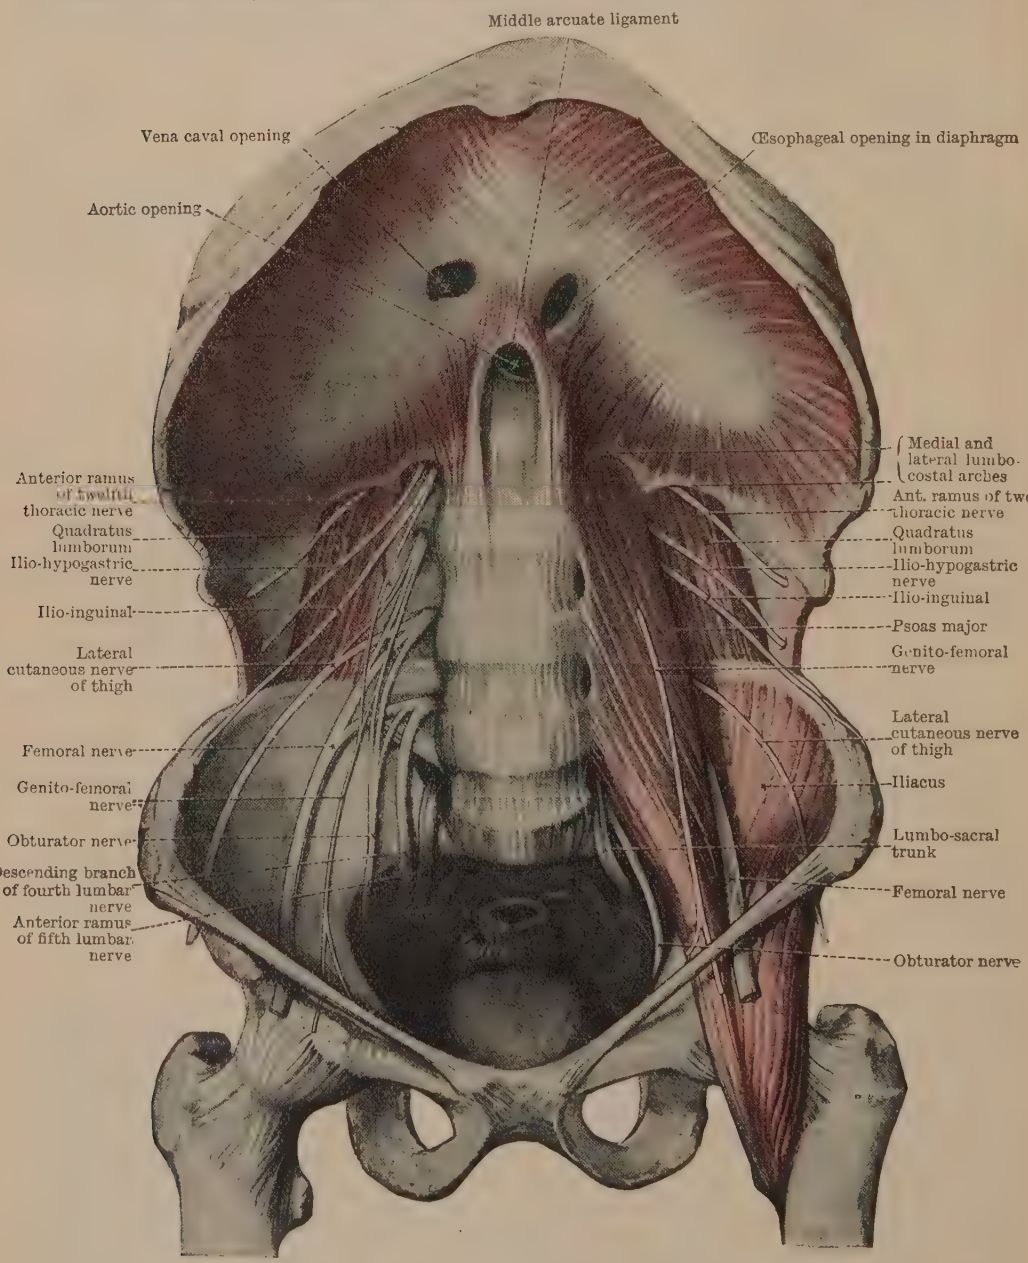

FIG. 395.—THE DIAPHRAGM AND POSTERIOR ABDOMINAL WALL.

intercostals (both groups), the subcostals, and the levatores costarum. As a result of the elevation of the ribs the sternum is thrust forwards, particularly in its lower part, thus increasing the thoracic capacity in an antero-posterior direction.

In forced inspiration, the transverse and antero-posterior diameters of the thorax are further increased by elevation of the first rib, elevation and forward movement of the upper part of the sternum, and diminution of the concavity of the curve of the thoracic part of the vertebral column, accompanied by further elevation and eversion of the ribs (2–8). Elevation of the first rib is produced by the scalenus anterior and medius muscles, and by the sterno-cleido-mastoid

(acting through the sternum, the sterno-clavicular joint, and the costo-clavicular ligament). Elevation and forward movement of the upper part of the sternum necessarily accompany this movement. Extension of the vertebral column by the sacrospinalis renders possible further elevation of the ribs, and this is produced by the action of the serratus anterior and pectoralis minor. For this purpose it is necessary that the scapula should be fixed by the trapezius, the rhomboids, and the levator scapulæ.

The effect of the contraction of the diaphragm is threefold. (1) When relaxed, the fibres of the diaphragm curve upwards over the liver, stomach, and spleen, and the disappearance of this curve and consequent straightening of the fibres, when the muscle contracts, provide a great increase in the depth of the thorax. (2) The central tendon descends to a slight extent. As a result of (1) and (2) the abdominal viscera are thrust downwards and the relaxed abdominal parietes are bulged outwards. (3) The eighth, ninth, tenth, and eleventh ribs are slightly elevated by the diaphragm, but the lower ribs as a whole tend to be thrust outwards by the abdominal viscera, and the twelfth rib is fixed by the quadratus lumborum muscle.

In **the movement of expiration**, diminution of the transverse and antero-posterior diameters is effected by the elastic recoil of the costal cartilages and the weight of the thoracic skeleton. The depth of the thorax is diminished by the reproduction of the concavity of the cupolæ of the diaphragm. This result is brought about by the contraction of the abdominal muscles. In forced expiration these muscles are reinforced by the latissimus dorsi (p. 372), which exerts a powerful compressing effect, and the vertebral column is flexed, thus allowing the ribs to be still further approximated.

There has been considerable diversity of opinion regarding the action of the intercostal muscles. It is generally agreed that the external muscles elevate the ribs; it is probable that the whole of each internal muscle acts in the same way, although it has been stated by different observers that the whole internal muscle is a depressor; or that the interosseous part is a depressor, the interchondral portion of the muscle an elevator of the ribs.

FASCIÆ AND MUSCLES OF THE ABDOMINAL WALL.

The space between the base of the bony thorax and the pelvis is filled up by a series of muscular sheets, covered externally and internally by fasciæ.

FASCIÆ.

The fasciæ of the abdominal wall are—*externally*, the superficial and deep fasciæ; *internally*, the fascia transversalis, which clothes the deep surface of the anterior and lateral walls of the abdominal cavity, and is continuous with the diaphragmatic, lumbo-dorsal, psoas, iliac, and pelvic fasciæ, and is lined within by the **subserous coat** of extra-peritoneal tissue. In this way a fascial envelope is formed, which encloses the abdominal and pelvic cavities, the retro-peritoneal viscera, and the great vessels.

The **superficial fascia** of the abdomen is liable to contain a large quantity of fat. In the groin it is separated into *two layers*: a superficial fatty layer continuous over the inguinal ligament with the fascia of the anterior surface of the thigh (p. 404), and a deeper membranous layer attached to the medial half of the inguinal ligament, and more laterally to the fascia lata of the thigh distal to the inguinal ligament. The two layers are separated by the lymph glands and the superficial vessels of the groin. Higher up in the abdominal wall the two layers blend together. As they pass downwards over the spermatic funiculus, they are replaced by the fascia and dartos muscle of the scrotum. The attachment of the fascia to the groin prevents the passage into the thigh of fluid extravasated in the abdominal wall.

The **deep fascia** of the abdominal wall resembles similar fasciæ in other situations. It forms an investment for the obliquus externus muscle, and becomes thin and almost imperceptible in relation to the aponeurosis of that muscle.

Fascia Transversalis.—The **fascial lining** of the abdominal cavity consists of a continuous layer of membrane which receives different names in different parts of its extent. The **fascia transversalis** covers the deep surface of the transversus muscle, and is continuous medially with the fasciæ of the quadratus lumborum and the psoas muscles. It is continuous above with the diaphragmatic fascia, and below the iliac crest and the inguinal ligament with the fascia iliaca. Along with the last-named fascia it forms the **femoral sheath**, enclosing the femoral vessels

and the femoral canal in their passage to the thigh behind the medial part of the inguinal ligament (p. 478). It is pierced by the spermatic funiculus or round ligament of the uterus at the abdominal inguinal ring, and its prolongation into the inguinal canal around the funiculus forms the **internal spermatic** or **infundibuliform fascia**. It is lined internally by the peritoneum, from which it is separated by a layer of **extraperitoneal tissue**.

The **subserous coat** or **extraperitoneal tissue** is usually loaded with fat; it envelops

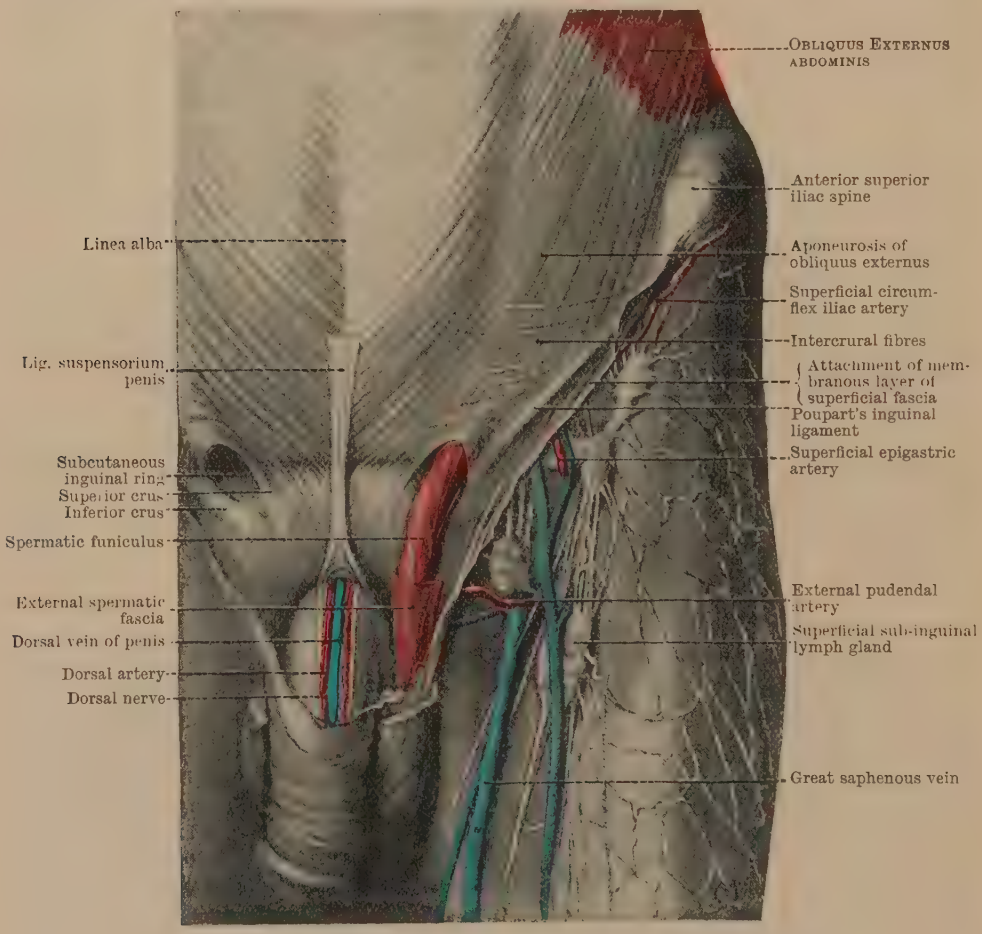

Fig. 396.—Superficial Anatomy of the Groin.

the kidneys, ureters, suprarenal glands, abdominal aorta, and inferior vena cava and their branches, and forms sheaths for the vessels and ducts (ureter, ductus deferens, etc.). It is continued upwards into the posterior mediastinum of the thorax through the aortic opening in the diaphragm, and below is in continuity with the extraperitoneal tissue in the pelvis. It not only completely invests the kidneys and suprarenal glands, but it also becomes interpolated between the layers of peritoneum upholding and enveloping the intestines. This tissue is absent in relation to the diaphragm, on the under surface of which there is no fat.

THE MUSCLES OF THE ABDOMINAL WALL.

The muscles of the abdominal wall are in three series—lateral, anterior, and posterior.

The **lateral muscles** of the abdominal wall comprise the obliquus externus abdominis, obliquus internus abdominis, and transversus abdominis.

M. Obliquus Externus Abdominis.—The **obliquus externus abdominis** is a broad thin sheet of muscle, with an **origin** from the lateral surfaces of the lower eight ribs, by slips which interdigitate with the serratus anterior and latissimus dorsi muscles. The muscular fibres radiate downwards and forwards, the lowest fibres passing vertically downwards.

The muscle fibres of the lower and posterior part of the muscle are **inserted**, directly, into the external lip of the iliac crest in its anterior half or two-thirds (Fig. 343, p. 417). The rest of the muscle fibres are inserted into an extensive triangular aponeurosis which forms part of the anterior abdominal wall. This aponeurosis is broader below than above; it is united with part of the aponeurosis

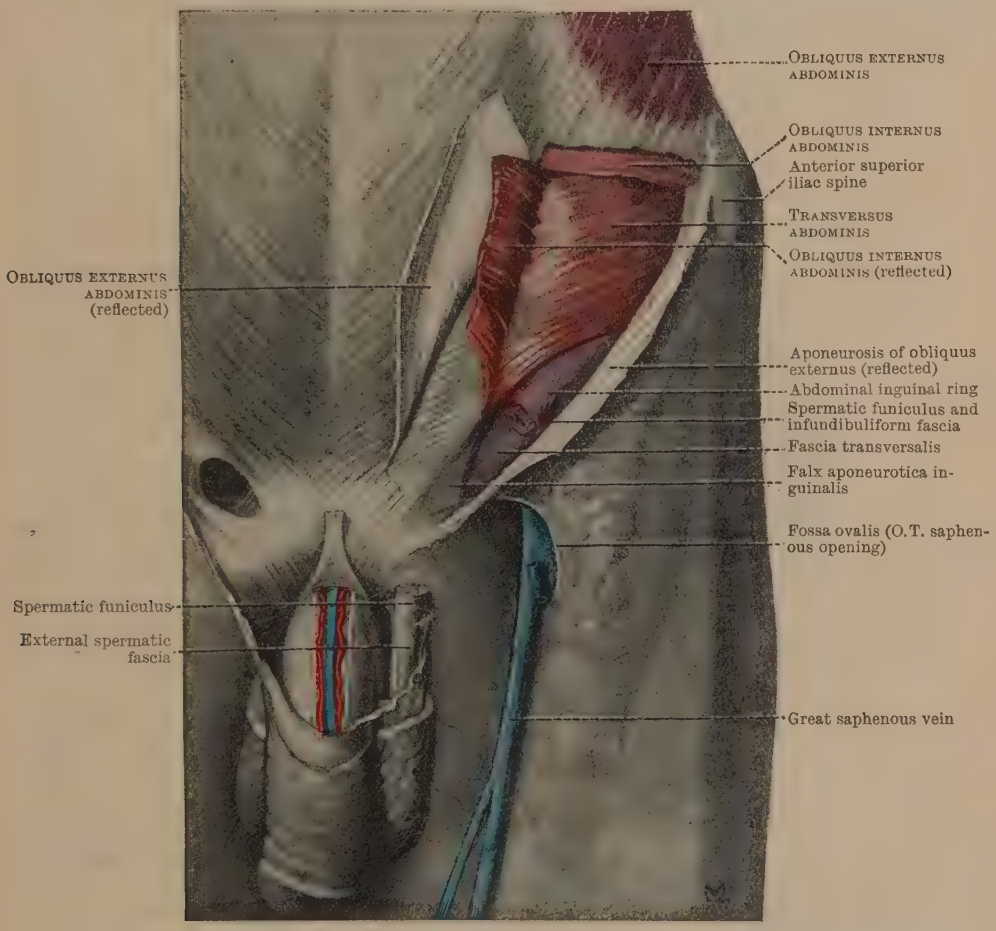

Fig. 397.—The Dissection of the Inguinal Canal.

of the obliquus internus in the superior three-fourths of its extent, and with the whole aponeurosis of that muscle as well as with that of the transversus abdominis in its lower fourth, thus forming the anterior wall of the **sheath of the rectus muscle.** It thus gains attachments, below to the symphysis pubis, above to the xiphoid process, and by its intermediate fibres to the **linea alba.**

The **linea alba** is a band of interlacing fibres, narrow below the umbilicus but increasing to about half an inch in width in its upper part. It occupies the median plane of the anterior abdominal wall in its whole extent, is pierced by the umbilicus (**annulus umbilicalis**), and forms the greater part of the ultimate insertion of all the lateral abdominal muscles.

The fleshy fibres of the muscle do not extend forwards as far as the linea semilunaris nor downwards below the level of the anterior superior iliac spine (Fig. 399, p 479).

The superior part of the aponeurosis covers the insertion of the rectus abdominis muscle on the chest wall, and gives origin to fibres of the pectoralis major. Inferiorly, in the groin, the lower part of the aponeurosis gives rise to the inguinal ligament, the ligamentum lacunare, the two crura of the subcutaneous inguinal ring, the external spermatic fascia and the intercrural fibres, and the ligamentum inguinale reflexum of Colles.

Lig. Inguinale [Poupart's].—The **inguinal ligament** is an aponeurotic band which extends from the anterior superior iliac spine to the tubercle of the pubis, arching over the iliacus, psoas, and pectineus muscles. It represents the inferior margin of the aponeurosis of the obliquus externus abdominis which is folded back upon itself, so as to present a grooved upper surface. Its lower convex surface gives attachment below to the iliac portion of the fascia lata of the thigh. Its upper surface affords partial origin to the obliquus internus and transversus muscles, and receives the attachment of the fascia transversalis and fascia iliaca in its lateral part; in its medial part it forms the gutter-like floor of the inguinal canal. At its medial end a triangular band of fibres is reflected horizontally backwards to the ilio-pectineal line, forming the **lig. lacunare [Gimbernat's]**, the lateral edge of which forms the medial boundary of the **femoral ring**. The femoral vessels, enclosed in the femoral sheath, enter the thigh posterior to the inguinal ligament, on the anterior surface of the psoas major muscle, and the term *superficial femoral arch* is given to the part of the ligament which covers the vessels.

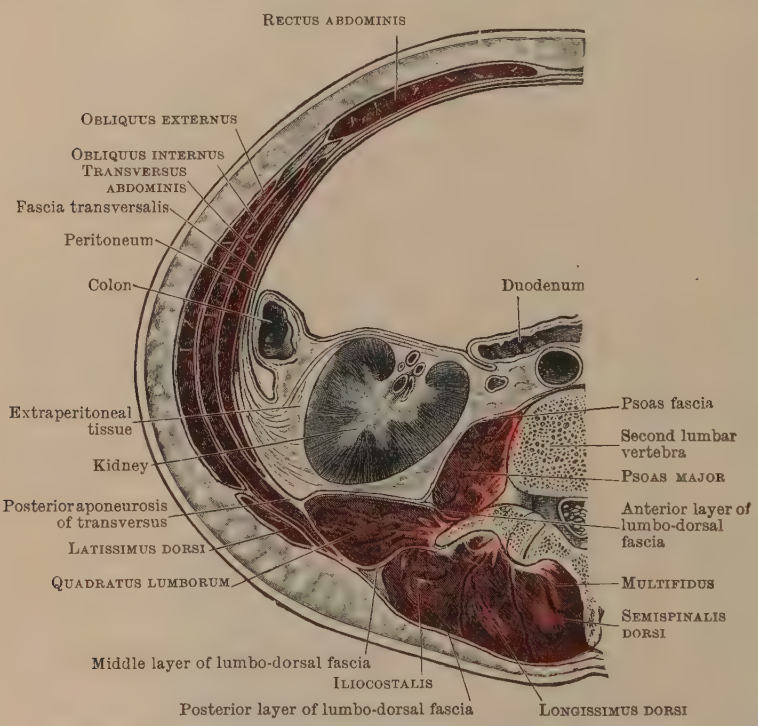

Fig. 398.—Transverse Section through the Abdomen, opposite the Second Lumbar Vertebra.

Annulus Inguinalis Subcutaneus.—The **subcutaneus inguinal ring** (O.T. **external abdominal ring**), the place of exit of an inguinal hernia, is a split in the aponeurosis of the obliquus externus, just above the tubercle of the pubis. It transmits the spermatic funiculus, or (in the female) the round ligament of the uterus, covered by the cremaster muscle or cremasteric fascia. The opening is of considerable extent, and its edges are drawn together by a thin fascia, strengthened superficially by a number of arched and horizontal fibres, called the **intercrural fibres**, which arise from the inguinal ligament and sweep medially across the cleft in the aponeurosis.

The margins of the ring constitute its crura. The **inferior crus** is narrow, and is formed from that part of the aponeurosis which joins the pubic tubercle, and is continuous with the medial end of the inguinal ligament. The **superior crus** is the part of the aponeurosis medial to the ring which is attached to the crest and symphysis of the pubis. It is flat and broad.

The intercrural fibres and the crura of the subcutaneous inguinal ring are

continuous with a thin tubular sheath, the **intercolumnar** or **external spermatic fascia**, which forms an envelope for the spermatic funiculus or round ligament after they have passed beyond the abdominal wall.

Lig. Inguinale Reflexum Collesi.—The **reflexed inguinal ligament of Colles** (O.T. **triangular fascia**) is a triangular band of fibres placed behind the (medial) superior crus of the subcutaneous inguinal ring. It consists of fibres from the

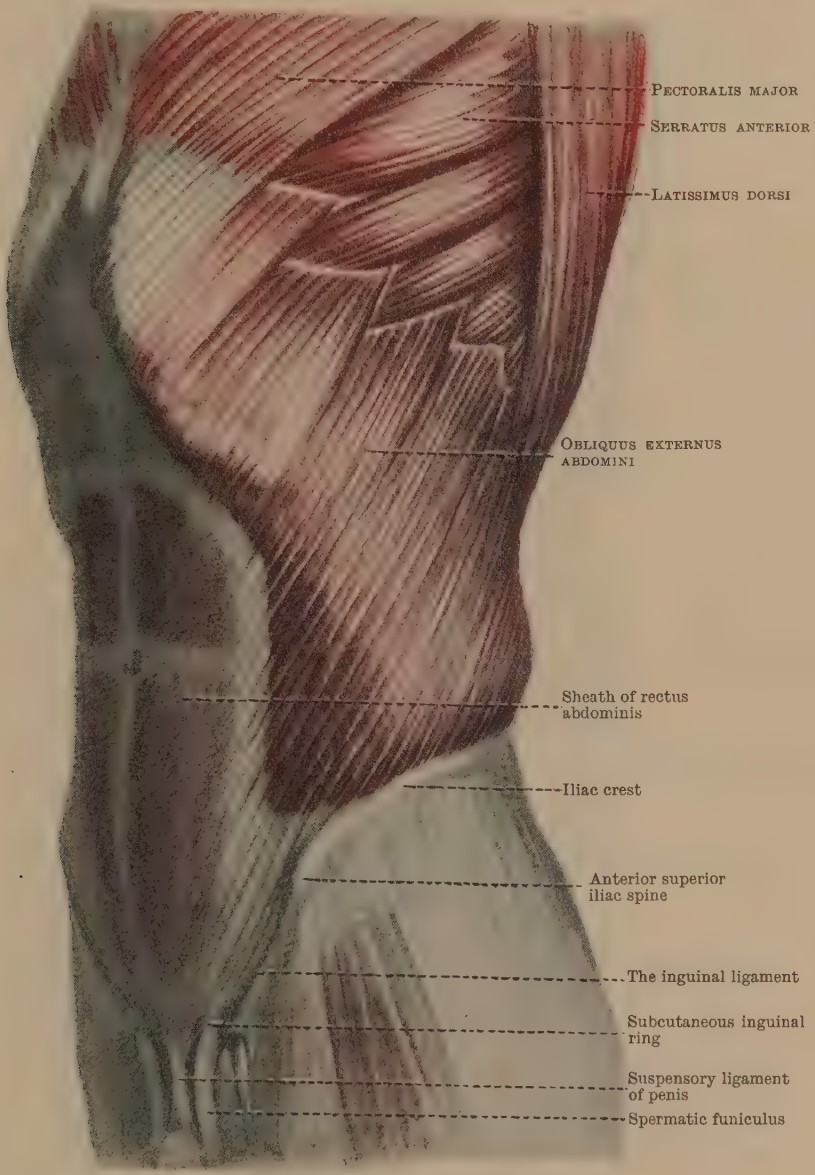

Fig. 399.—The Left Obliquus Externus Abdominis

opposite external oblique aponeurosis, which, having traversed the linea alba, gain an insertion into the front of the pubis. It is placed in front of the falx inguinalis (O.T. **conjoined tendon**) and, when well developed, is covered by the spermatic cord as it emerges from the subcutaneous inguinal ring.

The obliquus externus muscle is superficial in almost its whole extent. It is overlapped posteriorly by the latissimus dorsi muscle, but may be separated from it just above the iliac crest by an angular interval (**trigonum lumbale** or triangle of Petit).

M. Obliquus Internus Abdominis.—The **obliquus internus abdominis** is a broad thin sheet of muscle which lies between the obliquus externus and the transversus. It **arises** from (1) the lumbo-dorsal fascia, (2) the anterior two-thirds of the iliac crest, and (3) the lateral half of the inguinal ligament.

It runs for the most part, upwards and forwards, and its highest fibres are **inserted** directly into the last three ribs. The rest of the fibres extend almost to

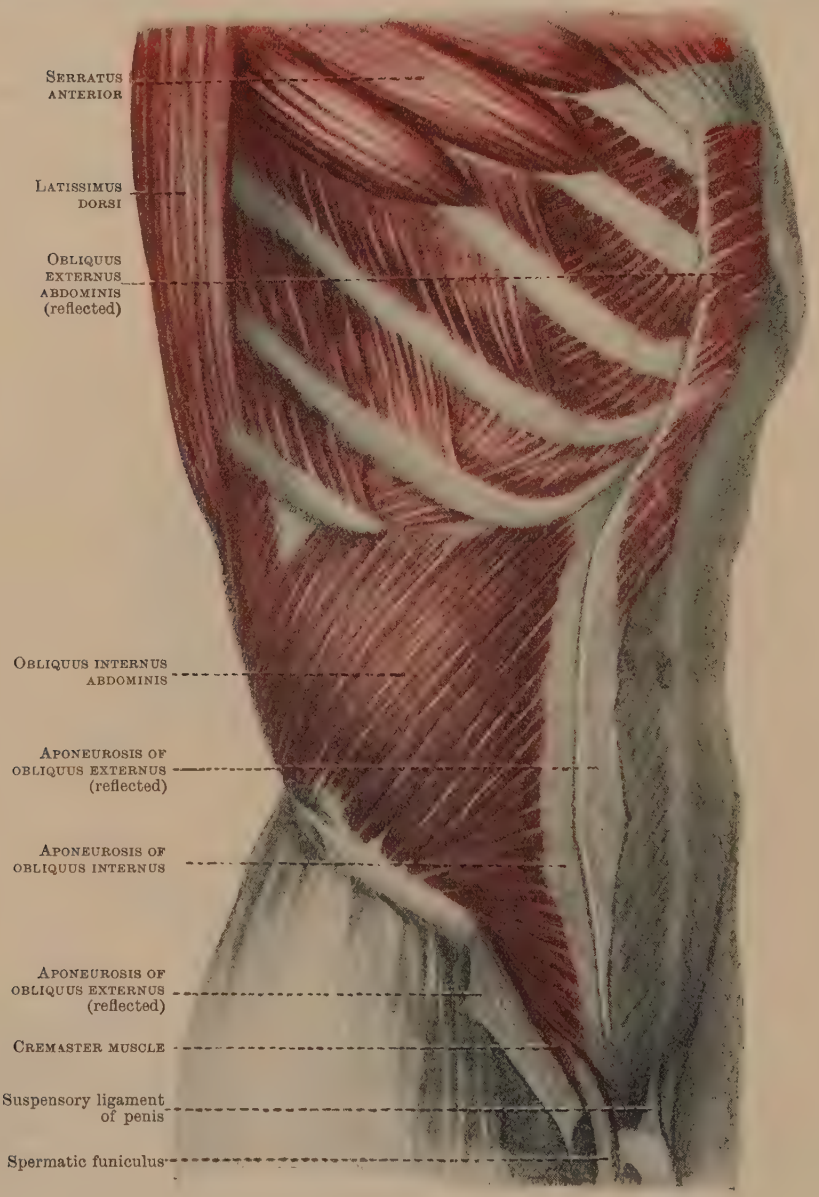

Fig. 400.—The Right Obliquus Internus Abdominis.

the linea semilunaris, where they give place to an aponeurosis, which at once splits to form, along with the aponeuroses of the obliquus externus and transversus muscles, the **sheath of the rectus abdominis**, and is **inserted** into the ninth, eighth, and seventh costal cartilages, and into the linea alba from the xiphoid process to the symphysis pubis. The fibres arising from the inguinal ligament join with those of the transversus muscle having a similar origin to form the **falx aponeurotica inguinalis** (O.T. **conjoined tendon**), which passes altogether anterior to the rectus muscle, to be attached to the pubic crest and tubercle, and to the ilio-pectineal line.

The obliquus internus is limited above by the inferior margin of the thorax. Its lower fibres, arching over the spermatic funiculus, assist in forming, laterally, the anterior wall of the inguinal canal; medially, by means of the falx inguinalis, they help to form the posterior wall of the canal.

Its lowest fibres are continued into the **cremaster muscle**, which is prolonged along the spermatic cord through the inguinal canal.

M. Cremaster.—The **cremaster muscle** forms an investment for the testis and spermatic funiculus deep to the external spermatic fascia. In the female it is more largely represented by fascia than muscular fibres, and constitutes the **cremasteric fascia.** It may be said to have an **origin** from the inferior edge of the obliquus internus and the

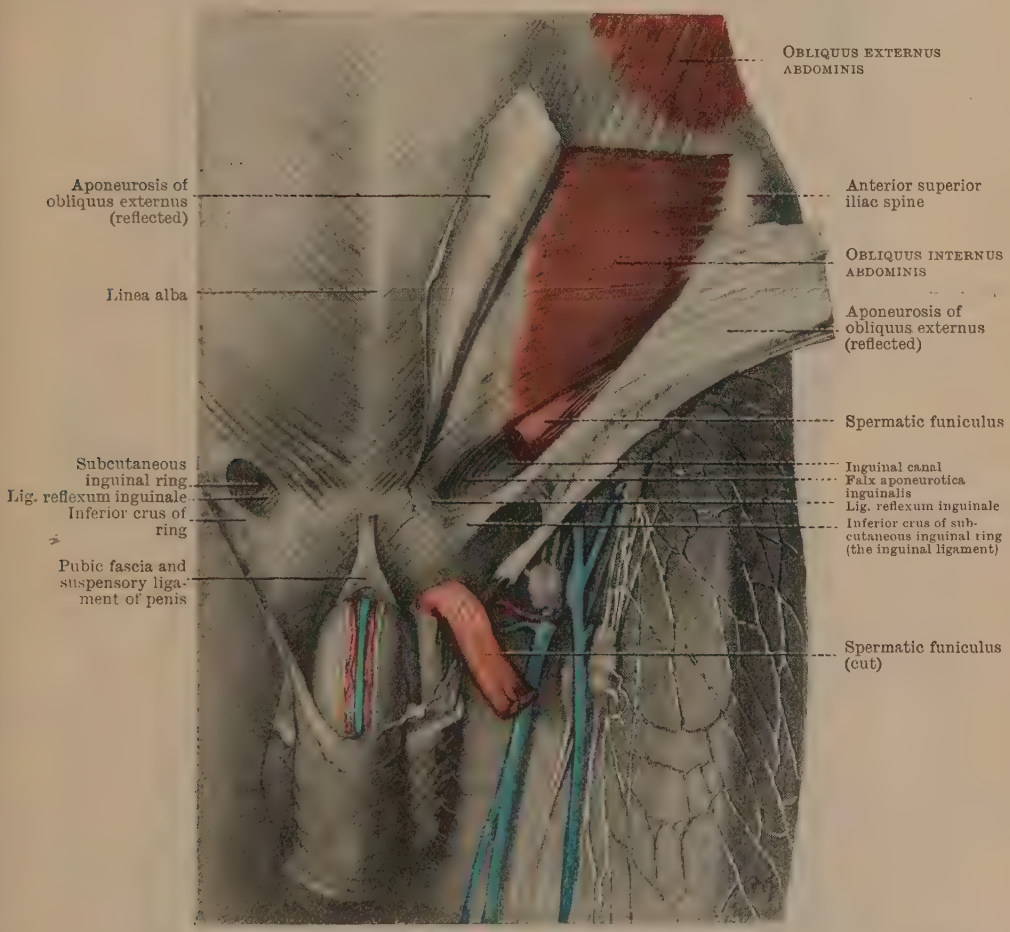

Fig. 401.—The Left Inguinal Canal. Structures seen on reflexion of the Obliquus Externus.

adjacent part of the inguinal ligament. Its fibres form loops over the spermatic funiculus and testis, the highest fibres getting an **insertion** into the pubic tubercle.

M. Transversus Abdominis.—The **transversus abdominis muscle** arises (1) from the deep surfaces of the costal cartilages of the lower six ribs, interdigitating with the origins of the diaphragm; (2) from the lumbo-dorsal fascia; (3) from the anterior two-thirds of the internal lip of the iliac crest; and (4) from the lateral third of the inguinal ligament.

The muscular fibres run, for the most part, horizontally forwards, and end in an aponeurosis which has a twofold **insertion.** (1) After taking part in the formation of the sheath of the rectus, the aponeurosis is attached to the xiphoid process, the whole length of the linea alba, and the symphysis pubis. (2) The inferior fibres of the muscle arising from the inguinal ligament are joined by

the inferior part of the obliquus internus to form the larger part of the **falx aponeurotica inguinalis** (O.T. **conjoined tendon**), which passes anterior to the inferior part of the rectus muscle, to be inserted into the front of the pubis, the pubic tubercle, and the ilio-pectineal line.

The aponeurosis of the transversus abdominis is widest opposite the interval between the last rib and the iliac crest, and it gradually becomes narrower above and below this region. Below the xiphoid process it is barely 3 cm. wide, and in this situation fleshy fibres of the muscle are separated from the rectus abdominis only by the posterior lamella of the aponeurosis of the obliquus internus (Fig. 403, p. 483).

The transversus muscle is separated by the lower intercostal nerves from the

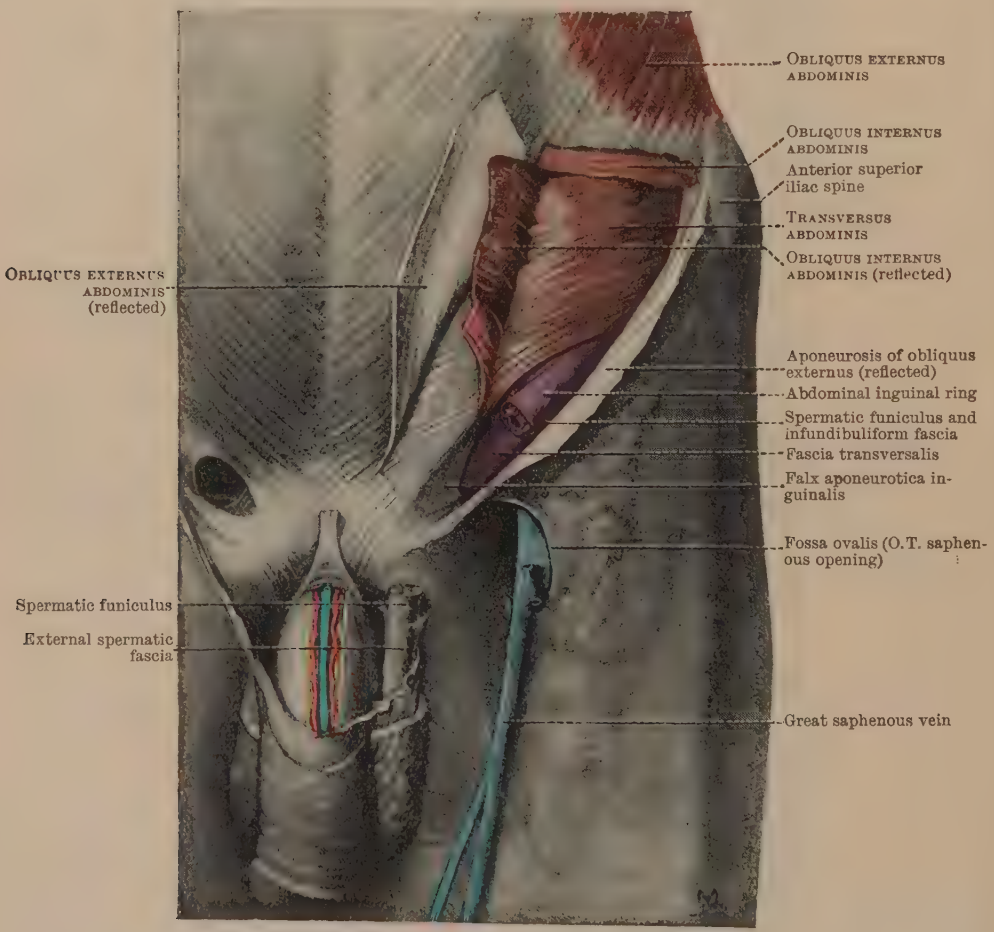

Fig. 402.—The Dissection of the Inguinal Canal.

obliquus internus muscle, and is lined on its deep surface by the fascia transversalis. Its inferior border forms a concave edge, separated from the inguinal ligament by a lunular interval in which the fascia transversalis appears, and through which the spermatic funiculus emerges at the abdominal inguinal ring, under cover of the obliquus internus muscle and the aponeurosis of the obliquus externus.

The **anterior muscles** of the abdominal wall include the pyramidalis and rectus abdominis, enveloped by the sheath of the rectus, on each side of the linea alba.

M. Pyramidalis Abdominis. — The **pyramidalis abdominis** is a small triangular muscle arising from the front of the pubis, below the rectus muscle (Fig. 403, p. 483).

It is directed obliquely upwards, to be **inserted**, for a variable distance, into the linea alba. The muscle is often absent.

M. Rectus Abdominis.—The **rectus abdominis muscle** is broad and strap-like, and **arises** by a medial head from the ligaments in front of the symphysis pubis, many of the fibres coming from the opposite side, and by a lateral head from the crest of the pubis (Fig. 340, p. 414).

The muscle expands as it passes upwards, and is **inserted**, from medial to lateral

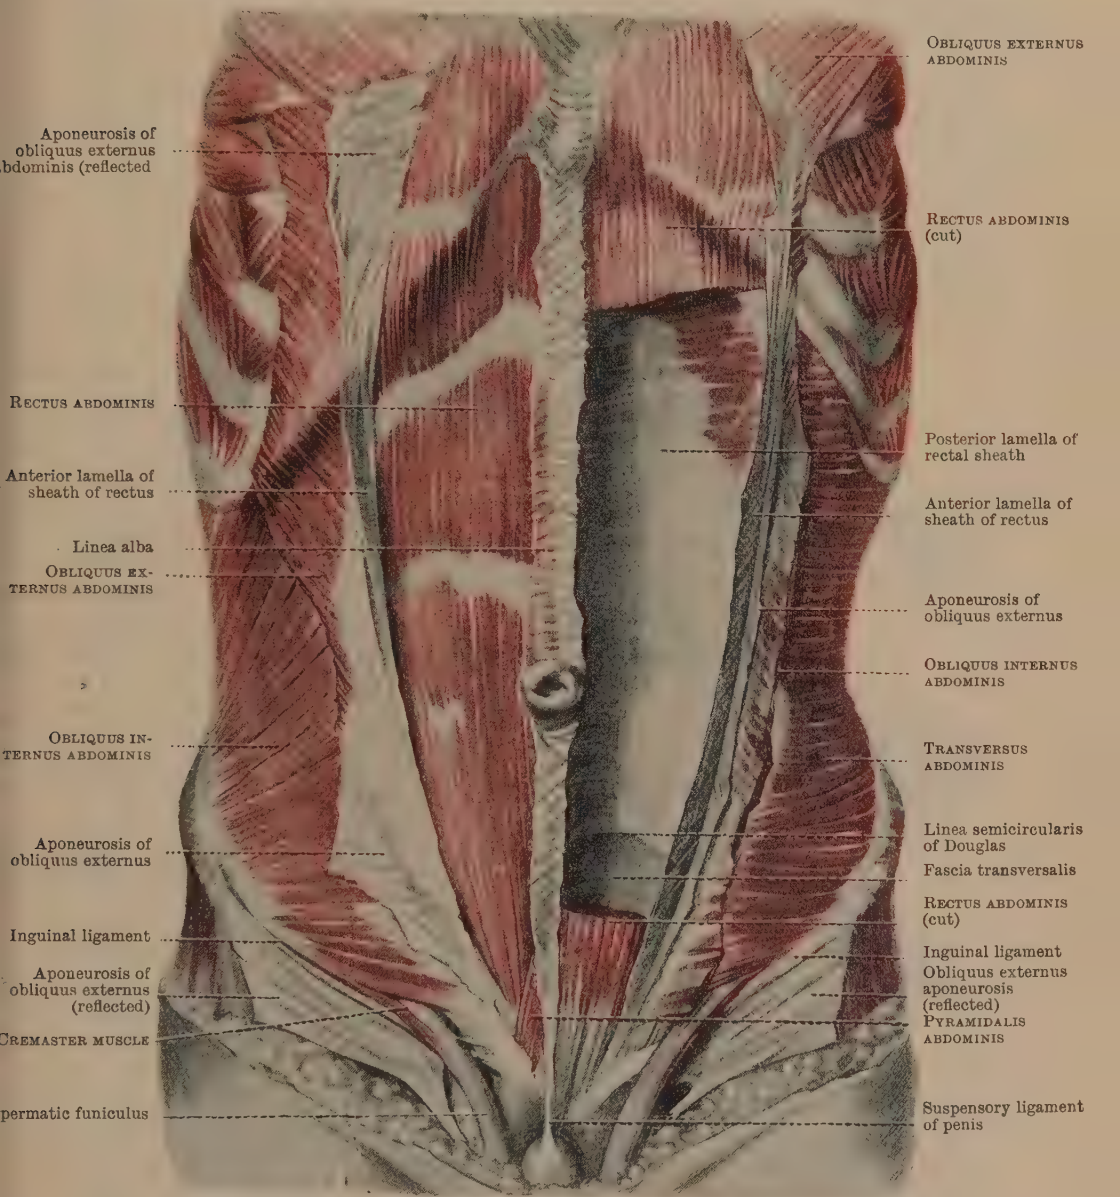

Fig. 403.—Deep Dissection of the Abdominal Wall. The Rectus Muscle and its Sheath.

side, into the anterior surface of the xiphoid process (Fig. 304, p. 374), and into the superficial surfaces of the seventh, sixth, and fifth costal cartilages. On its anterior surface, but not extending through the entire substance of the muscle, are three or more transverse tendinous intersections (**inscriptiones tendineæ**), firmly adherent to the sheath of the muscle; the lowest opposite the umbilicus, and the highest about the level of the xiphoid process. The medial border of the muscle lies alongside the linea alba; its lateral border is convex, and corresponds to the **linea semilunaris**. The muscle is pierced by the terminal branches of the lower thoracic nerves.

Vagina M. Recti Abdominis.—The **sheath of the rectus muscle** is derived from the aponeuroses of the lateral muscles of the abdominal wall, which, after enclosing the muscle, give rise, in the median plane, to the linea alba. At the linea semilunaris along the lateral border of the rectus muscle, the aponeurosis of the obliquus internus splits into anterior and posterior layers. The anterior layer, joined by the aponeurosis of the obliquus externus, passes in front of the rectus, and constitutes the anterior lamina of the sheath. The posterior layer, joined by the aponeurosis of the transversus muscle, passes behind the rectus, and constitutes the posterior lamina of its sheath. This arrangement obtains in the superior three-fourths of the abdominal wall. Below the level of the iliac crest the sheath of the muscle is deficient posteriorly, and a crescentic border, the **linea semicircularis (semilunar fold of Douglas)**, marks the inferior limit of the posterior lamina. In consequence, the rectus in the lower fourth of the abdominal wall rests directly upon the fascia transversalis. Close examination, however, usually reveals a thin layer behind the muscle in continuity with the fold of Douglas, and merging below with the fascia transversalis. In this region the rectus is covered anteriorly by the aponeurosis of the obliquus externus, obliquus internus and transversus (Fig. 404). The superior part of the rectus, lying on the chest wall, is only covered anteriorly by a single layer of aponeurosis derived from the obliquus externus, which in this situation is giving origin to the pectoralis major muscle.

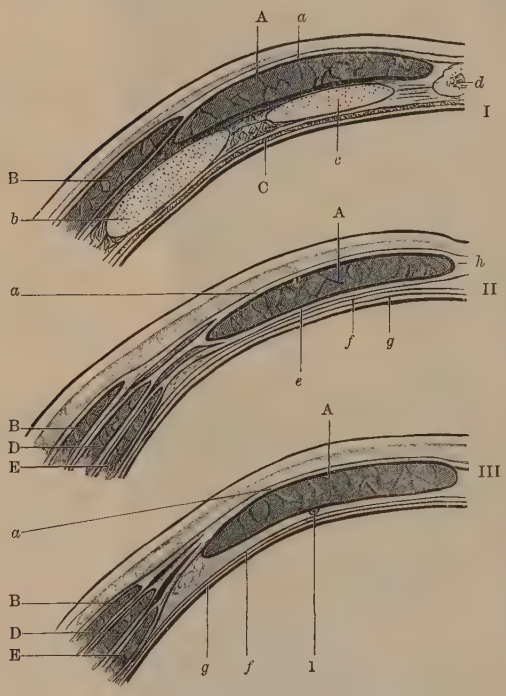

Fig. 404.—The Sheath of the Rectus Abdominis Muscle.

(I.) In the thoracic wall; (II.) In the superior three-quarters of the abdominal wall; (III.) In the inferior fourth of the abdominal wall.

A, Rectus muscle; B, Obliquus externus; C, Diaphragm; D, Obliquus internus; E, Transversus abdominis. *a*, Anterior layer of rectus sheath; *b*, Fifth costal cartilage; *c*, Sixth costal cartilage; *d*, Xiphoid process; *e*, Posterior layer of rectus sheath; *f*, Fascia transversalis; *g*, Peritoneum; *h*, Linea alba. 1, Inferior epigastric artery.

Canalis Inguinalis.—Inguinal canal.—The spermatic funiculus in the male, and the round ligament in the female, in their passage through the inferior part of the abdominal wall, pass through the inguinal canal, which is bounded by these abdominal muscles. The canal begins at the *abdominal inguinal ring*, which is an opening in the fascia transversalis, placed half an inch above the inguinal ligament, and midway between the anterior superior iliac spine and the symphysis pubis. It ends at the *subcutaneous inguinal ring*, placed above the tubercle and crest of the pubis. The *anterior wall* of the canal is formed by the aponeurosis of the obliquus externus, and in its lateral part by the muscular fibres of the obliquus internus; the *posterior wall* of the canal is formed by the fascia transversalis, and in its medial part by the falx aponeurotica inguinalis and by the ligamentum inguinale reflexum, when that structure is well developed. Thus the anterior wall is strongest opposite to the abdominal inguinal ring, and the posterior wall opposite to the subcutaneous ring. The *floor* of the canal is formed by the inguinal ligament, and in its medial part by the lacunar ligament. The spermatic funiculus, piercing the transversalis fascia, enters the inguinal canal at the abdominal inguinal ring, and is there invested by its *first envelope*, the **infundibuliform** or **internal spermatic fascia**, a sheath of fascia derived from the margins of the ring and continuous with the fascia transversalis. It then passes obliquely medially, downwards, and forwards, and escapes below the inferior

border of the obliquus internus muscle, from which it carries off a *second investment*, partly fascial, partly muscular,—the **cremaster muscle** or **cremasteric fascia**. Continuing its course, in front of the falx inguinalis, it emerges through the subcutaneous inguinal ring, from the edges of which the **intercolumnar** or **external spermatic fascia** is derived, the *third* or *external investment* for the funiculus.

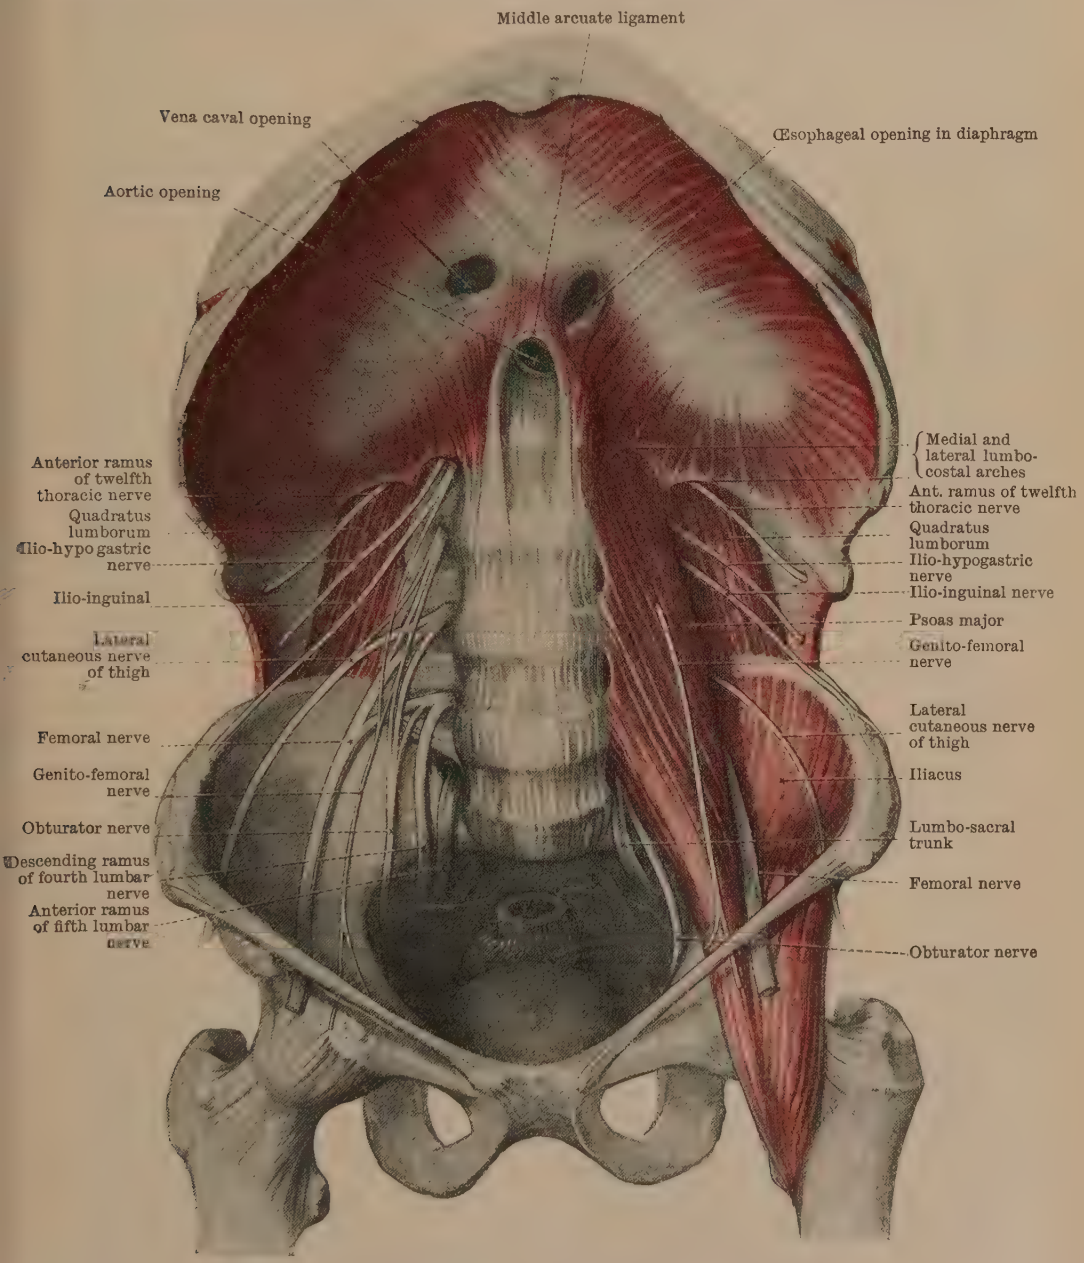

Fig. 405.—The Diaphragm and Posterior Abdominal Wall.

Hesselbach's triangle, bounded below by the line of the inguinal ligament medially by the rectus abdominis muscle, and laterally by the inferior epigastric artery, coursing upwards and medially behind the fascia transversalis on the medial side of the abdominal inguinal ring, is the site of one form of inguinal hernia The spermatic funiculus passes over the base of the triangle, covered over by the aponeurosis of the obliquus externus. Behind the funiculus, and forming the floor

of the triangle, is the fascia transversalis partially covered, in the medial portion of the triangle, by the falx inguinalis of the obliquus internus and transversus muscles.

Inguinal Hernia.—For an account of the anatomical relations of the inguinal canal to the various forms of inguinal hernia, see the section on "Applied Anatomy."

Nerve-Supply.—The nerve-supply of the majority of the foregoing muscles is derived from the anterior rami of the **lower six thoracic nerves.** The pyramidalis muscle is innervated by the **last thoracic nerve.** The cremaster muscle receives its supply from the **genito-femoral nerve** (L. 1. 2.). In addition, the lower fibres of the obliquus internus and the transversus abdominus are innervated by the ilio-hypogastric nerve (L. 1.).

Actions.—(1) By virtue of their normal tone, these muscles support the abdominal viscera and help to retain them in their respective positions. Acting in association with the diaphragm they can compress the contents of the abdomen, and are powerful agents in vomiting, defæcation, micturition, and parturition. (2) They take part in forced expiration. (3) They are also flexors of the vertebral column and pelvis—the muscles of both sides acting together; the vertebral column and pelvis are laterally flexed, when one set of muscles acts alone.

The **posterior muscles of the abdominal wall and pelvis major** include the psoas (major and minor) and iliacus, described already (p. 411), and the quadratus lumborum.

M. Quadratus Lumborum.—The **quadratus lumborum** lies in the posterior wall of the abdomen, lateral to the psoas, and extends between the iliac crest and the last rib. It **arises** from the posterior part of the iliac crest, from the ilio-lumbar ligament, and from the transverse processes of the lower lumbar vertebræ.

It is **inserted**, above, into the medial part of the inferior border of the last rib and the transverse processes of the lumbar vertebræ. Its lateral border is directed obliquely upwards and medially.

It is enclosed between the anterior and middle layers of the lumbo-dorsal fascia (p. 438), between the psoas major muscle, in front, and the sacrospinalis behind.

Nerve-Supply.—The quadratus lumborum is supplied directly by branches from the anterior rami of the first three or four lumbar nerves.

Actions.—The muscle is a lateral flexor of the vertebral column, and assists in inspiration by fixing the twelfth rib and so facilitating the action of the diaphragm.

FASCIÆ AND MUSCLES OF THE PERINEUM AND PELVIS.

FASCIÆ OF THE PERINEUM.

The **superficial fascia** of the perineum possesses certain special features. It is continuous with the superficial fascia of the abdominal wall, thigh, and buttock, and is prolonged on to the penis and scrotum. In the penis, it is devoid of fat and consists only of areolar tissue. In the scrotum, it is intermingled with involuntary muscular fibres, and constitutes the **dartos muscle**, which assists in suspending the testes and corrugating the skin of the scrotum. This fascia also forms the **septum of the scrotum**, which, extending upwards, incompletely separates the two testes and their coverings. In the female the superficial fascia, in which there is a considerable quantity of fat, takes a large share in the formation of the mons Veneris and labia majora pudendi.

The fascia over the posterior part of the perineum fills up the ischio-rectal fossæ, in the form of two pads of adipose tissue, on either side of the rectum and anal canal. Over the tuberosities of the ischium the fat is intermingled with bands of fibrous tissue closely adherent to the subjacent deep fascia.

The fascia in the anterior part of the perineum closely resembles the same fascia in the groin. It is divisible into a superficial fatty and a deeper membranous layer. The former is continuous with the same layer in the thigh, and with the fat of the ischio-rectal fossa posteriorly. The deeper membranous layer (fascia of Colles) is attached on each side to the body of the pubis and the pubic arch, posteriorly to the base of the fascia inferior of the urogenital diaphragm and in

the median plane to the bulb and corpus cavernosum urethræ by a median raphe continuous, farther forwards, with the septum of the scrotum mentioned above. Anteriorly the fascia invests the scrotum and gives a tubular covering to the penis. Finally it is continued over the spermatic funiculi to the anterior abdominal wall. The importance of this fascia lies in relation to the extravasation of urine from a rupture of the urethra in the perineum. By the fascial attachments the fluid is prevented from passing posteriorly into the ischio-rectal fossa, or laterally into the thigh. It is directed forwards into relation with the scrotum and penis, and along the spermatic funiculus to the anterior abdominal wall. The septum of the scrotum being incomplete, fluid extravasated on one side can pass across the median plane to the opposite half of the perineum and scrotum.

The **deep fascia** of the perineum exists only in the form of the delicate fasciæ of the muscles.

The **Central Point of the Perineum** is a fibro-muscular node of considerable importance in the anatomy of the perineum. It is placed in front of the upper part of the anal canal, behind the bulb of the urethra and below the postero-inferior portion of the prostate (Fig. 410). Both striated and plain muscle fibres enter into its constitution, and it is inseparably blended with the fasciæ of the urogenital diaphragm and the prostatic sheath. The superficial and deep transverse perineal muscles, the bulbocavernosus, the external sphincter ani, and the levatores prostatæ all contribute fibres to its constitution. In addition, it receives the insertions of the *recto-urethral muscles* (of Roux). The superior recto-urethralis is the downward and forward continuation of the longitudinal muscular fibres of the rectum which lie on its anterior wall in and near the median plane, and it passes into the upper and posterior part of the central point of the perineum. The inferior recto-urethralis, which is inserted into the lower and posterior part of the central point of the perineum, is formed by longitudinal fibres in the anterior wall of the anal canal, and curves upwards and forwards to reach its insertion.

THE MUSCLES OF THE PERINEUM.

The perineal muscles are naturally separated into a superficial and a deep set by the fascia inferior of the urogenital diaphragm. Superficial to it are the sphincter ani externus, transversus perinei superficialis, bulbocavernosus, and ischiocavernosus; deep to it are the sphincter muscle of the membranous urethra and the transversus perinei profundus.

M. Sphincter Ani Externus.—This muscle is fusiform in outline, flattened, and obliquely placed around the anus and anal canal. It can be separated into three layers,—subcutaneous, superficial, and deep. (1) The most superficial lamina consists of **subcutaneous fibres** decussating posterior and anterior to the anus, but without bony attachments. (2) The **sphincter ani superficialis** constitutes the main portion of the muscle. It is attached posteriorly to the coccyx, and, anterior to the anus, it reaches the central point of the perineum. (3) The **deep fibres** of the muscle form, for the most part, a complete sphincter for the anal canal. They are continuous above with the fibres of the pubo-rectalis portion of the levator ani; they encircle the anal canal, and blend anteriorly with the central point of the perineum and the transversus perinei superficialis muscle.

M. Corrugator Cutis Ani.—The **corrugator cutis ani** consists of bundles of unstriped muscular fibres which radiate from the margin of the anal opening superficial to the external sphincter.

Nerve-Supply.—The external sphincter is supplied by the inferior hæmorrhoidal branch of the pudendal nerve (S. 3. 4.), by the perineal branch of the fourth sacral nerve, and by the deep perineal branch of the pudendal nerve (S. 3. 4.).

Actions.—The muscle closes the anal aperture. It is a voluntary muscle.

M. Transversus Perinei Superficialis.—The **transversus perinei superficialis** is not always present. It consists of a more or less feeble bundle of fibres, which arises from the forepart of the medial aspect of the tuberosity of the ischium and

the fascia over it, and from the base of the fascia inferior of the urogenital diaphragm.

It passes obliquely over the base of the fascia inferior to be **inserted** into the central point of the perineum.

Nerve-Supply.—Deep perineal branch of pudendal nerve (S. 3. 4.).

Action.—The two muscles acting together draw backwards and fix the central point of the perineum.

M. Bulbocavernosus.—The **bulbocavernosus** (O.T. **ejaculatoı urinæ**), *in the male*, surrounds the bulb, corpus cavernosum urethræ, and root of the penis.

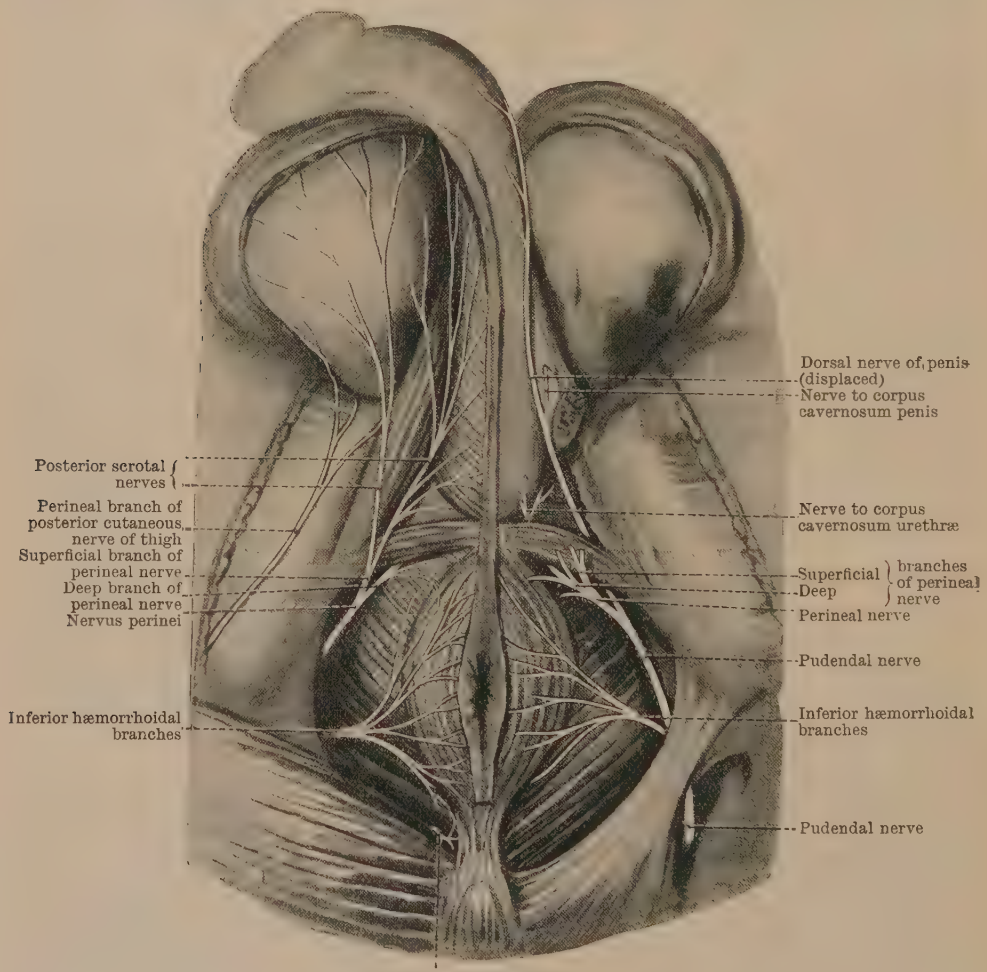

Fig. 406.—The Muscles and Nerves of the Male Perineum.

It is sometimes separated into two parts—*posterior* (compressor bulbi), and *anterior* (compressor radicis penis). It **arises** from the central point of the perineum, and from a median raphe on the under surface of the bulb and corpus cavernosum urethræ.

The muscular fibres pass laterally and forwards and have a triple **insertion**: from behind forwards, (1) into the inferior surface of the fascia inferior of the urogenital diaphragm; (2) into the dorsal aspect of the corpus cavernosum urethræ; and (3), after encircling the corpora cavernosa penis, into the fascia covering the dorsum of the penis.

The **ischiobulbosus**, not always present, **arises** from the ischium, and passes obliquely medially and forwards over the bulbocavernosus, to be **inserted** into the raphe

superficial to that muscle. It belongs to the same stratum as the transversus perinei superficialis and ischiocavernosus.

M. Bulbocavernosus.—The **bulbocavernosus**, *in the female* (O.T. **sphincter vaginæ**), is separated into lateral halves by the vaginal and urethral openings. It forms two thin lateral layers covering the bulb of the vestibule, and **arises** behind the vaginal orifice from the central point of the perineum.

Anteriorly it is **inserted** into the root of the clitoris, some of its fibres embracing the corpora cavernosa clitoridis so as to reach the dorsum of the clitoris.

Nerve-Supply.—Deep branch of the perineal nerve (pudendal, S. 3. 4.).

Actions.—In the male.—The bulbocavernosus contracts the urethra in the emission of urine and semen, and is an accessory muscle in erection of the penis.

In the Female.—The muscle contracts the vaginal orifice, and compresses the bulb of the vestibule of the vagina.

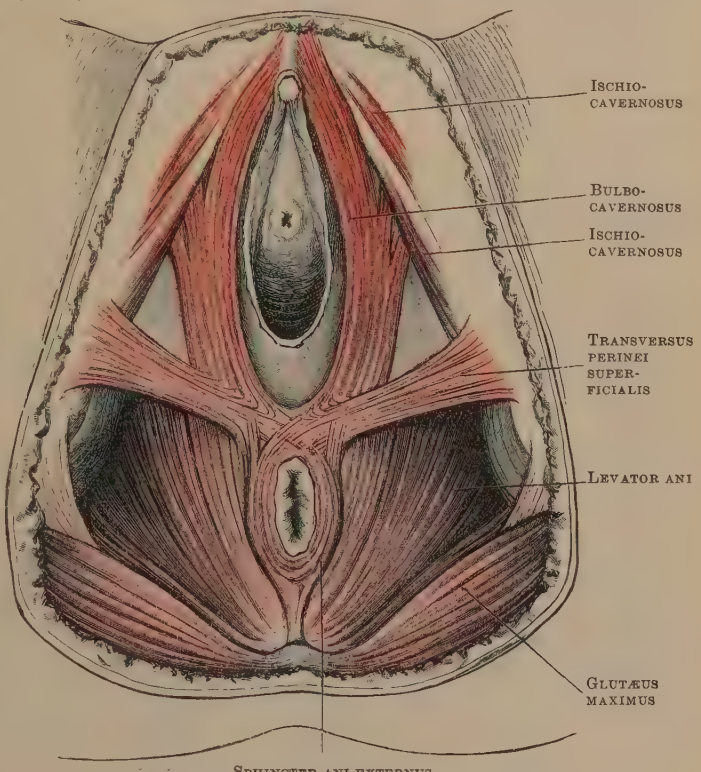

Fig. 407.—The Muscles of the Female Perineum. (After Peter Thompson.)

M. Ischiocavernosus.—The ischiocavernosus, *in the male*, covers the crus penis. It **arises** from the ischial tuberosity and the sacrotuberous ligament.

Passing forwards, it is **inserted** by a fascial attachment into the inferior surface of the crus penis, and into the lateral and dorsal aspects of the corpus cavernosum penis.

The **ischiocavernosus**, *in the female*, has a similar disposition, but is of much smaller size than in the male.

The **pubocavernosus** is an occasional slip **arising** from the pubic ramus, and **inserted** into the dorsum of the penis. It corresponds to the levator penis of lower animals.

Nerve-Supply.—Deep branch of the perineal nerve (pudendal, S. 3. 4.).

Action.—The muscle assists in erection of the penis (or clitoris).

Diaphragma Urogenitale.—The sphincter urethræ membranaceæ and the transversus perinei profundus constitute the deeper muscular stratum of the perineum and form the **urogenital diaphragm**. They lie between two layers of fascia called the *fascia inferior*, and *fascia superior* of the *urogenital diaphragm* (O.T. *superficial and deep layers of the triangular ligament*).

The fascia inferior is a strong layer which stretches across the pubic arch. Posteriorly, it extends between the foreparts of the ischial tuberosities, and, in the median plane, is intimately connected with the central point of the perineum. Anteriorly, it ends in a thickened band (*ligamentum transversum pelvis*) which is separated from the arcuate ligament by a small gap for the passage of the deep dorsal vein of the penis. This fascia is formed by the blending of the fascial sheath of the muscles of the urogenital diaphragm with the strong fibrous sheath which encloses the corpus cavernosum urethræ and the bulb, and it is to the latter constituent that it owes its strength.

The superior fascia of the urogenital diaphragm, as defined by its name, is a weak covering of the muscles of the diaphragm. It gains in strength but loses in definition by its intimate association with the sheath of the prostate gland and, more posteriorly, with the central point of the perineum. On each side, as it approaches the pubic arch, the fascia becomes blended with the dense connective tissue in which the dorsal nerve of the penis and the internal pudendal artery are embedded.

M. Sphincter Urethræ Membranaceæ.—The **sphincter** of the membranous urethra **arises** from the inferior part of the pubic ramus, and is directed medially, its fibres radiating so as to enclose the membranous urethra.

It is **inserted** into a median raphe, partly anterior to the urethra, but for the most part posterior to it. The fibres most intimately related to the urethra form a muscular sheath for the canal, and have no bony attachments.

M. Transversus Perinei Profundus.—The **transversus perinei profundus** consists of a bundle of fibres on each side which **arises** from the inferior ramus of the ischium just below the sphincter urethræ membranaceæ. It is **inserted** into a median raphe continuous, behind, with the central point of the perineum. The muscle, in fact, constitutes a separate bundle below and behind the sphincter.

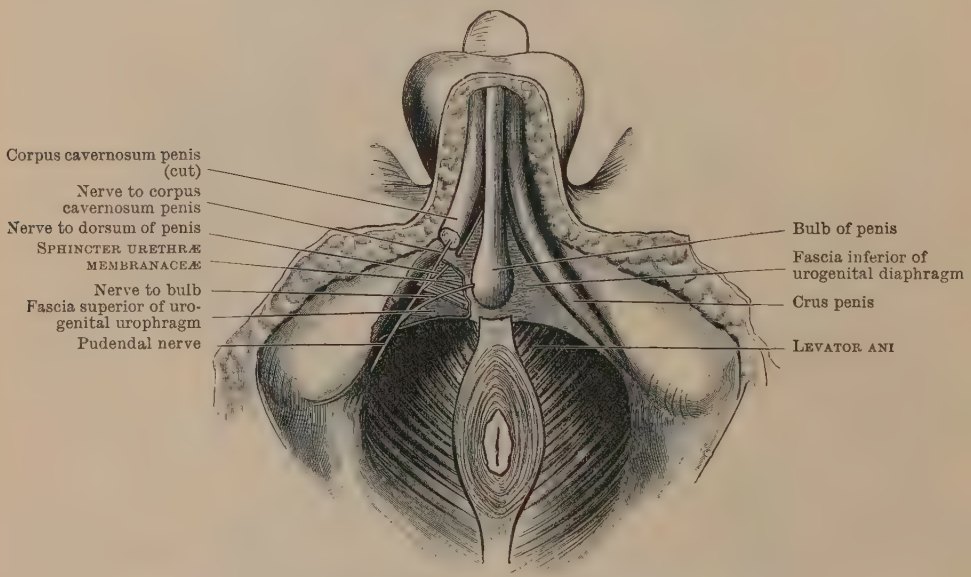

Fig. 408.—The Fasciæ of the Urogenital Diaphragm of the Perineum, and the Termination of the Pudendal Nerve.

The **ischiopubicus** is a term applied to a feeble bundle of fibres which, when present, lies above and in front of the sphincter urethræ membranaceæ. It **arises** from the pubic ramus, and is **inserted** into a median raphe on the dorsum of the membranous urethra. This muscle is homologous with the **compressor venæ dorsalis penis** of lower animals.

The **sphincter urethræ** *in the female* is smaller than in the male. Its insertion is modified by the relations of the urethra to the vagina. The anterior fibres are continuous with those of the opposite side above the urethra; the intermediate fibres pass between the urethra and vagina, and the posterior fibres are attached, along with the **transversus perinei profundus** (transversus vaginæ), into the side of the vagina.

Nerve-Supply.—Deep branch of the perineal nerve (pudendal, S. 3. 4.).

Action.—It is a feeble compressor of the membranous urethra, and by no means a sphincter. In the female it has an accessory influence in constricting the vagina.

THE FASCIÆ OF THE PELVIS.

The extra-peritoneal tissue in the pelvic cavity is of great importance. The hypogastric vessels and their branches, the visceral nerves and plexuses, the

ureters, and ductus deferentes, take their course in this tissue outside the peritoneum. It forms in relation to **the rectum** a thick sheath, for the most part devoid of fat, which encloses the lower part of the rectum completely, down to its termination in the anal canal. It forms a kind of packing for the parts of **the bladder** uncovered by peritoneum, and surrounds the prostate with a strong sheath. In the female it forms, in addition, the basis or matrix of the **broad ligament**, and also occurs as a layer devoid of fat, which loosely connects the anterior surface of the **cervix uteri** with the base of the bladder.

FASCIA PELVINA.

The muscles which line the walls (obturator internus and piriformis) and those which form the floor of the pelvis (levator ani and coccygeus) are covered on their

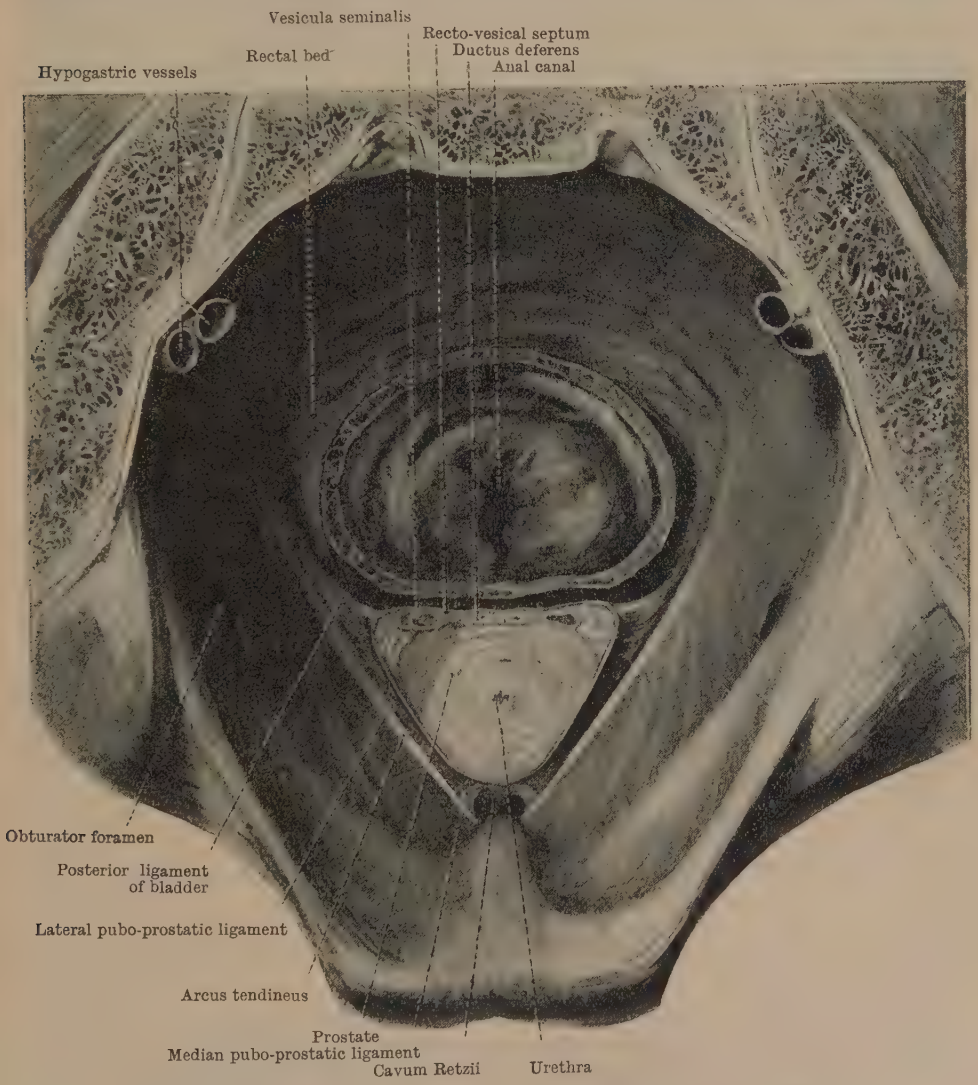

FIG. 409.—RELATIONS OF THE PELVIC FASCIA TO THE RECTUM AND PROSTATE.

pelvic surfaces by a layer of fascia, thicker over the obturator internus than it is elsewhere. This thickening is, in reality, the aponeurosis of origin of the ilio-coccygeus muscle (p. 495), and it is continued upwards to reach the ilio-pectineal line. The surface of this aponeurosis is crossed by a linear thickening (*arcus tendineus*) which extends from the ischial spine to the pelvic surface of the body

of the os pubis, where it blends with the median pubo-prostatic ligament. In its posterior part it marks the origin of the fleshy fibres of the ilio-coccygeus, but its anterior part crosses the pelvic surface of the pubo-coccygeus at least 1·5 cm. below its origin from the bone. It has been suggested that the anterior portion of the arcus tendineus represents an additional tendon of origin for the ilio-coccygeus.

As in other parts of the body, connective tissue is condensed around the viscera and the vessels. It will be sufficient to indicate the situations in which

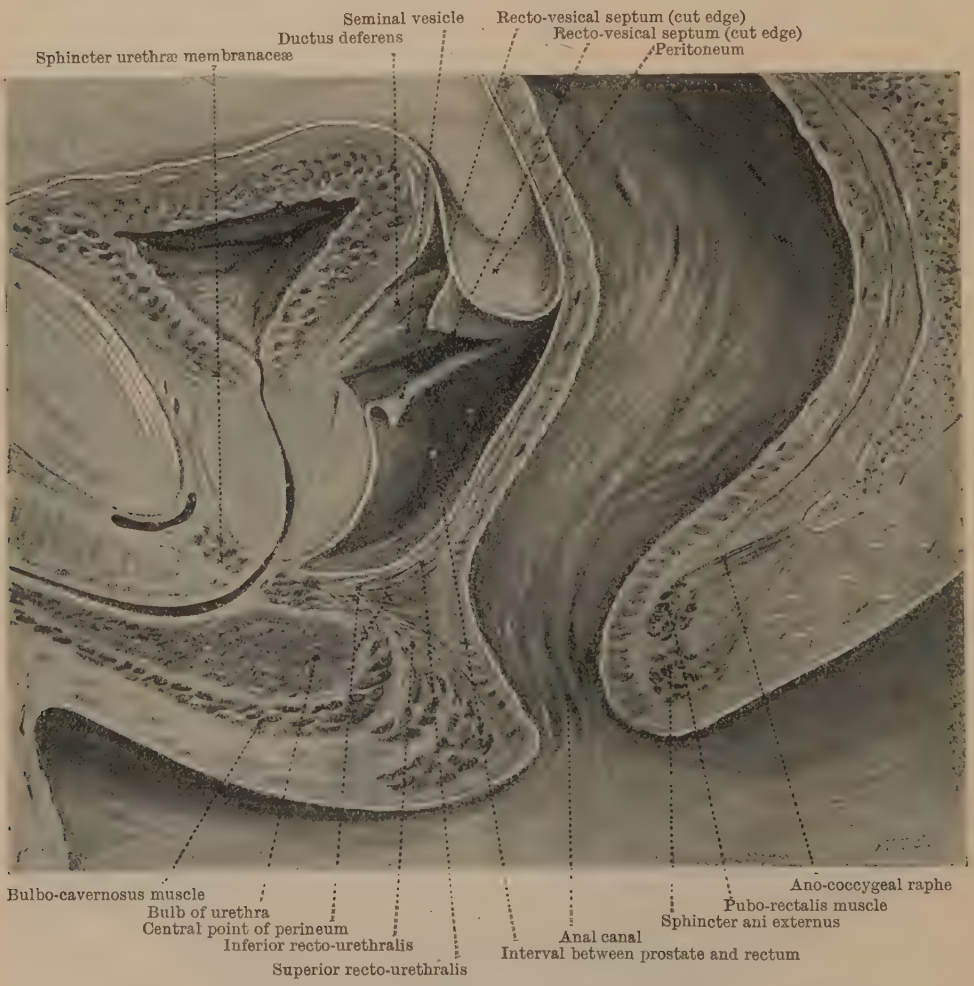

Fig. 410.—Median Sagittal Section of Male Pelvis to show the Relations of the Pelvic Fascia.

this condensation is best marked or gives rise to structures which have a practical bearing for the surgeon.

A strong fascial sheath is provided for the prostate, derived to a very large extent from the fibrous tissue which is condensed around the pudendal (O.T. prostatic) and the prostatico-vesical plexuses of veins. Inferiorly, it abuts on and is inseparably blended with the superior fascia of the urogenital diaphragm and the central point of the perineum, in the median plane (Fig. 410), and with the fascial sheaths of the levatores prostatæ, on each side. Superiorly, the prostatic sheath is continuous with the connective tissue which is condensed upon the infero-lateral aspect of the bladder in association with the vesical veins. Anteriorly, the sheath is attached to the pelvic surface of the pubic bones near the symphysis by the median pubo-prostatic ligaments. These bands and the

fascia which connects them to one another and to the sheaths of the levatores prostatæ contain a number of smooth muscle fibres.

It is necessary to point out that the posterior part of the prostatic sheath differs from the rest of the sheath in its mode of formation, and is a definite layer which can easily be demonstrated by dissection. In a four months' fœtus the recto-vesical peritoneal fossa is very much deeper than it is in the adult, and this alteration in level is brought about by the occlusion of the lower part of the fossa. The two fused layers retain their connexion with the floor of the recto-vesical fossa, above, and they constitute the posterior wall of the prostatic sheath (Fig. 410). This structure is the recto-vesical fascia (of Cunningham), the prostato-peritoneal aponeurosis (of Denonvilliers), and the recto-vesical septum (of Elliot-Smith). Roughly triangular in outline, it reaches the central point of the perineum, below, and the posterior ligaments of the bladder on each side. As it extends upwards to the floor of the recto-vesical fossa, it lies behind the prostate,

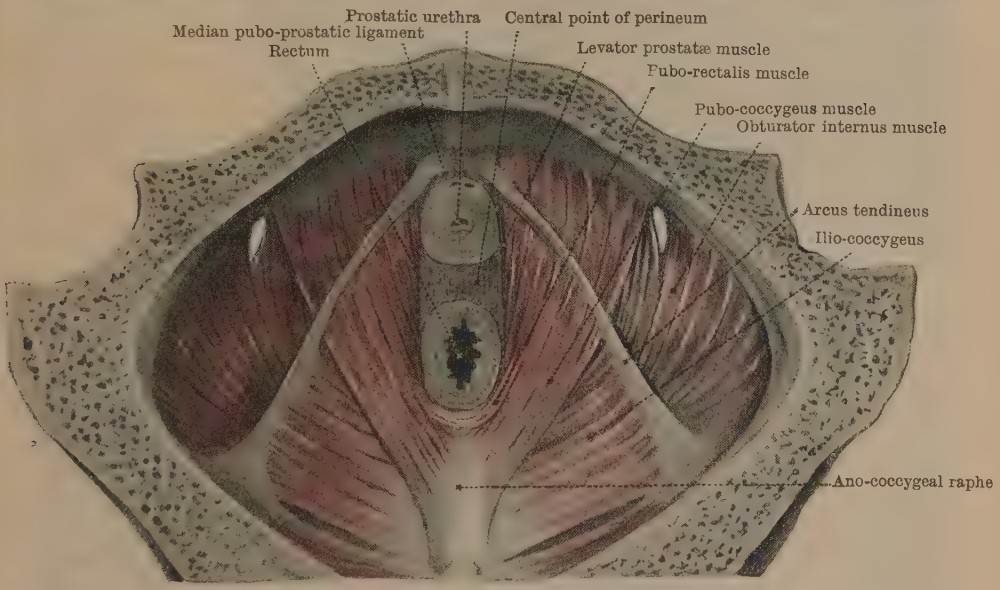

Fig. 411.—The Levator Ani Muscle viewed from above.

the seminal vesicles and the deferent ducts, and the base of the bladder, and is separated from all these structures by a cellular interval. Posteriorly, a similar cellular interval separates it from the anterior aspect of the rectal ampulla (Fig. 410).

The **posterior ligaments of the bladder** consist of a condensation of the sub-peritoneal connective tissue around the ureter, vesical arteries and corresponding veins as they extend between the postero-lateral borders of the urinary bladder and the hypogastric vessels. Anteriorly, this ligament becomes continuous with the condensations which surround the prostatico-vesical and pudendal plexuses of veins, *i.e.* with the fascial coverings of the urinary bladder and the prostate. As they sweep backwards from the bladder, these ligaments lie to the lateral side of the rectum.

A similar condensation of connective tissue surrounds the internal pudendal vessels, the dorsal nerve of the penis, and the perineal branch of the pudendal nerve, as they lie in the lateral wall of the ischio-rectal fossa, and is prolonged forwards around them into the urogenital triangle.

MUSCLES OF THE PELVIS.

Diaphragma Pelvis.—The **pelvic diaphragm** is formed by the levator ani and coccygeus muscles, which serve to uphold the pelvic floor, and are related to the rectum and the prostate or vagina.

M. Levator Ani.—The **levator ani** muscles form a flattened sheet which stretches across the pelvic cavity and separates it from the perineum. Anteriorly, the two muscles are separated by a narrow interval, which is occupied, in the male, by the apex of the prostate and the anal canal, and, in the female, by the urethra, the vagina, and the anal canal. Posteriorly, they meet one another in

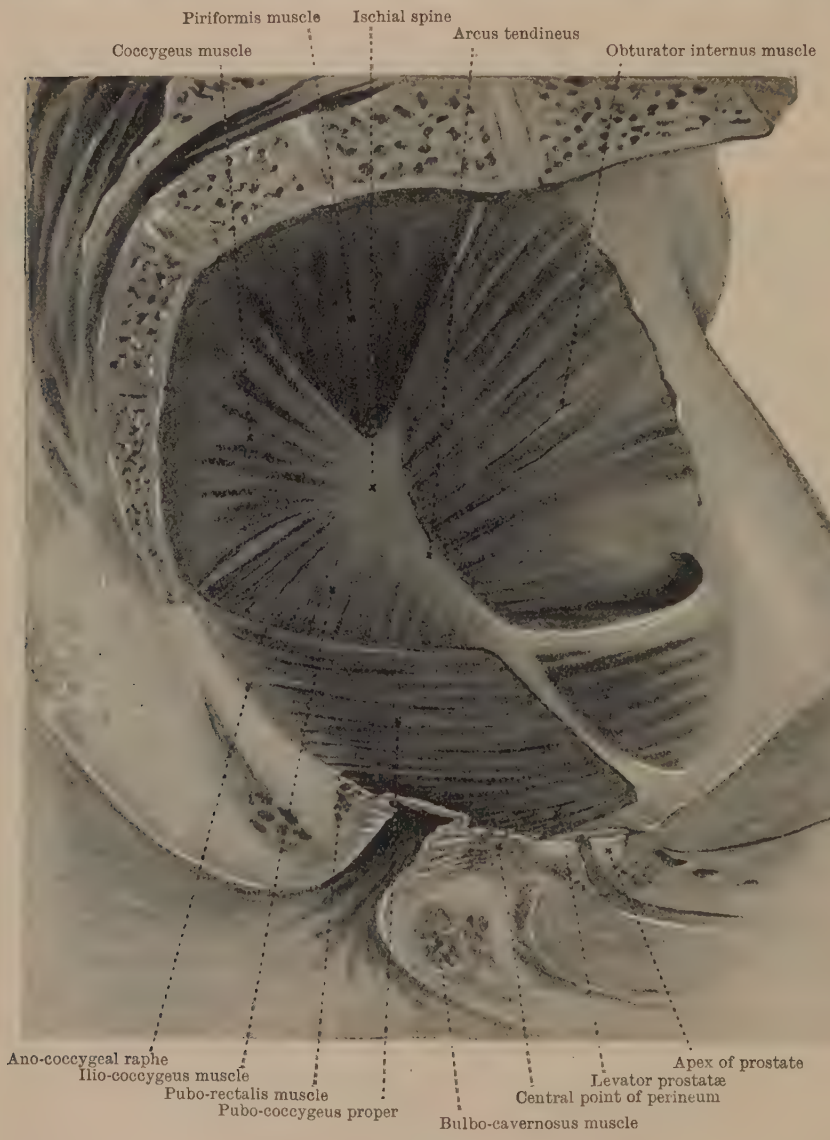

FIG. 412.—THE LEFT LEVATOR ANI MUSCLE.

the ano-coccygeal raphe, which extends between the upper end of the anal canal and the tip of the coccyx.

The muscle **arises** from the pelvic surface of the ischial spine, behind, and from the pelvic surface of the pubic bone, in front, but it does not extend medially so far as the symphysis. Between these two bony attachments it takes a linear origin from the thick fascia which covers the obturator internus muscle (*vide infra*).

Its fibres run backwards and medially and very slightly downwards, with varying degrees of obliquity, and are **inserted** (1) into the central point of the perineum and the wall of the anal canal, (2) into the ano-coccygeal raphe, and

(3) into the front and sides of the coccyx. In addition, some of the fibres form a sling around the upper end of the anal canal.

The levator ani is divisible into two distinct portions, namely, the **ilio-coccygeus** and the **pubo-coccygeus**, and the latter can be subdivided into three parts, imperfectly separated from one another, viz.—the *pubo-coccygeus proper*, the *pubo-rectalis*, and the *levator prostatæ*.

The **ilio-coccygeus** forms the posterior part of the levator ani and its origin extends as far forwards as the obturator canal. The strong fascia from which it arises represents the upward continuation of the muscle to reach the ilio-pectineal line, and has, secondarily, become blended with the fascial covering of the obturator internus. This attachment to the ilio-pectineal line is the primitive origin of the ilio-coccygeus and is the normal condition in many mammals. The fibres run medially to be inserted into the side of the coccyx and the ano-coccygeal raphe, but, at their insertion, they are covered, on their pelvic aspect, by the backward running fibres of the pubo-coccygeus (Fig. 411).

The **pubo-coccygeus** is composed of those fibres of the levator ani which arise in front of the obturator canal. The most anterior (medial) fibres constitute the *levator prostatæ*. They pass backwards in contact with the lateral aspect of the prostate and are inserted into the central point of the perineum and into the wall of the anal canal, where they mingle with the deeper fibres of the sphincter ani externus.

The fibres which arise from the pubic bone lateral to the origin of the levator prostatæ form the *pubo-rectalis*. This muscle sweeps backwards over the lateral aspect of the prostate (or vagina) and the upper part of the anal canal, around which it becomes directly continuous with the corresponding muscle of the opposite side. The pubo-rectales, therefore, form a U-shaped sling for the ano-rectal junction (Fig. 411), and they can constrict the anal canal in the male, and the vagina and anal canal in the female.

The *pubo-coccygeus proper* forms the remainder of this part of the levator ani muscle. Its fibres run backwards and medially, above the fibres of the ilio-coccygeus, and are inserted (1) into the ano-coccygeal raphe, where they meet the fibres of the opposite side, and (2) into the sides and front of the coccyx.

The **coccygeus**, which lies on the same plane as the ilio-coccygeus, is a fan-shaped muscle, **arising** from the pelvic surface of the ischial spine and the sacro-spinous ligament, and being **inserted** into the lateral border of the lower two pieces of the sacrum and the upper two pieces of the coccyx. Its anterior border may be closely applied to the posterior border of the ilio-coccygeus, or a distinct interval, occupied by fat and areolar tissue, may intervene between them (Fig. 412).

Nerve-Supply.—Branches from the anterior rami of the third and fourth sacral nerves supply the levator ani and the coccygeus on their pelvic surfaces. In addition the levator ani is supplied on its perineal surface by the perineal branch of the pudendal nerve.

Actions.—Both these muscles play a very important part in retaining the pelvic viscera in position. In addition, the pubo-rectales reinforce the sphincters of the vagina and anal canal, and the levatores prostatæ draw the central point of the perineum upwards and forwards. This latter action assists in the later stages of expulsion, during defæcation and parturition.

Comparative Morphology.—In pronograde mammals, the ilio- and pubo-coccygei are inserted into the caudal vertebræ and act, respectively, as abductors and flexors of the tail. Although the pubo-coccygei may have a compressing effect on the vagina and rectum, such action is purely secondary. In these animals there is not the same need for a muscular pelvic diaphragm, and, consequently, the two muscles are separated from one another both dorsal and ventral to the rectum.

The adoption of the erect attitude necessitates the provision of a strong, but elastic, pelvic floor, to maintain the pelvic viscera in position and to permit the downward passage of the fœtus. This function is assumed by the pubo- and the ilio-coccygei, which are no longer needed to act on a tail.

THE DEVELOPMENT AND MORPHOLOGY OF THE SKELETAL MUSCLES.

The mesoderm on either side of the embryonic medullary tube separates into three main parts—the **myotome**, **nephrotome**, and **sclerotome** or **lateral plates** (somatopleure and splanchnopleure).

The skeletal muscles are derived for the most part from the myotomes of the mesodermic somites. The limb muscles, however, appear to be formed from the mesenchymal core of the limb-bud, and the visceral muscles of the head and neck are derived from the mesenchyme of the branchial arches. Each **myotome** consists at first of a quadrilateral bilaminar mass, resting against the medullary tube and notochord on either side. The cleft between its two layers represents a diverticulum of the cœlomic cavity. In the early stages of embryonic life the growth of the myotome is rapid. On its medial side masses of cells arise, which grow medially

and surround the medullary tube and notochord to form the foundation of the vertebral column. On its lateral side cells appear to be given off which participate in the formation of the cutis vera. At the same time the dorsal and ventral borders of the myotome continue to extend, and present extremities (growing points) with an epithelial structure for a considerable period. *On the dorsal side* it overlies the medullary tube, and gives rise to the muscles of the back; while by its *ventral extension*, which traverses the somato-pleuric mesoderm in the body wall, it produces the lateral and ventral muscles of the trunk. By a medial extension it probably gives rise also to the hypaxial muscles of the neck. The cells of the medial layer of the myotome are responsible for the formation of the muscle fibres. The innervation of a myotome or of a pre-muscle mass is determined at a very early stage of development, and the nerve-supply of a muscle is consequently the best guide to its morphology.

Portions of two or more neighbouring myotomes may fuse to form a skeletal muscle, and this

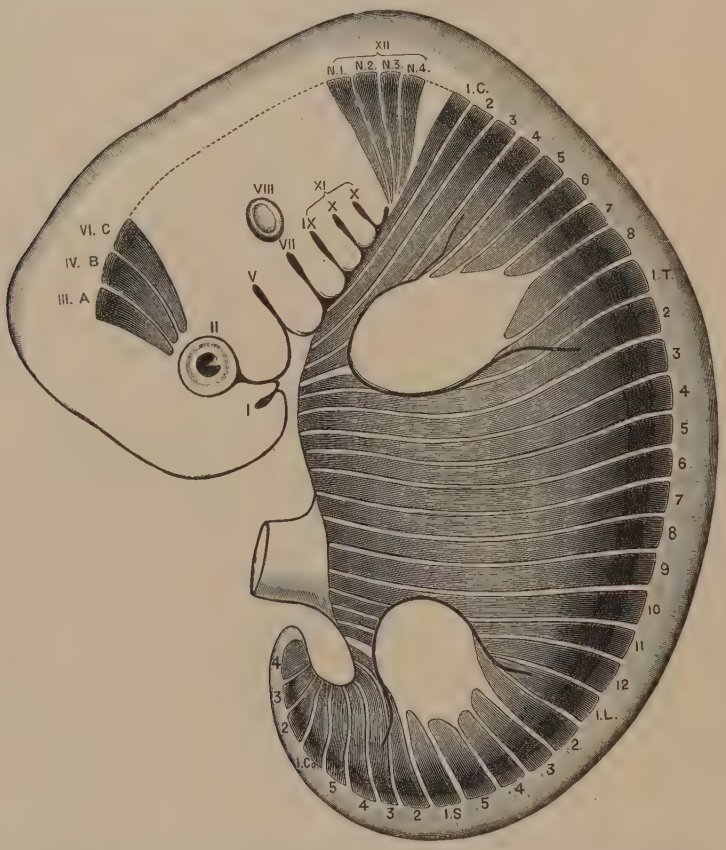

FIG. 413.—SCHEME TO ILLUSTRATE THE DISPOSITION OF THE MYOTOMES IN THE EMBRYO IN RELATION TO THE HEAD, TRUNK, AND LIMBS.

A, B, C, First three cephalic myotomes; N, 1, 2, 3, occipital myotomes; C., T., L., S., Co., The myotomes of the cervical, thoracic, lumbar, sacral, and caudal regions; I., II., III., IV., V., VI., VII., VIII., IX., X., XI., XII., refer to the cerebral nerves and the structures with which they may be embryologically associated.

is the common mode of origin, as it is only in a few groups that the individual muscles can be referred to single myotomes.

In the course of growth and development a muscle may become widely separated from the skeletal elements which are derived from the same somites as its myotomic constituents. The diaphragm (C. 3. 4. and 5.) is an excellent example of "muscle migration." In the same way muscles derived from the mesenchymal core of the limb-buds may spread to the trunk and there obtain attachments to skeletal elements at a considerable distance. Such "migration" occurs to a very marked extent in the case of the latissimus dorsi muscle.

Musculature of the Trunk.—The **dorsal portion** of each myotome becomes separated off and becomes continuous with the corresponding portions of neighbouring myotomes, so that a longitudinal pre-muscle column is formed, to which the posterior rami of the spinal nerves are distributed. This column gives rise to the muscles of the back of the neck and the back of the trunk, and they become differentiated from one another by the formation of longitudinal septa. The deeper parts of the dorsal portions of the myotomes remain separate in certain regions and constitute the rotatores and interspinales.

The **ventral portion** of each myotome carries off the anterior ramus of the corresponding nerve and spreads ventrally into the somatopleure, dorsi-lateral to the derivatives of the intermediate cell tract. (*a*) The dorsal portion of this strip separates off from the rest and fuses with the corresponding portions of neighbouring segments. The column so formed persists in man only in the cervical region, where it gives rise to the longus colli, longus capitis, and the crura of the diaphragm. (*b*) The ventral extremities of this extension into the somatopleure behave in a similar way, giving rise, in man, to the rectus abdominis, the pyramidalis, the sterno-costal portions of the diaphragm, and, probably, the infra-hyoid group of muscles. (*c*) The intermediate portions of these strip-like extensions into the somatopleure become fused and then are delaminated into as many as five layers in some vertebrates. In man, only three such layers are formed, viz. the obliquus externus, the obliquus internus, and the transversus abdominis. Dorsally, the quadratus lumborum, with its enclosing layers of the lumbo-dorsal fascia, is derived from the same source. In the thoracic region, however, the fusion of the individual myotomic derivatives is only carried out in the case of the transversus thoracis. The more superficial derivatives constitute the external and internal intercostal muscles, which retain their segmental characters. In the cervical region it appears probable that the corresponding myotomic derivatives in part disappear and in part form the scalene muscles and the remaining portion of the diaphragm.

The ventral portions of the lumbar (with the exception of the first) and the upper sacral myotomes disappear in man, but they persist in the third and fourth sacral somites and give rise to the levator ani and the coccygeus.

The occipital myotomes form the muscles of the tongue.

It may here be pointed out that the diaphragm, which may justly be termed the most essential of all the skeletal muscles in man, is derived to a very large extent, if not entirely, from the ventral portion of the fourth cervical myotome. The crura are on the same morphological plane as the longus colli; the sterno-costal portions are on the same morphological plane as the rectus abdominis; and the rest of the muscle is on the same morphological plane as the transversus abdominis. The phylogenetic history of the diaphragm shows that it represents the detached cervical portion of the transversus sheet. In Amphibia and Reptilia there is no separation of the pleural and peritoneal cavities, and the whole transversus sheet functions as a compressor of the cœlom and so as a muscle of expiration. In Mammalia, on the other hand, the diaphragm intervenes between the pleural and the peritoneal cavities, and its action as a cœlomic compressor is restricted to the latter. At the same time, its new position makes it a powerful inspiratory muscle, and in man it is of very much greater importance than all the other muscles which, primarily or secondarily, help to increase the capacity of the thorax. In pronograde mammals, on the other hand, inspiration depends much more on elevation of the ribs by the external respiratory muscles, and the principal action of the diaphragm in these animals would seem to be its primitive action as a compressor of the cœlom.

The **branchial musculature** is formed in the mesenchyme of the branchial arches and is quite distinct from the musculature derived from the occipital and cervical myotomes, not only in its source but also in its innervation, which is obtained from certain of the cranial nerves. Although laid down in the substance of the arches, the branchial muscles may undergo extensive "migration." This change of position is best exemplified by the muscles of the second arch (*vide infra*).

The accompanying table indicates the muscles derived from the individual branchial arches with their nerves of supply:—

Arch.	Nerve.	Muscles.
First (mandibular)	Mandibular division of trigeminal nerve	Muscles of mastication Tensor tympani Tensor veli palatini
Second (hyoid)	Facial	Muscles of facial expression (including mm. of scalp and platysma) Stylo-hyoid Posterior belly of digastric Stapedius
Third	Glosso-pharyngeal	Stylo-pharyngeus Constrictors of pharynx (in part) ? Muscles of soft palate (in part)
Fourth Fifth ? Sixth	Vagus (superior laryngeal and recurrent branches)	Muscles of larynx Constrictors of pharynx (in part) Muscles of soft palate (in part)

Muscles of the Orbit.—It has not been possible to identify cephalic myotomes in the human embryo. The muscles of the orbit can be distinguished in the embryo as a single pre-muscle mass, closely related to the optic vesicle and receiving the terminations of the third, fourth, and sixth cranial nerves. Myotomes have been demonstrated in the head region of elasmobranch fishes: the precise number is uncertain, but there are probably at least nine, of which the last four are occipital. The first three cephalic myotomes form the muscles of the orbit, the first giving

rise to the group supplied by the oculo-motor nerve, the second to the superior oblique, and the third to the lateral rectus muscle. The fourth and subsequent myotomes disappear, but the occipital myotomes persist to form the muscles of the tongue.

Musculature of the Limbs.—The developing limb-bud consists of an ectodermal envelope enclosing a mass of mesenchyme, from which both the skeletal elements and the musculature of the limb are derived. Ventral and dorsal sheets of muscle are laid down, and they are at first continuous with one another along the pre- and post-axial borders of the bud. The anterior rami of the spinal nerves which eventually enter into the formation of the limb plexus are at first arranged segmentally in the developing limb, and each gives ventral and dorsal branches to exactly corresponding portions of the muscle sheets. It will therefore be found that the muscles which develop along the pre-axial border, whether ventral or dorsal, are innervated by the highest nerve of the plexus, while those which develop along the post-axial border are innervated by the lowest nerve of the plexus. This early subdivision of the limb musculature into ventral and dorsal sheets, and the innervation of portions of both sheets by every nerve of the limb plexus, are indicated in the upper limb of the adult by the division of the trunks of the brachial plexus into anterior and posterior divisions prior to the formation of the cords.

The proximal portions of these muscle sheets extend towards the trunk and eventually constitute the muscles which connect the limb or its girdle to the trunk (with the exception of the trapezius). These muscles are much more numerous in the upper than they are in the lower limb, where their only representatives are the psoas magnus and the psoas parvus.

THE NERVOUS SYSTEM.

I.—THE CENTRAL NERVOUS SYSTEM.

Originally written by D. J. Cunningham, F.R.S.,
Late Professor of Anatomy, University of Edinburgh;
Revised and partly rewritten by G. Elliot Smith, F.R.S.,
Professor of Anatomy, University of London.

ELEMENTS OF THE CENTRAL NERVOUS SYSTEM.

Every type of nervous system with which we are acquainted, from the simplest and most primitive, such as that of Hydra, to the most complex and highly elaborated mechanism found in man, is composed essentially of three categories of elements. These are (1) **sensory cells,** so situated and so specialised in structure as to be capable of being affected by changes in the animal's environment, and of transmitting the effects of such stimulation, directly or indirectly, to (2) **efferent nerve-cells,** which influence the muscles or other active tissues, so that the stimulation may find expression in some appropriate action; and (3) **intercalated nerve-cells,** which regulate such responsive behaviour by bringing it under the influence of other sensory impressions and of the state and activities of the body as a whole.

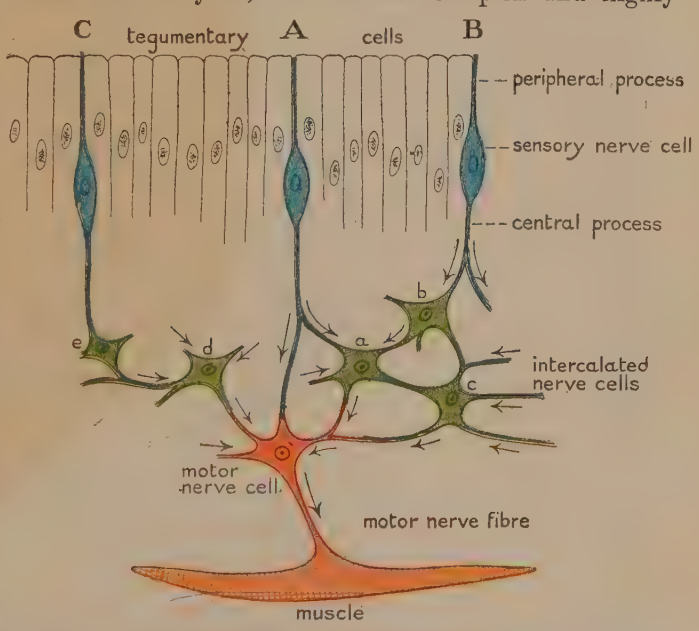

Fig. 414.—A Diagram representing the Essential Features in the Arrangement of the most primitive Type of Nervous System.

The study of a simple scheme representing the relationship that obtains between these three classes of elements in the extremely primitive animal, Hydra (Fig. 414), will make these fundamental facts plain. Changes in the animal's environment affect the extremities of the **peripheral processes** of the sensory cells (*A*, *B*, and *C*), which in Hydra are situated amongst the ordinary tegumentary cells: the effect is transmitted by the **central processes** of such cells (*A*, for example), either directly to the efferent cell, represented in the diagram by a **motor nerve-cell,** or

more usually to an intercalated nerve-cell (*a*, *b*, or *e*). Into this (*a*) impulses stream from other intercalated cells (*b* and *c*), bringing the impulse from the sensory cell *A* under the influence of those coming from *B* and from more distant parts of the body through the intermediation of the intercalated cell *c*. The cells *a*, *c*, and *d* are connected with the motor nerve-cell. Thus, there is provided a mechanism whereby the conditions affecting other regions of the body, *B* and *C*, may influence the nature of the response which the stimulation of *A* evokes—either increasing or diminishing its effect or perhaps altering its character.

In this way the intercalated nerve-cells form a great co-ordinating mechanism, linking together all parts of the body in such a way that the activity of any part of the organism may be influenced by the rest, and thus be enabled to act in the interest of the whole.

Hence the nervous system becomes the chief means whereby the various parts of the body are brought into functional relationship one with the other, and co-ordinated into one harmonious whole.

Throughout the whole course of its subsequent evolution the nervous system is formed of these three kinds of elements; and the essential feature in its elaboration and increasing complexity is the multiplication of the intercalated cells, and their concentration, together with the motor nerve-cells, to form a definite organ, which we call the **central nervous system**.

During this process of development of the more complex forms of nervous system, most of the sensory cells migrate from their primitive positions in the skin (Fig. 414); and, as the free extremity of the peripheral process retains its primitive relationship to the skin, such migration of the cell bodies necessitates a great elongation of their peripheral processes. Although these sensory cells thus move inwards into the deeper tissues of the body, the great majority of them do not become incorporated in the central nervous system, but become collected into groups, which form the **ganglia** of the sensory nerves.

In addition to its primary functions of (*a*) providing the means whereby the organism can be brought under the influence of its surroundings, and (*b*) co-ordinating the activities of the whole body, the nervous system also comes to perform other functions of wider significance.

In the course of its evolution the co-ordinating mechanism formed by the intercalated cells becomes so disposed in each animal that an appropriate stimulus applied to the sensory nerves can evoke a definite response, often of great complexity and apparent purposiveness. In other words, the nervous system becomes the repository of those inherited dispositions of its constituent parts which determine the instincts: and in the course of time it eventually provides also the apparatus by which individual experience and the effects of education can be brought to bear upon and modify such instinctive behaviour. In other words, from the nervous system is formed the instrument of intelligence; and the relatively great bulk and extreme complexity of that instrument—the brain—in man are in a sense the physical expression of human intellectual pre-eminence.

In conformity with its primary function of affording a means of communication with the outside world, a great part or, according to most writers, the whole of the nervous system in the human embryo, as in other animals, is developed from the ectoderm, as has already been explained in the chapter dealing with General Embryology (p. 35 *et seq.*). In the most primitive Metazoa the sensory cells remain in the ectoderm (Fig. 414), but other cells become converted into motor nerve-cells and intercalated nerve-cells, which are found in the underlying tissues (Fig. 415). In the human embryo there is an analogous process of development, but with the important difference that the various nervous elements do not wander into the mesoderm individually. A definite patch of ectoderm is set apart to produce the greater part of the nervous tissues for the whole body; and all except the margins of this area sinks into the body, *en masse*.

In one area all the motor nerve-cells develop (Fig. 415, *d*), in another (*c*) only intercalated nerve-cells, in yet another (*b*) the sensory cells originate; and the rest forms the epidermis of the skin (*a*). With our knowledge of the fact that the sensory cells were originally distributed throughout the skin (Fig. 414), the

idea naturally suggests itself that in man also the units of the sensory ganglia might be formed *in situ* in the ectoderm, and that the collection of sensory cells in the ganglia might possibly be brought about by the migration of such sensory cells inwards, while their peripheral processes elongate to permit such migration of the cell bodies without disturbing their original endings in the skin. But there is no evidence to show, or even to suggest, that such a process takes place in the human embryo. The facts at our disposal seem to indicate that the sensory cells are derived from sharply circumscribed patches of ectoderm, and that the peripheral processes of these cells are distributed to the outlying area of ectoderm beyond them, from which the epidermis is eventually formed (Fig. 415).

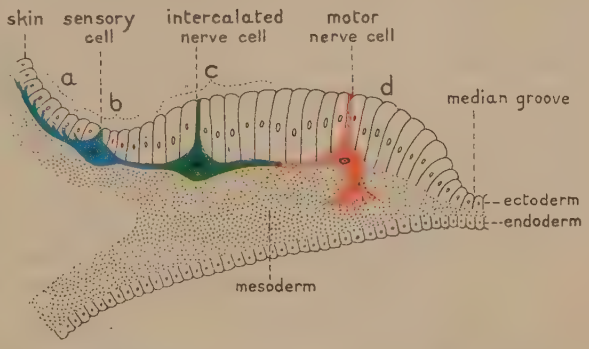

Fig. 415.—Diagram representing (in black) the Left Half of a Transverse Section of a 2 mm. Human Embryo. Superimposed upon it there is shown (in colours) the hypothetical primitive arrangement of the nervous elements derived from each part of the ectoderm.

At the beginning of the second week the nervous system of the human embryo is represented by two thickened plates of ectoderm lying parallel the one to the other, alongside the median axis of the embryo (Fig. 416), which is occupied by a shallow furrow.

Upon a diagram (Fig. 415), representing a transverse section through one-half of such an embryo (the uncoloured part), colours corresponding to those employed in Fig. 414 have been placed to indicate the nature of the elements that are known to

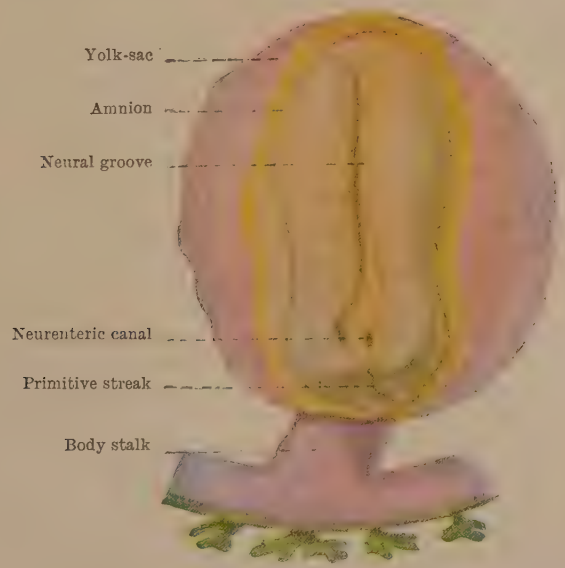

Fig. 416.—The Dorsal Aspect of a Very Early Human Embryo. (After von Spee.)

develop in relation with each area of the ectoderm at a later period in the history of the embryo: *b* represents an area which later will form the **crista neuralis**, from which the sensory cells will be developed. The peripheral processes of these cells will pass into the skin (*a*) and their central processes into the area *cd*, which will become part of the neural tube. In the area *c* intercalated cells will develop to

receive the incoming sensory nerves; and in connexion with the area *d* the motor nerve-cells (as well as other intercalated cells) will be formed.

While we are studying Fig. 415 it is important to emphasise the fact that in accordance with the commonly accepted ideas it is taught that the area *b* becomes completely severed from *a* and *c*, and shortly afterwards fibres are budded off from the cells in the area *b* to form the sensory nerves linking *a* to *c*, thus re-establishing a connexion which existed a few days earlier. This suggests the possibility that the connexions between these three series of elements may not have been completely sundered during the intermediate phase of development. Early in the second week in the human embryo the axial groove separating the two bands of thickened ectoderm (Fig. 416) that form the medullary plate becomes deepened by the tilting-up of the lateral margins of the two bands. This process becomes accentuated during the next day or two until a deep cleft is formed, the walls of which consist of the thickened ectoderm and the floor of the thinner ectoderm **(floor-plate)** joining them together. Before the end of the week the dorsal edges of these thickened plates become joined in the region which will develop into the neck; and during the third week the sealing of the lips of the neural groove extends upwards (headwards) and downwards (tailwards), so that the neural tube becomes completely closed by the end of that week. The extreme anterior (head-) end and the dorsal aspect of the caudal extremity of the tube are the last parts to close, the latter being, as a rule, a little later than the former. When the tube is in the stage of being patent only at its two ends, the openings are known as the **neuroporus anterior** and **neuroporus posterior**, respectively.

In the process of closing, the extreme dorsal edge of the medullary plate becomes excluded, in the greater part of its extent, from participation in the constitution either of the neural tube or of the skin, and forms a column of cells lying between the two. This is the **neural crest** (Fig. 417, A, B, and C; *x* and *y* represent the places where the apparent sundering occurs).

It is commonly supposed that the neural crests do not extend the whole length of the neural tube. Nevertheless, peculiar ectodermal areas, which ultimately give origin to sensory nerves, are found at the junction of the medullary plate with the skin in those regions where the neural crest is supposed to be lacking. At the extreme anterior end of the neural tube the margins of the anterior neuropore become thickened to form crest-like patches; but when the tube closes these areas do not separate from the skin (at *x*, Fig. 417, D), as the rest of the neural crest does. They remain part of the skin and become the olfactory areas, in which sensory cells, precisely like those found in Hydra (Fig. 414), develop.

A little farther on the caudal side of the olfactory region a very large crest-like mass of ectoderm fails to separate from the medullary plate as it closes, and becomes a constituent part of the neural tube (Fig. 417, E). When the optic diverticulum grows out it carries out to the periphery these sensory cells mixed with intercalated cells of the medullary tube to form the composite sensitive membrane of the eye known as the retina.

In several other regions sensory nerves originate from cells of ectodermal, and possibly even entodermal, areas which do not form parts of the neural crest, as that term is usually understood. The nerves of hearing and taste are developed in a way that seems at first sight utterly abnormal, until it is remembered that they afford examples of very primitive methods of nerve-formation.

The essential part of the organ of hearing is an ectodermal sac (otic vesicle) that develops as a diverticulum on the side of the head, from a thickened patch of ectoderm, which in the lower vertebrates forms part of a more extensive area, known as the **dorso-lateral placode.** Some of the cells of this area seem to become transformed into nerve-cells, which migrate into the space between the otic vesicle and the neural tube (Fig. 418) and form the acoustic ganglion.

At the upper margins of the branchial clefts a series of ectodermal and entodermal thickenings develop, which are known as the **epibranchial placodes.** Comparison with the process of development in fish embryos, which has been elucidated by Landacre (*Journal of Comparative Neurology and Psychology*, 1910–1912), suggests that the nerve-cells arise from these placodes, which give

origin to the nerves of taste. Such fibres are constituent elements of the facial, glosso-pharyngeal, and in some animals also the vagus cerebral nerves (Fig. 418), in connexion with the ganglia of which epibranchial placodes are formed (Froriep and Streeter). The observations of Professor J. P. Hill upon embryos of Echidna seem to suggest that in mammals the gustatory neuroblasts are derived from the entoderm.

When first formed, the neural tube is compressed from side to side and presents an elliptical outline in transverse section (Fig. 419). The two side walls are very thick, whilst the narrow dorsal and ventral portions of the wall are thin, and are termed the **roof-plate** and **floor-plate** respectively (Fig. 419). The cavity of the tube in transverse section appears as a narrow slit. The wall of the neural tube consists at first of low columnar epithelium arranged in a fairly regular series, but with a certain number of large spherical so-called **germinal cells** scattered between the columns. But this regular disposition as a single layer of cells does not last long. For even by the second week the rapid proliferation of the cells has led to a marked increase in the thickness of the side wall and a scattering of the more numerous nuclei, apparently irregularly, throughout its substance (Fig. 419). The latter consists of a network of protoplasm in which definite outlines of cells cannot be detected. As growth proceeds the innermost part of this nucleated protoplasmic syncytium becomes condensed to form a delicate membrane termed the **internal limiting membrane**, which lines the lumen of the tube, whilst its outermost part presents a similar relation to an **external limiting membrane**, which invests the outer surface of the tube. Toward the end of the first month the side walls of the tube show signs of a differentiation into three layers. Next to the central canal there is an epithelial-like arrangement of the innermost cells of the syncytium, forming the **ependyma**. Then there is an intermediate layer crowded with nuclei, hence known as the nuclear or **mantle layer**. On the surface is a layer singularly free from nuclei, which is called the non-nuclear or **marginal layer**. The germinal cells are placed in the ependymal layer between its radially arranged cells as they pass in towards the internal limiting membrane; and the protoplasm of the germinal cells forms part of the syncytium.

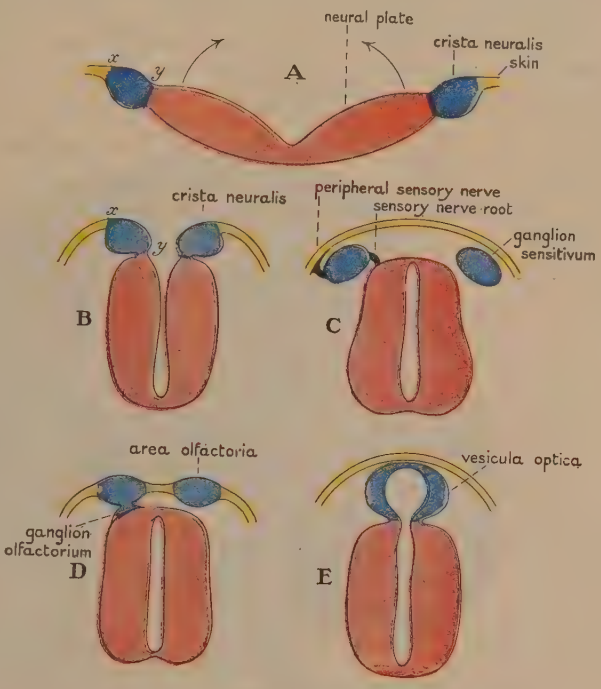

FIG. 417.—DIAGRAMS OF TRANSVERSE SECTIONS REPRESENTING THREE STAGES (A, B, AND C) IN THE DEVELOPMENT OF A SENSORY GANGLION FROM THE NEURAL CREST; AND TWO DIAGRAMS (D AND E) SUGGESTING A POSSIBLE HOMOLOGY OF THE OLFACTORY (D) AND VISUAL (E) EPITHELIUM WITH THE NEURAL CREST. The optic vesicle is a mixture of sensory and intercalated nerve-cells: hence it is not correct to represent it as a purely sensory element. The hypothetical arrangement labelled "vesicula optica" is the optic placode, the sensory elements of which mingle with the neuroblasts of the neural tube and a mixture of the two elements grows out to form the true optic vesicle.

At one time it was imagined that the germinal cells were embryonic nerve-cells, the parent-cells of the real **neuroblasts**, and that the whole of the rest of the syncytium represented the supporting tissues, which in the adult form the **neuroglia.** But it is now known that from the proliferation of the germinal cells, in which

mitotic figures can usually be seen, some cells are formed which become ependymal epithelium, and others which migrate peripherally into the mantle layer. There, while forming part of the mantle syncytium, they undergo further proliferation and some of the resulting cells develop into **spongioblasts**, which constitute the supporting framework, the embryonic neuroglia; others become rudimentary nerve-cells or **neuroblasts**, and others again are known as **indifferent cells**. The latter are destined to undergo further subdivision and become the parents of more spongioblasts and neuroblasts.

From this it is clear that the greater part—all except the germinal cells—of the syncytium, which is known as the **myelospongium**, is not merely supporting neuroglial tissue, as was once supposed, but is the rudiment of both neuroglia and true nervous tissues.

The details of the process by which the neuroblasts become dissociated from the neuroglial network are quite unknown. It is commonly supposed that a spherical cell in the mantle layer that is to be transformed into a neuroblast

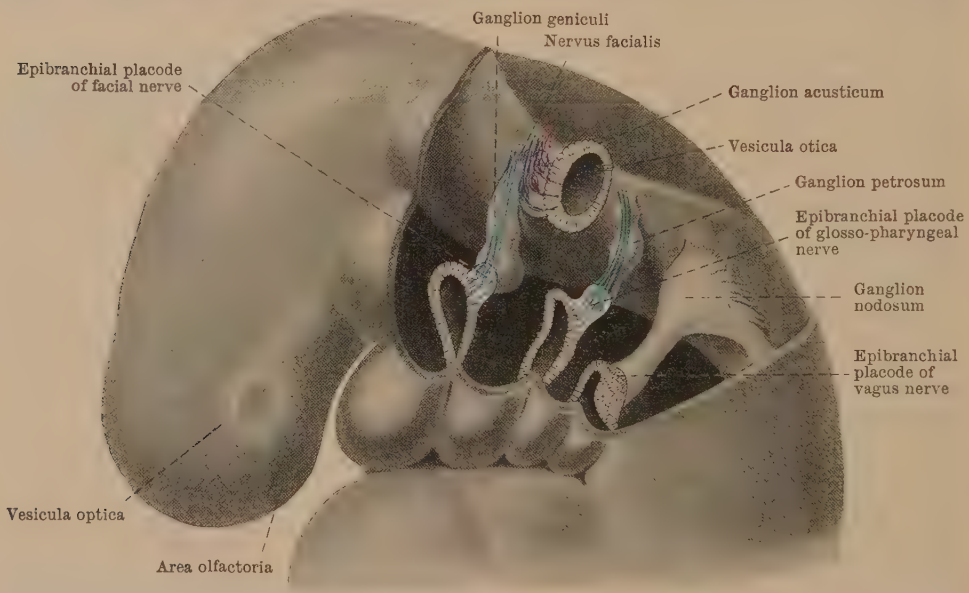

FIG. 418.—RECONSTRUCTION OF THE GANGLIA OF THE FACIAL, ACOUSTIC, GLOSSO-PHARYNGEAL, AND VAGUS NERVES OF A HUMAN EMBRYO 5 MILLIMETRES LONG (ABOUT THREE WEEKS OLD).

The epithelium of three branchial clefts and the otic vesicle is represented diagrammatically; and the supposed mode of origin of the gustatory nerve-cells (and their fibres) from the epibranchial placodes is indicated in blue, and of the acoustic nerve-cells from the otic vesicle in purple.

frees itself from the syncytium, and remains for a time independent and wholly unattached amidst the meshes of the neuroglial network: it is supposed further that its true nature as a neuroblast becomes revealed when it takes on a pear-shape, and a protoplasmic process, the stalk of the pear, pushes its way into some other part of the nervous system, or out of it into the mesoderm to reach some muscular or glandular tissue, and becomes the axis cylinder process or axon of the nerve-cell.

Such an interpretation of the appearances exhibited in the walls of the neural tube at the end of the first month is adduced in support of a view concerning the constitution of the nervous system known as the **neurone theory**. "Neurone" is the term applied to a nerve-cell and all its processes; and the neurone doctrine assumes that there is no continuity whatever between the substance of one neurone and that of another, such as occurs in Hydra (Fig. 414), and that the functional connexions between them are brought about merely by the contact of the processes of one element with the processes, or the cell-body itself, of another element. In accordance with this conception the facts of embryology are supposed (by His) to demonstrate that when the axon grows out from a previously spherical and unattached cell

it is able to push into the surrounding tissues, and, as it were guided by some instinct, eventually finds its way to that particular area of skin, muscle, gland, or other part of the body where nature intends it to go.

This is the current teaching in regard to the neurone theory; and it is supposed to have been conclusively demonstrated by the facts revealed not only by embryology and the study of the minute structure of the nervous system, but also by the phenomena of degeneration and regeneration. Harrison has shown that the outgrowth of processes can be witnessed in the living nerve-cells of the frog. There are certain facts, however, which have always led some anatomists to refuse to believe in the validity of the neurone doctrine as a true expression of the real constitution of the nervous system. It has been clearly demonstrated by Graham Kerr that at a very early stage of development the neural syncytium of the spinal medulla (of the mud-fish Lepidosiren) is in free and uninterrupted continuity with

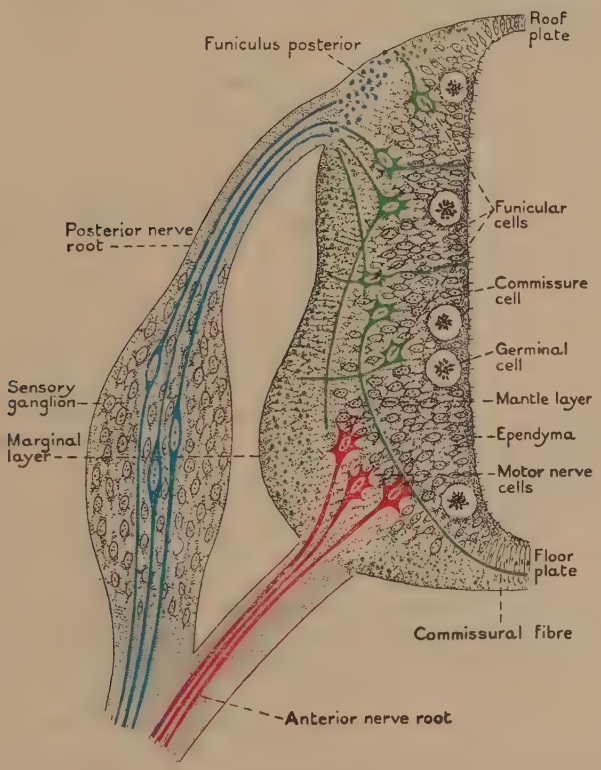

Fig. 419.—Diagram of Transverse Section of Early Neural Tube.

the protoplasm of the muscle-plate, which lies in contact with the neural tube; and no stage is known in which these connexions do not exist. When, in the course of the subsequent growth of the embryo, the muscle-plate becomes removed further and further away from the central nervous system the protoplasmic strand, which links them the one to the other, gradually becomes stretched and elongated. As the neuroblast matures its chemical constitution becomes modified; it becomes specialised in structure to fit it for the peculiar functions it has to perform. These changes manifest themselves first in the body of the neurone itself and thence spread along its processes. With the knowledge that protoplasmic bridges exist long before the time His supposed the axon of his neuroblast to push its way outward, it seems not unreasonable to suppose that it is the chemical modification of these existing bridges which has been revealed in stained specimens, as it spreads from the cell-body outwards into its processes.

It is now a well-recognised fact that soon after the neural tube becomes closed the outlines of its constituent cells become blurred and then disappear, and a continuous protoplasmic network or syncytium is formed. No one has ever been

able to detect the process of detachment of embryonic nerve-cells (neuroblasts) from this syncytium; and it is at least a possibility that the free anastomosis of the protoplasmic processes of many of the cells is not destroyed in the way demanded by the neurone doctrine. The known facts might be interpreted, at least as reasonably, by supposing that when nerve currents begin to traverse the syncytium (Fig. 419) structural modifications occur around the nuclei of the cells affected, and gradually spread along their processes, so as to give the appearance (in sections stained by special methods) of processes growing out from each neurone.

Impulses brought from the skin by the sensory nerves, the nutrition of which is controlled by the cells in the sensory ganglion (Fig. 419), are carried into the wall of the neural tube, where they are received by processes of intercalated cells, which in turn transmit their effects directly or indirectly to (*a*) motor nerve-cells (or other kind of efferent nerve-cells), which stimulate a muscle, a viscus, or other active tissue to perform some work, or (*b*) to intercalated cells, the axons of which proceed to some other part of the nervous system, perhaps above or below the place where the sensory nerve enters (Fig. 419, *funicular cells*). As the walls of the neural tube increase in size the various neurones gradually become drawn apart, and the protoplasmic links uniting them become stretched and extended to form processes of varying length.

It is right to explain that most writers give an explanation of the process of development which is at variance with that just sketched. The neuroblast is supposed to originate as a free-lying spherical cell, which is stimulated by some unknown force, sometimes assumed to be of the nature of a chemical attraction (chemotaxis), to protrude a process, which gradually elongates and pushes its way through the tissues, perhaps to some particular patch of skin, muscle, gland, or some other nerve-cell. The difficulty involved in such a conception is not only that it is opposed to all that is known of the early stages in the evolution of the nervous system, but also that it is difficult to conceive that every one of the millions of nerve-cells, muscle-cells, visceral and cutaneous elements can each have some specific attractive power which leads every individual nerve fibril to its appropriate and predestined place in the body.

The Efferent Nerves.—The efferent cells of the neural tube are distinguished by the fact that their axons leave the central nervous system and traverse the mesoderm for a longer or shorter distance to end in relation to some muscle or nerve-cell outside the nervous axis. In the course of the growth of the body the various structures supplied by efferent fibres become removed progressively further and further from the central nervous system; and in this process a distinction can be detected in the behaviour of the efferent fibres (*a*) proceeding to the striped or voluntary muscles, and those (*d*) conveying impulses destined for viscera and unstriped muscle, respectively. The efferent cells (*a*) which innervate voluntary muscles take up their positions in the central nervous system, their axis-cylinder processes (motor nerves) becoming elongated in proportion to the migration of the muscle from its original situation. But the cells (*c*) innervating non-striped muscles and viscera are disposed in a different manner. They lie outside the central nervous system either as constituent elements of one of the so-called **sympathetic** or **autonomic ganglia**, or as peripheral ganglia near to or within the walls of the viscera. Impulses from the central nervous system are transmitted to these sympathetic ganglia by means of fibres (white rami communicantes) arising from cells (*d*) within the central organ; and it is customary to distinguish these latter elements as **splanchnic efferent cells**. It is, however, a matter of fundamental importance to recognise clearly that the real splanchnic efferent cells, the homologues of the **somatic efferent cells**, are found in the sympathetic ganglia, and that the elements to which this term is usually applied are in reality intercalated cells.

Nerve Components.—From the statements in the preceding paragraphs it must be evident that there are several varieties of afferent and efferent nerves respectively entering and leaving the central nervous system. The cells of origin of the efferent nerves collect in the ventral part of the side wall of the neural tube; and for this reason this part of the wall becomes swollen at an early stage of develop-

ment (Figs. 420 and 421). It is called the **basal lamina.** Most of the cells that emit afferent fibres are situated in the sensory ganglia outside the central nervous system, so that their growth can have no direct influence upon the form of the neural tube; but their central processes become inserted into the dorsal part of the side wall of the tube, which is called the **alar lamina**; and groups of intercalated cells collect around the entering fibres to form **receptive** or **terminal nuclei.** The growth of these terminal nuclei leads to an expansion of the alar lamina which is analogous to, but much less extensive than, that seen in the basal lamina. This unequal swelling of the dorsal and ventral parts of each side wall of the neural tube leads to the development of a longitudinal groove, **sulcus limitans**, as a demarcation between the alar and basal laminæ.

The nuclei of origin of the efferent fibres, which are found in the basal laminæ, may be divided into two (and, in some regions of the nervous axis, three) main groups. There is first the group of large multipolar nerve-cells which emit fibres to innervate the ordinary striped voluntary muscles. This is commonly called the **somatic efferent nucleus.** Then there is a group of small multipolar cells, the axons of which pass out into sympathetic ganglia, and indirectly control the involuntary unstriped muscles and other active parts of viscera. These cells form the **splanchnic efferent nucleus.**

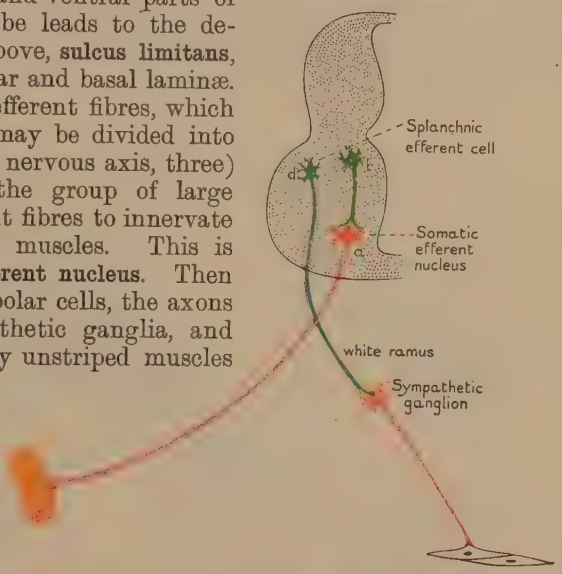

FIG. 420.—DIAGRAM OF A TRANSVERSE SECTION THROUGH THE LEFT HALF OF THE NEURAL TUBE REPRESENTING THE ARRANGEMENT OF THE EFFERENT NERVES, TO SUGGEST THE POSSIBLE HOMOLOGY OF A SYMPATHETIC GANGLION CELL AND A CENTRAL MOTOR CELL AND OF A WHITE RAMUS WITH THE AXONS OF INTERCALATED CELLS.

In the upper cervical and lower cranial region a portion of the somatic efferent nucleus is set apart to innervate the striped muscles developed in the branchial arches. This is the **lateral somatic** or **intermediate efferent nucleus.** Many recent writers are of the opinion that this nucleus is **splanchnic**; but its component nerve-cells are typically somatic and its fibres directly innervate striped voluntary muscles, which are developed from the same material (myotomes) from which the other striped muscles are formed (Agar and Graham Kerr). Hence it is altogether unjustifiable to refuse it the appropriate designation "somatic."

The alar lamina also can be subdivided into a series of functional areas (Fig. 421).

At the dorsal edge is the **somatic afferent terminal nucleus**, which receives impulses coming from the skin. In one region a part of this nucleus is specialised for the reception of impulses coming from the internal ear (**acoustico-lateral terminal nucleus**). Then there is a group of cells collected around the incoming visceral sensory nerves—the **splanchnic afferent terminal nucleus.** A part of this is specialised to receive taste impressions—the **gustatory nucleus**—but this has not yet been clearly demarcated from the rest of the nucleus.

This analysis of the various functional elements that may enter into the constitution of the various cerebral and spinal nerves is made use of in elaborating the **theory of nerve components**, which will help us to understand many features of the structure of the nervous system that otherwise would be unintelligible.

Nerve-cells.—We have already noticed that there is a broad distinction between the nerve-cells which are found in the ganglia of sensory nerves and those found in the rest of the nervous system. They differ not only in their mode of origin and in their subsequent development, but also in the connexions of their nerve-fibre processes.

Nerve-cells of the Brain and Spinal Medulla.—The cells in the cerebro-

spinal axis are variable both in size and form. Some are relatively large, as, for example, certain of the pyramidal cells of the cerebral cortex and the motor cells in the spinal medulla, which almost come within the range of unaided vision; others are exceedingly minute, and require a high power of the microscope to bring them into view. The cell consists of a protoplasmic nucleated body, from which the **axon** proceeds, and the **protoplasmic processes of Deiters,** or the **dendrites** (Fig. 422).

The **axon** presents a uniform diameter and a smooth and even outline. It gives off in its course fine collateral branches, but does not suffer thereby any marked diminution in its girth. The most important point to note in connexion with the axon, however, is the fact that it becomes continuous with the axis-cylinder of a nerve-fibre. The axon then is simply a nerve-fibre, and in certain circumstances

FIG. 421.—DIAGRAM OF A TRANSVERSE SECTION THROUGH THE RIGHT HALF OF THE FŒTAL RHOMBENCEPHALON AND EPITHELIAL AREAS ASSOCIATED WITH IT TO ILLUSTRATE THE DIFFERENT CATEGORIES OF NERVE COMPONENTS AND THEIR CENTRAL NUCLEI.

it assumes one or two investing sheaths, of which more will be said later. The axon may run its entire course within the substance of the brain or spinal medulla, either for a short or a long distance (intercalated cells), or it may emerge from the brain or spinal medulla in one of the cerebral or spinal nerves as the essential part of an efferent nerve-fibre, and run a variable distance before it finally reaches the peripheral structure in relation to which it ends (efferent nerve-cells). The axon and the collaterals which spring from it appear to terminate either in small button-like swellings or knobs, or more frequently in terminal arborisations, the extremities of which seem to be furnished with exceedingly small terminal varicosities. In those cases where the axon or its collaterals end within the brain or spinal medulla, some of the terminal arborisations interlace with the dendrites of nerve-cells, whilst others are twined around the bodies of other cells. In the latter case the interlacement may be so close and complete that it almost presents the appearance of an enclosing basket-work. In cases where the axon emerges from the cerebro-spinal axis its terminal arborisa-

tion ends in relation to a muscle-fibre or some other tissue in the manner described below.

Nerve-fibres.—Nerve-fibres, arranged in bundles of greater or less bulk, form the nerves which pervade every part of the body. They also constitute the greater part of the brain and spinal medulla. Nerve-fibres are the conducting elements of the nervous system; they serve to bring the nerve-cells into relation both with each other and with the various tissues of the body.

There are different varieties of nerve-fibres, but in all the leading and essential constituent is a delicate thread-like axon. The most obvious difference between individual fibres depends upon the nature of the covering of the axon. When it is coated on the outside by a more or less thick sheath of a fatty substance, termed **myelin**, it is said to be a myelinated or medullated fibre. When the coating of myelin is absent, the fibre is termed a non-myelinated or a non-medullated fibre. A second sheath—thin, delicate, and membranous, and placed externally—may also be present in both cases. It is termed the **primitive sheath** or the **neurolemma.** From a structural point of view, therefore, four different forms of nerve-fibre may be recognised:—

Non-medullated—
1. Naked axis-cylinders.
2. Axis-cylinders with primitive sheaths.

Medullated—
3. Primitive sheath absent.
4. Primitive sheath present.

Fig. 422.—Three Nerve-cells from the Anterior Column of Gray Matter of the Human Spinal Medulla.

Every nerve-fibre near its origin and as it approaches its termination is unprovided with sheaths of any kind, and is simply represented by a non-medullated, naked axis-cylinder. The fibres of the olfactory nerves afford us an example of non-medullated fibres furnished with a primitive sheath.

Medullated fibres are present in greater quantity in the cerebro-spinal system than non-medullated fibres. Thus, all the nerves attached to the brain and spinal medulla, with the exception of the olfactory and optic, are formed of medullated fibres provided with a primitive sheath; whilst the entire mass of the white substance of the brain and spinal medulla, and also the optic nerves, are formed of medullated fibres devoid of a primitive sheath.

It is important to note that the distinction between the medullated and non-medullated fibres is not one which exists throughout all stages of development. As will be presently pointed out, every fibre is the prolongation of a cell, and in

the first instance it is not provided with a medullary sheath. Indeed, it is not until about the fifth month of fœtal life that those fibres which are to form the white substance of the cerebro-spinal axis begin to acquire their coating of myelin. Further, this coating appears in the fibres of different fasciculi or tracts at different periods, and a knowledge of this fact has enabled anatomists to follow out the connexions of the tracts of fibres which compose the white matter of the brain and spinal medulla.

Every nerve-fibre is directly continuous by one extremity with a nerve-cell, whilst its opposite extremity breaks up into a number of ramifications, all of which end in relation to another nerve-cell, or in relation to certain tissues of the body, as, for example, muscle-fibres or the epithelial cells of the epidermis. The

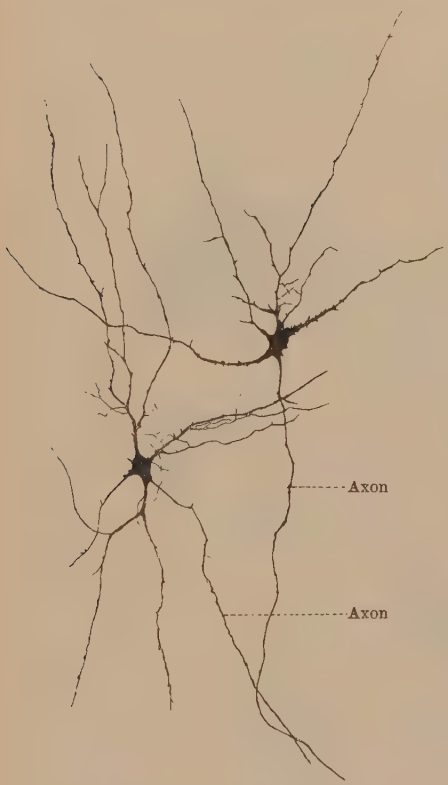

FIG. 423.—TWO MULTIPOLAR NERVE-CELLS. (From a specimen prepared by the Golgi method.)

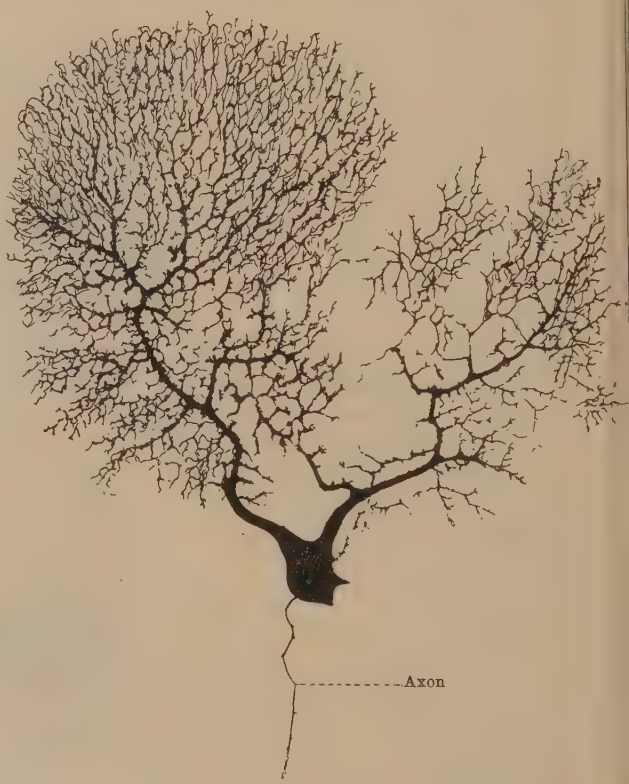

FIG. 424.—NERVE-CELL FROM CEREBELLUM (CELL OF PURKINJE) SHOWING THE BRANCHING OF THE DENDRITIC PROCESSES. (From a photograph by Professor Symington.)

length of nerve-fibres, therefore, varies very greatly. Some fibres are short and merely bring two neighbouring nerve-cells into relation with each other; others travel long distances. Thus, a fibre arising from one of the motor cells of the lower end of the spinal medulla may, after leaving the spinal medulla, extend to the most outlying muscle in the sole of the foot, before it reaches its destination. But even when a fibre does not leave the central axis, a great length may be attained, and cells situated in the uppermost part of the brain give origin to fibres which pass down to the lower end of the spinal medulla.

It has already been explained that fibres which form the nerves may be classified into two sets, afferent and efferent. **Afferent nerve-fibres** conduct impressions from the peripheral organs into the central nervous system; and as a change of consciousness, or, in other words, a sensation, is a frequent result, these fibres are often called *sensory*. **Efferent nerve-fibres** carry impulses out from the brain and spinal medulla to peripheral organs. The majority of these fibres go to muscles and are termed *motor*; others, however, go to glands and are called *secretory*;

whilst some are *inhibitory* and serve to carry impulses which restrain or check movement or secretion.

The **dendrites**, or protoplasmic processes of the nerve-cell, are thicker than the axon, and present a rough-edged irregular contour. They divide into numerous branches, and these gradually, as they pass from the cell-body, become more and more attenuated until finally they appear to end in free extremities. The branching of the dendritic processes sometimes attains a marvellous degree of complexity (Fig. 424), but it is commonly supposed that there is no anastomosis between the dendrites of neighbouring cells, or between the dendrites of the same cell.

It is commonly believed that the neuroblast passes through stages analogous to those shown in the diagram (Fig. 426); that just as a seed gives off a root which strikes downward, and leaves which grow upward, so the neuroblast sprouts out an axon (*a*) and subsequently develops a bunch of dendritic processes (*b*). In the case of the axon reasons have already been given for not accepting this view as the whole explanation; and in the case of the dendrites, although the appearance of microscopic sections seems to favour the view expressed in the diagrams, the fact that the neuroblasts are united into a continuous network or syncytium at an early stage of development (see p. 505) raises the possibility that the dendrites may be formed by the gradually drawing out of the existing bridges as the linked cell-bodies become moved apart.

FIG. 425. NERVE-FIBRE FROM A FROG. (After v. Kölliker.)

The Ganglia of the Sensory Nerves.—The cells found in the ganglia of the cerebral nerves and on the posterior or dorsal roots of the spinal nerves have a different origin, and present many points of contrast with neurones in the gray matter of the brain and spinal medulla. As already indicated, the ganglia in question are derived from the neural crest. The cells forming these ganglionic masses are somewhat oval in form, and each extremity or pole becomes drawn out into a process, so that the neurones become bipolar. These processes are distinguished as central and peripheral, according to the direction which they take. The central processes penetrate the wall of the neural tube. In the region of the spinal medulla they form almost the whole of the fibres which enter into the composition of the posterior roots of the spinal nerves. In the substance of the cerebro-spinal axis they give off numerous collaterals, and after a course of varying extent they end, after the manner of an axon, in terminal arborisations, which enter into relationships with certain nerve-cells in the cerebro-spinal axis. The peripheral processes proceed along the path of the particular nerve with which they are associated, and they finally reach the skin or other sensory surface. Thus, to take one example: the majority of the fibres which go to the skin break up into fine terminal filaments, which end freely between the epithelial cells of the epidermis. The two processes of a ganglion cell, therefore, form the afferent fibres of the cerebro-spinal nerves, and constitute the path along which the influence of peripheral impressions is conducted towards the brain and spinal medulla. The body of the cell is, as it were, interposed in the path of such impulses.

FIG. 426.—RAMÓN Y CAJAL'S INTERPRETATION OF THE DEVELOPMENTAL STAGES EXHIBITED BY A PYRAMIDAL CELL OF THE BRAIN.

a, Neuroblast with rudimentary axon, but no dendrites; *b* and *c*, The dendrites beginning to sprout out; *d* and *e*, Further development of the dendrites and appearance of collateral branches on the axon.

But the original bipolar character of these cells, with very few exceptions (ganglia in connexion with the acoustic nerve and the bipolar nerve-cells in the

olfactory mucous membrane), gradually undergoes a change which ultimately leads to their transformation into unipolar cells. This is brought about by the tendency which the cell-body has to grow to one side, viz., the side towards the surface of the ganglion (v. Lenhossek). This unilateral growth leads to a gradual approximation of the attached ends of the processes, and finally to a condition in which they appear to arise from the extremity of a short common stalk in a T-shaped manner (Fig. 427). It is interesting to note that in fishes the original bipolar condition of these cells is retained throughout life, without change.

Both the central and peripheral processes of these ganglionic cells become the axis-cylinders of nerve-fibres, which, acquiring a medullary sheath, belong therefore to the medullated variety. From this it might very naturally be thought that the ganglionic neurone, with its two axons and no typical dendrites, is a nervous unit very different from a neurone in the gray matter of the cerebro-spinal axis. It is believed by some, however (van Gehuchten and Cajal), that the peripheral process, in spite of its enclosure within a medullary sheath, and though presenting all the characters of a true axon, is in reality a dendrite. If this is the case, the morphological difference between a dendrite and an axon disappears, and van Gehuchten's functional distinction alone remains characteristic, viz., that the axon is *cellulifugal* and conducts impulses away from the cell, whilst the dendrites are *cellulipetal* and conduct impulses towards the cell.

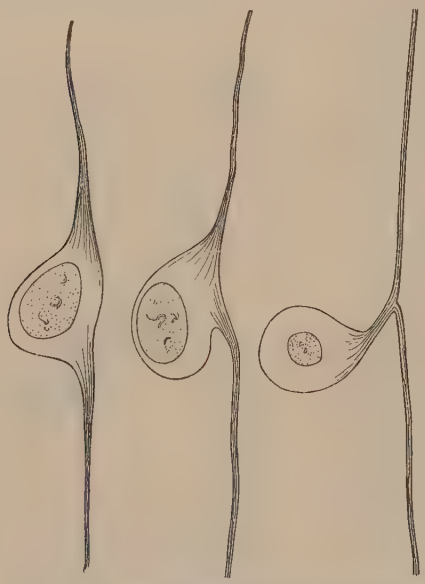

Fig. 427.—Three Stages in the Development of a Cell in a Spinal Ganglion.

It is, however, more in accordance with the facts to regard the sensory neurones as genetically quite distinct from the rest of the nervous system (see p. 500).

Neuroglia.—The neuroglia is the supporting tissue of the cerebro-spinal axis. It may be considered to include two different forms of tissue, viz., the lining ependymal cells and the neuroglia proper. We place these under the one heading, seeing that they have a common developmental origin.

The **ependymal cells** are the columnar epithelial cells which line the central canal of the spinal medulla and the ventricles of the brain. In the embryonic condition a process from the deep extremity of each cell traverses the entire thickness of the neural wall and reaches the surface. It is not known whether this process exists in the adult.

The **neuroglia proper** is present in both the white and the gray matter of the cerebro-spinal axis. It constitutes an all-pervading basis substance, in which the various nerve elements are embedded in such a way that they are all bound together into a consistent mass, and are yet all severally isolated from each other. Neuroglia consists of cells and fine filaments. The fibrils are present in enormous numbers, and by their interlacements they constitute what appears to be a fine feltwork. At the points where the fibrils intercross may be seen the flattened *glial cells.* Whilst the neuroglia is for the most part intimately intermixed with the nerve elements, there are, in both brain and spinal medulla, certain localities where it is spread out in more or less pure layers. Thus, upon the surface of the brain and of the spinal medulla there is such a layer; likewise beneath the epithelial lining of the central canal and of the cavities of the brain there is a thin stratum of neuroglia.

The ependymal cells are derived from the original neuro-epithelial cells of the early neural tube, and in all probability the neuroglia proper has a similar origin. They both, therefore, are products of the ectoderm.

Summary.—1. The cerebro-spinal nervous system is composed of two parts, viz.,

(*a*) a **central part**, consisting of the brain and spinal medulla, with the efferent nerve-fibres which pass out from them; (*b*) the **ganglionic part**, with the afferent nerve-fibres.

2. Each of these parts has a different origin, and is composed of neurones which possess characteristic features.

3. The ganglionic neurones are derived from the primitive cells of the neural crest, and have each one process, which divides into two. Of these the central division enters the cerebro-spinal axis, whilst the peripheral division becomes connected with a peripheral part. The central fibres from the ganglionic cells in the region of the spinal medulla form the dorsal or posterior roots of the spinal nerves. The cells of origin of these posterior roots are outside the spinal medulla, and carry impulses into its substance.

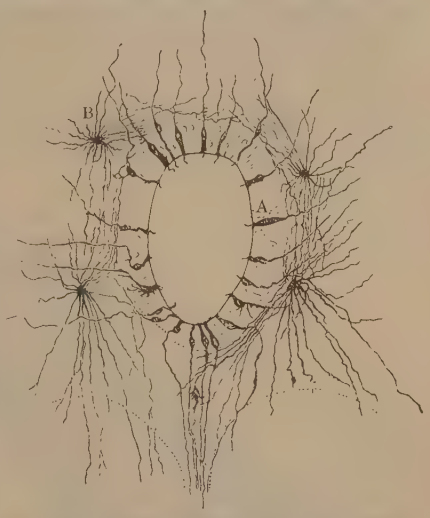

FIG. 428.— SECTION THROUGH THE CENTRAL CANAL OF THE SPINAL MEDULLA OF A HUMAN EMBRYO, SHOWING EPENDYMAL AND NEUROGLIAL CELLS. (After v. Lenhossek.)
A, Ependymal cell. B, Neuroglial cell.
[Note that the dorsal (posterior) aspect is *below*.]

4. The cerebro-spinal neurones are derived from the neuroblasts in the wall of the early neural tube. Certain of these furnish efferent nerve-fibres, which issue from the spinal medulla in separate bundles termed the anterior or ventral roots of the spinal nerves. In the case of the cerebral nerves, however, with the exception of the trigeminal and facial nerves, the efferent fibres are not thus separated from the afferent fibres at their attachment to the brain.

5. The brain and spinal medulla, when studied by the naked eye, are seen to be composed of white matter and gray matter. The white matter forms very nearly two-thirds of the entire cerebro-spinal axis. It is composed of medullated nerve-fibres embedded in neuroglial tissue. The gray matter is composed of nerve-cells with their dendrites and axons. Some of the axons are in the form of naked axis cylinders, whilst others have a coating of myelin. Intimately intermixed with these parts is the neuroglia, which isolates them more or less completely from each other.

THE NATURE OF THE BRAIN.

In the foregoing account it has been explained that the nervous system is composed of a series of afferent nerves bringing information from every part of the body into the central nervous system, from which efferent nerves pass out to the muscular and other active parts of the body, providing the means for translating such information into appropriate action. But it has been seen that the essential part of the central nervous system is the intercalated cells, which provide the means whereby the information brought in by any sensory nerve may be placed at the service of the whole body, and the response which it excites may be controlled and regulated by the condition of the rest of the body. The system of intercalated cells links together into one co-ordinated mechanism the whole nervous system, and, through it, every part of the body itself.

In some very primitive and remote ancestor of man (and in fact of the vast majority of animals) the front end of the nervous system became enhanced in importance to form a brain, which assumed a dominant influence over the rest. This was brought about in the first place by the fact that in an elongated prone animal moving forwards, the front end would naturally come first into relationship with any change in environment; and this earlier acquisition of information concerning the outside world would necessarily give the head end of the nervous system exceptional opportunities for influencing the rest of the nervous system.

This predominance is further accentuated by the development in the head region of the organs of special sense, which provide mechanisms specially adapted to be influenced by light, sound, and such delicate chemical forms of stimulation as excite in ourselves sensations of smell and taste. As the information conveyed by these special senses, such as the scent of food or the visual impression of some enemy, must be able immediately to influence the movements of the whole body, it follows that a specially abundant system of intercalated elements link the central ends of these nerves of the special senses with the rest of the central

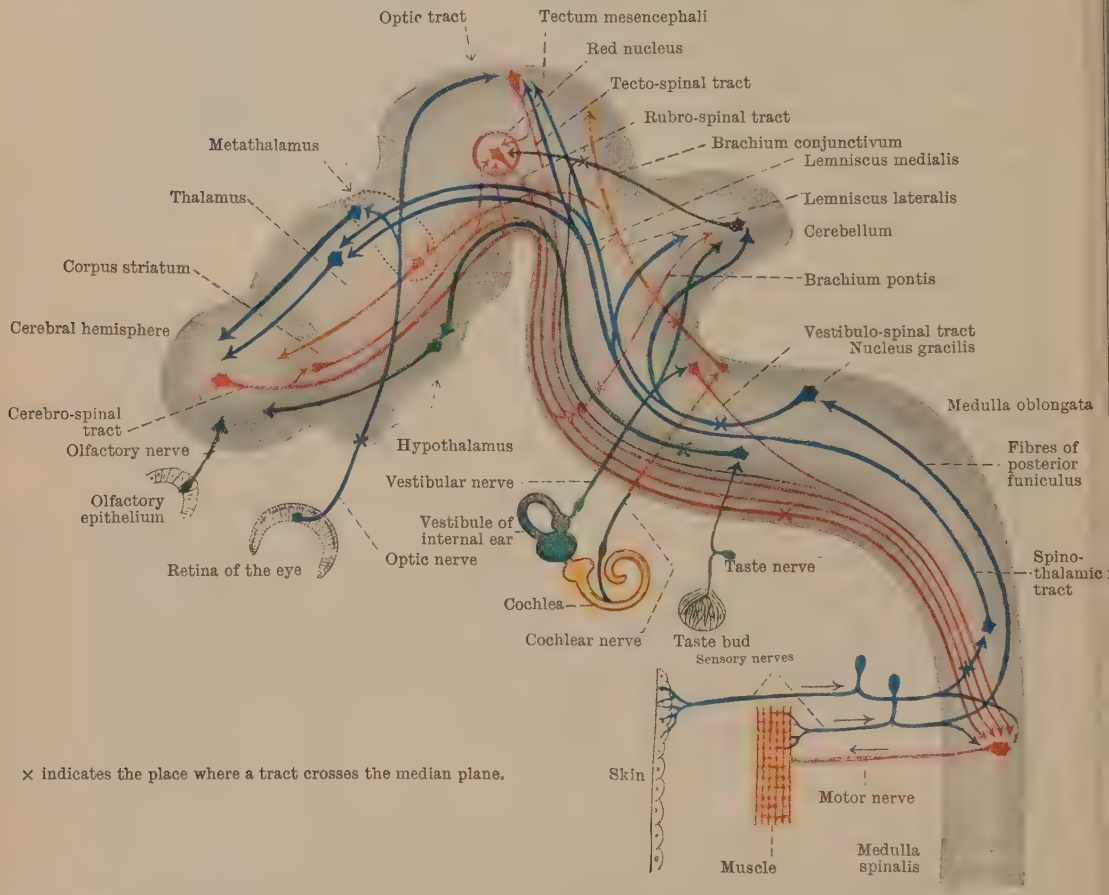

FIG. 429.—DIAGRAM REPRESENTING THE CONNEXIONS OF SOME IMPORTANT SENSORY AND MOTOR TRACTS IN THE BRAIN to which references are made in pages 515 to 519. Motor paths in red; sensory in other colours.

nervous system. Moreover the predominant influence of the head end of the central nervous system implies that it must be provided with a specially large series of nerve-fibres, not only for the purpose of bringing this influence to bear upon the rest of the nervous system, but also of being itself brought into intimate relationship with the nervous system as a whole, seeing that sensory impulses are constantly pouring into every part of it.

Thus the head end of the central nervous system becomes the brain, which is characterised by a series of large irregular swellings, due to (*a*) the development around the insertion of each special sensory nerve of a mass, or group of masses, of intercalated cells which will enable the effects of the visual, acoustic, olfactory, gustatory or other sensations to influence the whole nervous system, and (*b*) the evolution of complicated systems of intercalated cells, which receive, and in a sense blend, impressions coming from all parts of the nervous system, and emit fibres which pass, directly or indirectly, to the various groups of motor nerve-cells and control their activities and, through them, the behaviour of the animal.

In the development of the human embryo this distinction between the head end and the rest of the central nervous system is indicated even before the medullary plate is completely folded up to form the neural tube. The widened part represents the rudiment of the **encephalon** or brain; and the rest of the tube will become converted into the **medulla spinalis.**

If the attempt is made to analyse the meaning of the early broadening of the brain rudiment it will be found to be due in great measure to the fact that there is added to the margins of the medullary plate (see Fig. 417, E, p. 503) the material from which the sensitive part of the eye and the optic nerve will be developed; but soon after the neural tube is closed irregular swellings will make their appearance around the attachments of the nerves of smell, vision, hearing, and taste (Fig. 429), and also the great vagus nerve that is widely distributed to the viscera of the neck, thorax, and abdomen.

But there are other factors besides these irregularities of growth of its walls which add complexity to the form of the encephalon in the embryo. In the course of their growth both parts (encephalon and medulla spinalis) of the neural tube undergo great extensions in length, breadth, and thickness; but in the case of the spinal medulla it is the increase in length that is most distinctive, whereas in the encephalon, the irregular expansion in breadth and thickness is more obtrusive. Nevertheless, the brain elongates more rapidly than that part of its mesodermal capsule which ultimately becomes the brain-case or cranium; and hence it becomes bent to permit of its being packed in the limited length of the cranial cavity. But if it is admitted that these mechanical considerations are in a measure responsible for the three bends which develop in the embryonic encephalon, their situation and the forms they assume are determined by the irregularities of growth inherent in the brain itself.

Even at a time, during the second week, when the anterior (oral) end of the neural tube is still open (**neuroporus anterior**), a right-angled bend has already developed in the rudiment of the brain (**cerebral vesicle**). Slightly less than half of the length of the vesicle had projected beyond the upper (anterior) end of the notochord and became flexed ventrally round it (Fig. 430).

This bend is known as the **cephalic flexure.** The region of the brain vesicle in which it develops will later on become the **mesencephalon** or **mid-brain**; and even at the early stage of development now under consideration (Fig. 430) there is a slight narrowing of the tube (**isthmus**) that marks the boundary between the mid-brain and the **rhombencephalon** or **hind-brain.** Just beyond the end of the notochord there is an even fainter trace of a constriction indicating the line of demarcation between the mid-brain and the **prosencephalon** or **fore-brain.**

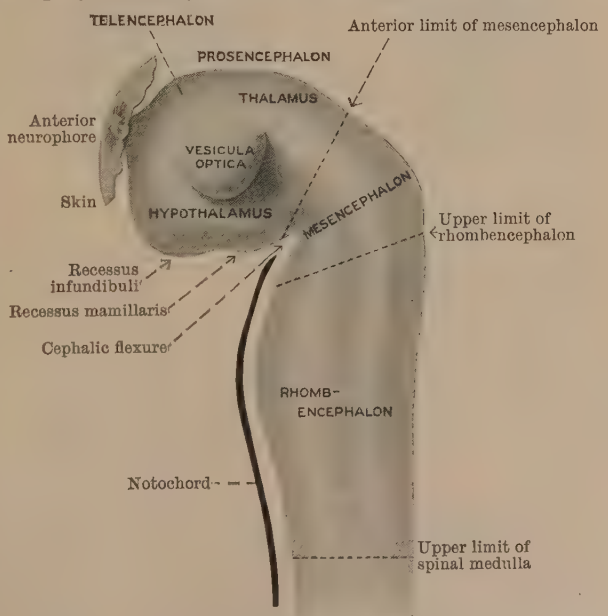

FIG. 430.—LEFT LATERAL ASPECT OF AN EARLY HUMAN EMBRYO. (After His's model, reversed.)

Shortly after the appearance of the cephalic flexure a similar bending occurs in the region where the encephalon becomes continuous with the medulla spinalis (Fig. 431, A). This is the **cervical flexure.**

But at this stage, or even earlier (Fig. 430), there has been developing a third

bend which produces effects differing from those just mentioned. At the end of the second week a slight bulging can be detected on the ventral side of the hind-brain (Fig. 431): during the next four weeks this steadily becomes accentuated and forms the **pontine flexure.** The convexity of the bend is directed ventrally,

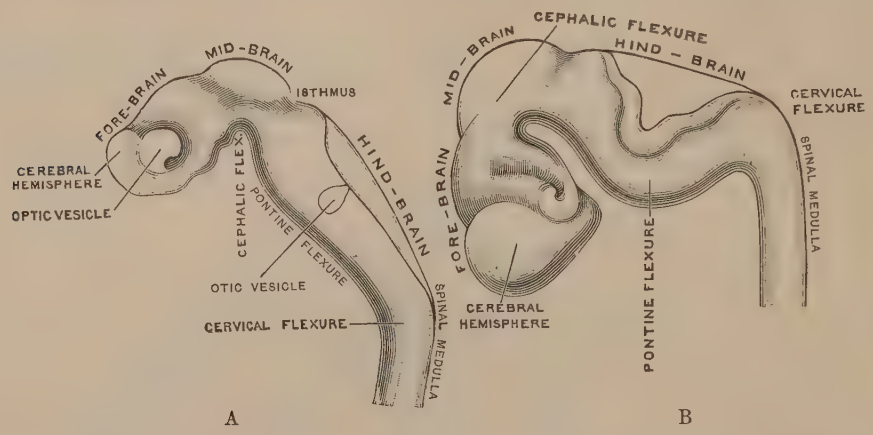

FIG. 431.—TWO STAGES IN THE DEVELOPMENT OF THE HUMAN BRAIN. (After His.)
A, Brain of an embryo of the third week. B, Brain of an embryo of five weeks.

differing in this respect from both of the other flexures. This difference in direction has a profound influence upon the form which the hind-brain assumes. If a plastic tube is bent a strain is thrown upon the wall in the concavity of the flexure. If this wall is strong and resisting, like the floor-plate of the neural tube (in the cases of the cephalic and cervical flexures) the bending does not affect the outline of the tube (in section) very materially. But when the strain is thrown upon the thin roof-plate during the development of the pontine flexure it is not strong enough to resist; it becomes stretched and allows the side walls of the neural tube to splay laterally in precisely the same manner as occurs when a rubber tube is bent towards a side which has been split (or weakened) longitudinally (Fig. 432). This mechanical factor determines the form assumed by the hind-brain at the end of the first month; and gives its cavity, the fourth ventricle, a lozenge or rhomboid form, when seen from its dorsal aspect through the thin translucent roof. For this reason the hind-brain is known as the **rhombencephalon.**

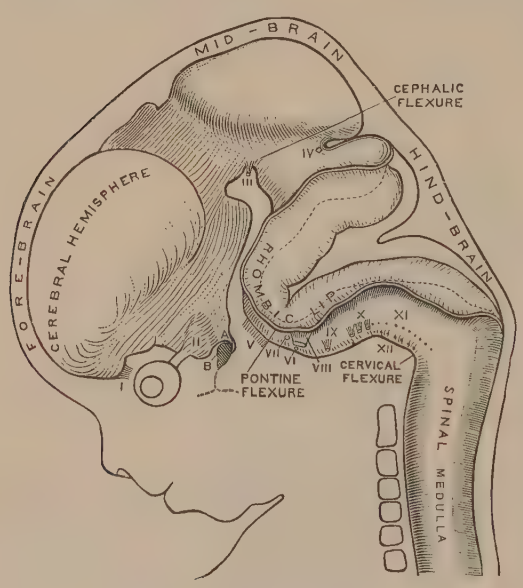

FIG. 432.—PROFILE VIEW OF THE BRAIN OF A HUMAN EMBRYO OF TEN WEEKS. (His.)
The various cerebral nerves are indicated by numerals.
A, Cerebral diverticulum of hypophysis cerebri.
B, Buccal diverticulum of hypophysis cerebri.

The rhombencephalon forms at first more than half of the encephalon, and as it expands it appears to become marked off from the rest by a constriction (the **isthmus rhombencephali**).

The development of the pontine flexure subdivides the rhombencephalon into two parts, one joined to the spinal medulla, the **myelencephalon**, and the other, joined to the rest of the brain, the **metencephalon.**

In the myelencephalon develop the nuclei of the nerves that regulate the

activities of the heart, lungs, and a considerable part of the alimentary canal, and also the receptive nuclei of the nerves of taste. It is known as the **medulla oblongata.**

The insertion of the nervus acusticus in the neighbourhood of the outsplayed lateral angle of the rhombencephalon leads to the profound transformation of the metencephalon. The nervus acusticus conveys into the hind-brain impulses which are stimulated by movements of fluid in the closed sac developed from the otic vesicle (Fig. 418, p. 504). The truly acoustic function of this apparatus is called into activity when the movements of this fluid are caused by waves of sound transmitted to it from the outside world. But it is obvious that motion may also be set up in this fluid by changes in position of the body itself; in other words, movements in the fluid of the otic vesicle may stimulate nerves to convey to the brain information concerning the position and movements of the body itself. A great mass of nerve-cells develops around the insertion of the nervus acusticus (that part of it, however, which is called vestibular and is not concerned with the function of hearing) to make use of this information for the regulation of the movements of the body in balancing or equilibration. To enable this terminal vestibular nucleus the better to perform this function of equilibration, depending as it does upon the co-operation and adjustment of the movements of vast numbers of widely separated muscles, nerve tracts coming from muscles and skin areas of all parts of the body make their way into this vestibular nucleus; and it expands and forms a great excrescence which is known as the **cerebellum.** And as this cerebellum has to adjust the activities of all the muscles of the body it necessarily becomes the great organ of muscular co-ordination, and as such it is made use of by those parts of the brain which have to initiate and control complex actions such as skilled movements. It will be shown in the subsequent account how the cerebellum becomes linked to the mesencephalon to co-ordinate the movements of the body which are excited by this part of the encephalon; and later how it becomes associated with the prosencephalon, when the latter becomes responsible for the acquisition and control of the most highly skilled actions. For the latter purpose a great pathway of nerve-fibres is laid down to connect the fore-brain with the cerebellum: the terminal stage of this connexion is situated upon the ventral (anterior) aspect of the metencephalon in the form

of a great mass of transverse fibres. At one time these strands of nerve-fibres were looked upon as a bridge between the two hemispheres of the cerebellum: hence the name **pons** was applied to them. This term is now applied not only to the fibres themselves, but also to the upward prolongation of the medulla oblongata, to the surface of which they are applied.

The subdivision of the rest of the encephalon into **mesencephalon** and **prosencephalon** develops later and is less fundamental than the primary demarcation between them and the rhombencephalon.

The visual apparatus is connected with both the mid-brain and the fore-brain, but at first more intimately with the former, to which nerve pathways are established to convey from the spinal medulla and medulla-oblongata sensory impressions of touch and hearing. From the alar laminæ of the mesencephalon there are developed four little hillocks (**colliculi**) — **corpora quadrigemina** — to receive these varied impressions and to enable them to influence the actions of the whole body. Special nerve paths are laid down from the corpora quadrigemina (Fig. 429) to the spinal medulla to enable the mid-brain to control the motor nuclei of the muscles of the trunk and limbs. These are called the **fasciculi tectospinales** (*tectum* being a synonym for corpora quadrigemina). A group of intercalated cells known as the **nucleus ruber** develops upon each side of the mesencephalon for the purpose of establishing connexions between the cerebellum and the mid-brain. When an impulse passes out of the mid-brain by the tectospinal bundle to excite some movement of the body, the red nucleus provides the link by which the cerebellum can co-ordinate the actions of the muscles involved. By means of a **fasciculus rubrospinalis** it can bring its influence to bear directly upon the nuclei of motor nerves in the brain and spinal medulla (Fig. 429).

The prosencephalon is at first, and in some of the lower fishes remains, the most insignificant of the three brain vesicles, but in the human brain (as also in that of most other vertebrates, though in varying degrees) a pair of enormous excrescences—the cerebral hemispheres—are budded off from it; and they become the dominant part of the nervous system (Fig. 433).

Each hemisphere is formed, however, from a relatively small part of the side wall of the prosencephalon, the rest of which goes to form the optic diverticula, the thalamus, and the hypothalamus, among other structures. The cerebral hemisphere is at first pre-eminently olfactory in function, the nerves of smell being inserted directly into it. But impressions of the associated sense of taste make their way into the cerebral hemisphere in the most primitive vertebrates: the gustatory nerves are inserted into the medulla oblongata, but fibre-paths are laid down to establish connexions with the hypothalamus, which in turn emits fibres to the cerebral hemisphere (Fig. 429). The thalamus is a greatly swollen part of the prosencephalic wall adjoining the mesencephalon. Its main part receives sensory impressions brought up from the spinal medulla and the terminal nuclei of the sensory cerebral nerves and transmits them to the cerebral hemisphere. Its caudal portion becomes specialised as a special receptive nucleus for visual and acoustic impressions for transmission to the cerebral hemisphere. It is called the **metathalamus** or **corpora geniculata**. Thus the cerebral hemisphere from being essentially a receptive organ for smell impressions ultimately becomes the terminus of all the sensory paths, and the structure that is concerned with the consciousness of all kinds of sensations. It also controls the voluntary movements of one-half of the body and emits a great strand of fibres—**pedunculus cerebri**—to establish relations with the cerebellum and all the motor nuclei on the other side of the encephalon and spinal medulla (Fig. 429, p. 514).

MEDULLA SPINALIS.

The **spinal medulla** is that part of the central nervous system which occupies the upper two-thirds of the vertebral canal. It is an elongated cylindrical structure, slightly flattened in front and behind, which extends from the margin of the foramen magnum to the level of the inferior border of the body of the first lumbar vertebra or to the superior border of the body of the

second lumbar vertebra. Its average length in the male is 45 cm. and in the female 43 cm.

A considerable amount of variation within certain limits (viz., the mid-point of the body of the last thoracic vertebra and the superior border of the body of the third lumbar vertebra) is observed in different individuals as to the precise level at which the spinal medulla ends inferiorly, and in the female there would appear to be a tendency for the medulla to reach a slightly lower point in the canal than in the male. Further, the relation presented by the spinal medulla to the vertebral column differs in a marked degree in the fœtus and infant at different periods of development. Up to the third month of intra-uterine life the spinal medulla occupies the entire length of the vertebral canal; it extends downwards to the lowest limit of the vertebral canal. But from this time onwards, as growth proceeds, the vertebral column lengthens at a more rapid rate than the medulla. The spinal medulla, therefore, has the appearance of shrinking in an upward direction within its canal, and at birth its inferior end is usually found to be opposite the body of the third lumbar vertebra.

The attitude assumed by the individual affects to a small degree the position of the inferior end of the spinal medulla. Thus, when the trunk is bent well forwards, the terminal part of the spinal medulla rises slightly within its bony canal.

At the margin of the foramen magnum the spinal medulla becomes continuous with the medulla oblongata of the brain, whilst below, it tapers rapidly to a point and forms a conical extremity termed the **conus medullaris**. From the end of the conus medullaris a slender glistening thread is prolonged downwards within the vertebral canal, and finally anchors the spinal medulla to the back of the coccyx. This prolongation receives the name of the **filum terminale**.

The diameter of the spinal medulla is very much smaller than that of the vertebral canal within which it lies. A wide interval is left between its surface and the walls of its canal, and this excess of space is clearly a provision for allowing free movement of the vertebral column without producing any jarring contact between the delicate spinal medulla and the surrounding bones.

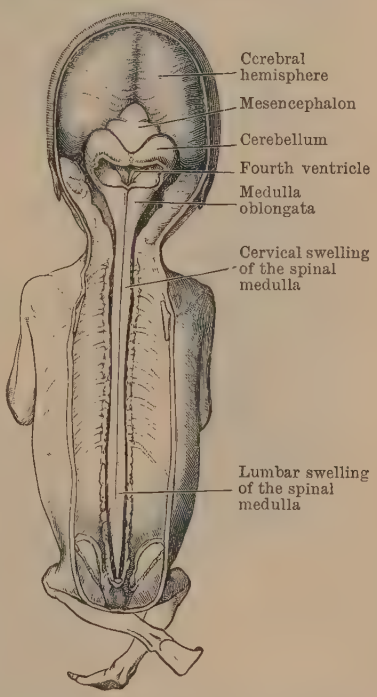

FIG. 434.—HUMAN FŒTUS IN THE THIRD MONTH OF DEVELOPMENT, WITH THE BRAIN AND SPINAL MEDULLA EXPOSED FROM BEHIND.

Three protective membranes are wrapped around the spinal medulla. From within outwards these are termed (1) the pia mater, (2) the arachnoid, and (3) the dura mater. The **pia mater** is a fibrous membrane which forms the immediate investment. It is closely applied to the spinal medulla, and from its deep surface numerous fine septa penetrate into the substance of the spinal medulla. The **arachnoid** is an exceedingly delicate transparent membrane which is loosely wrapped around the spinal medulla so as to leave a considerable interval, between itself and the pia mater, termed the subarachnoid space, in which there is always a varying amount of cerebro-spinal fluid. Outside the arachnoid, the **dura mater** forms a wide, dense, fibrous, tubular sheath, which extends downwards within the vertebral canal for a considerable distance beyond the conical extremity of the spinal medulla. The spinal medulla is suspended within its sheath or *theca* of dura mater by two lateral wing-like ligaments, termed the **ligamenta denticulata**. These extend laterally from the sides of the spinal medulla and are attached by a series of pointed or tooth-like processes to the inner surface of the theca of dura mater. Between the wall of the vertebral canal and the dura mater there is a narrow interval, which is filled up by soft areolo-fatty tissue and numerous thin-walled veins arranged in a plexiform manner.

Thirty-one pairs of spinal nerves arise from the sides of the spinal medulla. These are classified into eight cervical, twelve thoracic, five lumbar, five sacral, and one coccygeal; and according to the attachments of these groups of nerves the spinal medulla is arbitrarily subdivided into cervical, thoracic, lumbar, and sacral regions. In employing these terms, therefore, for different districts of the spinal medulla, it must be understood that the regions are determined by the nerve attachments and not by any direct relationship between these parts of the spinal medulla and the sections of the vertebral column which bear the same names.

Each spinal nerve is attached to the spinal medulla by an anterior or ventral and a posterior or dorsal root, and as these are traced to their central attachments they are seen to break up into a number of separate nerve fascicles or bundles, which spread out, in some cases very widely from each other, as they approach the side of the spinal medulla (Fig. 436). Each pair of nerves is therefore attached to a portion of spinal medulla of some length, and such a portion, with its pair of nerves, receives the name of a "segment of the spinal medulla." It must be clearly

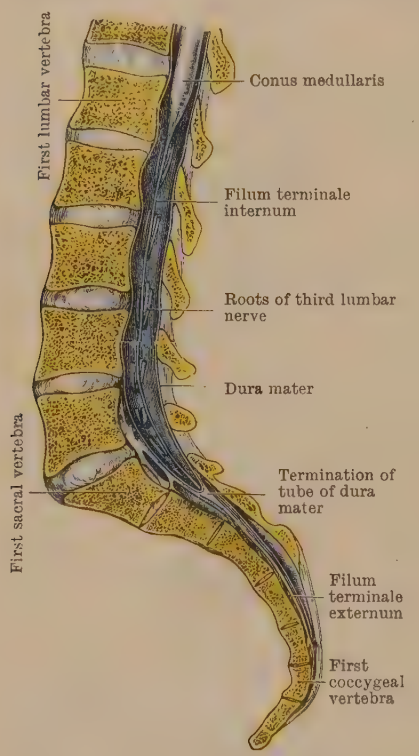

FIG. 435.—THE CONUS MEDULLARIS AND THE FILUM TERMINALE EXPOSED WITHIN THE VERTEBRAL CANAL.

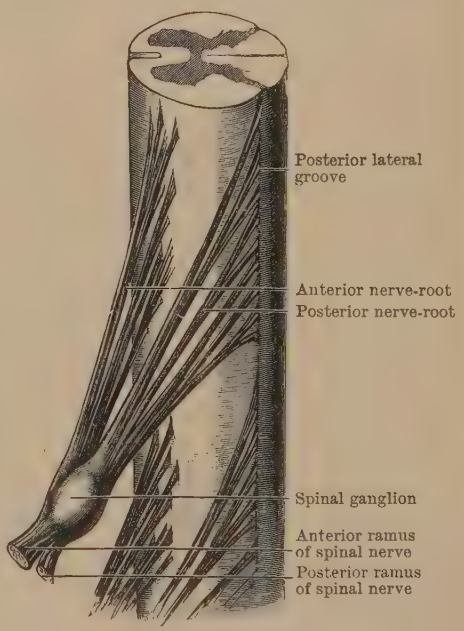

FIG. 436. — THE ROOTS OF ORIGIN OF THE SEVENTH THORACIC NERVE (semi-diagrammatic).

understood, however, that, in so far as the surface of the spinal medulla is concerned, there is no means of marking off one segment from another except by the nerve attachments.

In the cervical and lumbar regions of the spinal medulla the nerve-roots are somewhat crowded together, so that little or no interval is left between the adjoining root fila or fascicles of neighbouring nerves. In the thoracic region, however, distinct intervals may be observed, and the root fila are more loosely arranged. From this, it will be evident that the segments in different parts of the spinal medulla are not of equal length. In the cervical region the segments measure about 12 mm. in length, in the thoracic region from 20 to 24 mm., and in the lumbar region about 10 mm. The number of fila which attach the different nerve-roots to the spinal medulla is very different in different nerves, and is not necessarily the same in the same nerve-root in different individuals.

Owing to the great difference which exists between the length of the spinal medulla and the length of the vertebral column, the farther we pass down the greater the distance becomes between the attachment of the various nerve-roots to the spinal medulla and the intervertebral foramina through which the corresponding

nerves leave the vertebral canal. The lower nerve-roots, therefore, have to traverse the vertebral canal for a considerable distance before they reach their apertures of emergence. It thus happens that the nerve-roots which spring from the lumbar and sacral regions of the spinal medulla attain a very great length and descend vertically in the lower part of the vertebral canal in a bunch or leash, in the midst of which lie the conus medullaris and the filum terminale. This great bundle of nerve-roots receives the appropriate name of the **cauda equina**.

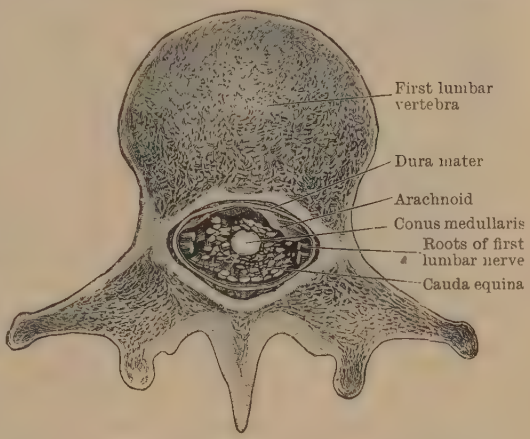

FIG. 437.—SECTION THROUGH THE CONUS MEDULLARIS AND THE CAUDA EQUINA AS THEY LIE IN THE VERTEBRAL CANAL.

Enlargements of the Spinal Medulla.—Throughout the greater part of the thoracic region, the spinal medulla presents a uniform girth and a very nearly circular outline when seen in transverse section. In the cervical and lumbar regions, however, it shows marked swellings. The **intumescentia cervicalis** or **cervical enlargement** is the more evident of the two. It begins very gradually at the upper end of the spinal medulla, attains its greatest breadth (12 to 14 mm.) opposite the fifth or sixth cervical vertebra, and finally subsides opposite the second thoracic vertebra. To

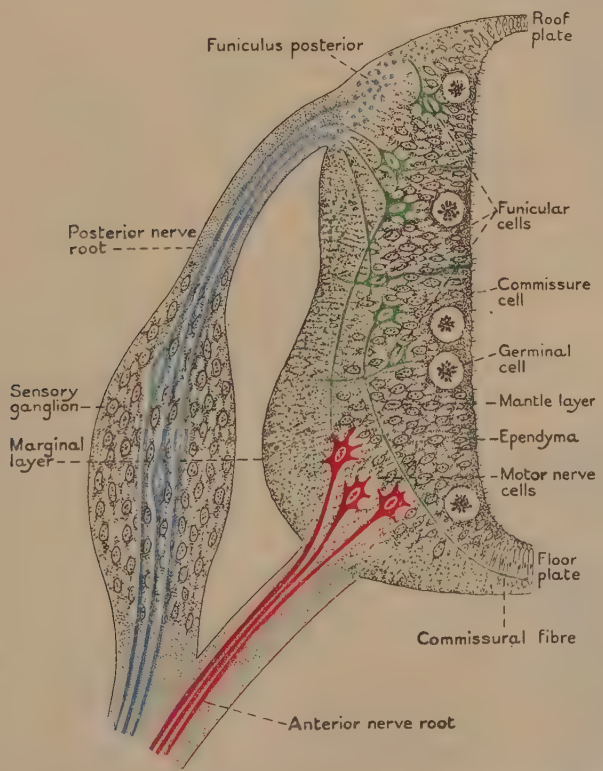

FIG. 438.—DIAGRAM OF TRANSVERSE SECTION OF THE LEFT HALF OF EARLY NEURAL TUBE.

this portion of the spinal medulla are attached the great nerves which supply the upper limbs. The **intumescentia lumbalis** or **lumbar enlargement** begins at the level of the tenth thoracic vertebra, and acquires its maximum transverse diameter (11 to 13 mm.) opposite the last thoracic vertebra. Below, it rapidly tapers away into

the conus medullaris. To the lumbar enlargement are attached the great nerves of the lower limbs.

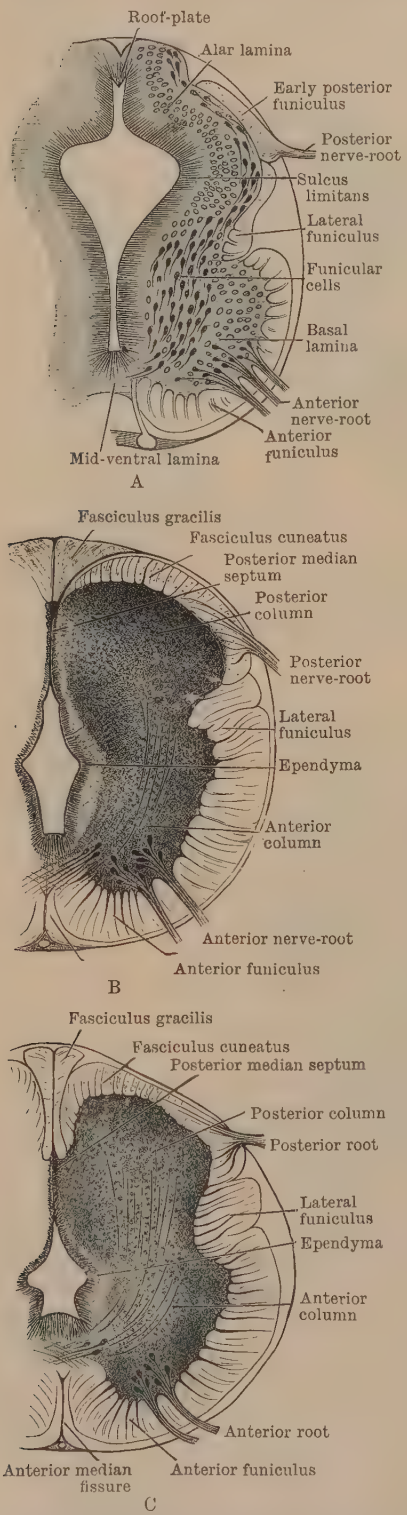

FIG. 439.—THREE STAGES IN THE DEVELOPMENT OF THE SPINAL MEDULLA. (His.)

These enlargements of the spinal medulla are associated with the outgrowth of the limbs. In the earlier developmental stages of the spinal medulla they are not present, and they take form only as the limbs become developed. In different animals their size corresponds with the degree of development of the limbs. Thus, in the long-armed orang and gibbon the cervical swelling stands out with a remarkable degree of prominence.

Development of the Spinal Medulla.—The early stages of the process by which the originally simple epithelial neural tube becomes converted into the central nervous system have already been considered. It remains to be explained how the features specially distinctive of the spinal medulla are produced.

In the early stages of the development of the spinal medulla (Fig. 438), the neuroblasts are found to be scattered in the intermediate of the three bands of which the thick side wall of the neural tube is composed — the mantle layer. The motor nerve-cells soon congregate in large numbers in the ventral part of the basal lamina (Fig. 439), so that the mantle layer expands there into a broad excrescence, which is the rudiment of the **columna anterior** or anterior cornu of gray matter. This anterior column contains the efferent or motor nerve-cells, the axons of which emerge as the **anterior root** of a spinal nerve. At this stage the rest of the mantle layer consists of a thin stratum of neuroblasts (Fig. 439), mainly intercalated cells, which receive the sensory impressions entering the spinal medulla through the **radix posterior**, and transmit impulses into axons passing (*a*) to the motor nuclei, (*b*) to the other side of the spinal medulla through the floor-plate (Fig. 438), or (*c*) into the superficial stratum (peripheral layer) of the spinal medulla, where they bend upwards or downwards as constituent elements of the **funiculi** (or white columns). As development proceeds (Fig. 438) the **substantia grisea** (gray substance) formed of these intercalated cells becomes much more abundant and forms a broad blunt boss (Figs. 439, B and C), which is the rudiment of the **columna posterior** (O.T. **posterior cornu**).

The surfaces of these gray columns become coated with a layer of white substance, composed at first mainly of the axons of cells in the root ganglia and intercalated cells in the spinal medulla; and as these funiculi increase in size they help to mould the form of the gray columns. This is displayed best in the case of the posterior column (O.T. posterior

cornu). The major portion of the white substance, **funiculus posterior**, which accumulates behind (and afterwards lies on the medial side of) the posterior column, does not consist of fibres springing from intercalated cells, either of the spinal medulla or any other part of the central nervous system, but of the direct continuations of the central processes of the cells in the spinal ganglion on the posterior root (Figs. 438 and 439). A large proportion of the fibres of the posterior root do not enter the gray columns immediately after their insertion into the alar lamina, but bifurcate to form two vertical nerve-fibres, one passing upwards, and the other downwards, in the funiculus posterior before they end in the gray column, some distance above or below the place where they gained admission to the medulla spinalis. As the spinal medulla grows, the originally blunt posterior column becomes drawn backwards into an increasingly attenuated process, and the funiculus posterior, which was placed originally upon its lateral surface (Fig. 439, A), and then upon its posterior surface (Fig. 439, B), gradually assumes a wedge-shaped form (Figs. 439, C, and 441), upon the medial side of the gray matter.

Development of the Anterior Median Fissure, Posterior Median Septum, and of the Central Canal.—As the anterior columns of gray matter and the anterior funiculi of white matter increase in size, the anterior surface of the spinal medulla, on each side of the median plane, bulges forwards, and the **fissura mediana anterior** (Fig. 439, A, B, and C) is produced as the natural result.

There has been considerable discussion as to the mode of formation of the **posterior median septum**; but there is now no doubt as to the essential facts. Early in the third month the walls of the posterior three-fourths (of the sagittal extent) of the **central canal** of the spinal medulla become approximated (Fig. 439), and later they fuse to obliterate that part of the canal. But the part of the septum thus formed is only an insignificant portion of the whole. For most of the septum is produced by the gradual elongation of the epithelial cells lining the remnant of the central canal as the fibre-masses of the posterior funiculi expand and separate the posterior surface of the spinal medulla further and further from the situation of the canal (see Fig. 428, p. 513).

Furrows of the Spinal Medulla.—When cross-sections of the adult spinal medulla are made, it is seen to be a bilateral structure which is partially subdivided into a right and a left half by a median cleft (fissura mediana anterior) in front and a septum (septum medianum posterius) behind. The anterior median fissure penetrates only for a distance corresponding to somewhat less than a third of the antero-posterior diameter of the spinal medulla. The pia mater dips down into it and forms a fold or reduplication within it. The posterior median septum in the cervical and thoracic regions penetrates into the spinal medulla until it reaches a point somewhat beyond its centre. It is extremely narrow, and consists of ependymal and neuroglial elements, and is intimately connected with the adjacent sides of the two halves of the spinal medulla, between which it intervenes. The pia mater, which invests the surface of the spinal medulla, passes continuously over the posterior median septum and sends no prolongation of any kind into it. In the lumbar

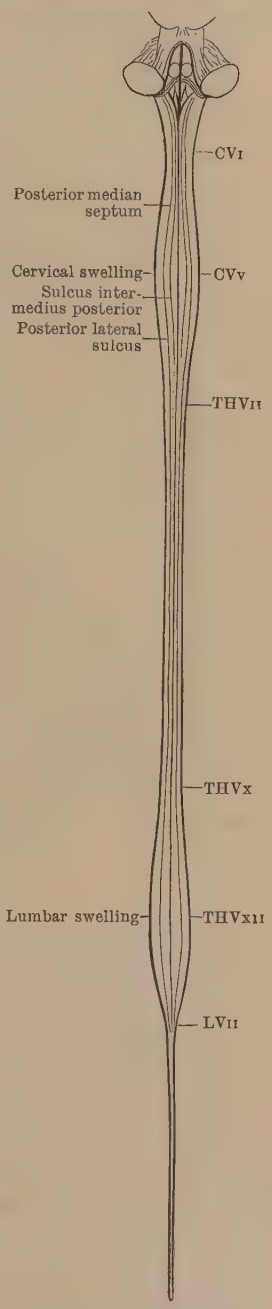

FIG. 440.—DIAGRAM OF THE SPINAL MEDULLA AS SEEN FROM BEHIND.

CVI shows the level of the 1st cervical vertebra; CVv of the 5th cervical vertebra; THVII of the 2nd thoracic vertebra; THVx of the 10th thoracic vertebra; THVXII of the 12th thoracic vertebra; LVII of the 2nd lumbar vertebra.

region of the spinal medulla the septum becomes shallower, whilst the anterior median fissure deepens, and ultimately in the inferior part of the spinal medulla the fissure and septum present a very nearly equal depth.

The two halves of the spinal medulla may show trifling differences in the arrangement of the parts which compose them; but to all intents and purposes they are symmetrical. They are joined together by a more or less broad band or commissure, which intervenes between the median fissure and the septum.

An inspection of the surface of each half of the spinal medulla brings into view a longitudinal groove or furrow, at some little distance from the posterior median septum, which extends along the whole length of the spinal medulla. Along the bottom of this groove the fila of the posterior nerve-roots enter the spinal medulla in accurate linear order. It is called the **sulcus lateralis posterior.** There is no corresponding furrow on the anterior part of each half of the spinal medulla in connexion with the emergence of the fila of the anterior nerve-roots. These fila emerge irregularly over a broad strip of the surface of the spinal medulla, which corresponds in its width to the thickness of the subjacent anterior surface of the anterior column of gray matter.

The sulcus lateralis posterior subdivides each half of the spinal medulla into a small **funiculus posterior** and a much larger **antero-lateral funiculus**, and it is customary to map the latter arbitrarily off into a **funiculus lateralis** and a **funiculus anterior** by a line corresponding to the emergence of the most lateral of the fila or fascicles of the anterior nerve-roots.

In the cervical region a distinct longitudinal groove may be observed on the surface of the posterior funiculus. It is placed rather nearer to the posterior median septum than to the posterior lateral sulcus, and as it is traced down into the thoracic region it gradually becomes indistinct and finally disappears. This is called the **sulcus intermedius posterior**, and it marks on the surface the position of a septum of pia mater which dips into the spinal medulla and subdivides the posterior funiculus into a lateral part, termed the **fasciculus cuneatus** (O.T. **column of Burdach**), and a medial portion, which receives the name of the **fasciculus gracilis** (O.T. **column of Goll**).

Internal Structure of the Spinal Medulla.

The spinal medulla is composed of a central core of gray matter thickly coated on the outside by white matter. At only one spot does the gray matter come close to the surface, viz., at the bottom of the sulcus lateralis posterior.

Gray Matter of the Spinal Medulla.—The gray matter in the interior of the spinal medulla has the form of a fluted column, but it is customary to describe it as it appears in transverse sections. It then presents the appearance of the capital letter H. In each half of the spinal medulla there is a semilunar or crescentic mass, shaped somewhat like a comma, the concavity of which is directed laterally and the convexity medially. The two crescents of opposite sides are connected across the median plane by a transverse band, which receives the name of the **commissura grisea** (gray commissure). The posterior median septum extends forwards in the spinal medulla until it reaches the gray commissure. The bottom of the anterior median fissure, however, is separated from it by an intervening strip of white matter, which is termed the **commissura anterior alba**, or anterior white commissure. In the gray commissure may be seen the central canal of the spinal medulla (**canalis centralis**), which tunnels the entire length of the spinal medulla and is just visible to the naked eye as a minute speck. The portion of the gray commissure which lies behind the central canal is called the *commissura posterior*; whilst the portion in front receives the name of the *commissura anterior grisea.*

Each crescentic mass of gray matter presents certain well-defined parts. The projecting portions which extend behind and in front of the connecting transverse gray commissure are termed respectively the posterior and the anterior columns of gray matter (**columnæ griseæ**). These stand out in marked contrast to each other. In section the **columna anterior** is short, thick, and very blunt at its extremity.

Further, its extremity falls considerably short of the surface of the spinal medulla and is separated from it by a moderately thick coating of white matter. Through this the fila of the anterior nerve-roots, as they emerge from the gray matter of the anterior column, pass on their way to the surface. Throughout the greater part of the spinal medulla the **columna posterior** (O.T. **posterior cornu**) is elongated and narrow, and is drawn out to a fine point, which almost reaches the bottom of the posterior lateral sulcus. This pointed extremity receives the name of the **apex columnæ posterioris**; the slightly swollen part which succeeds it is the **caput columnæ**; whilst the slightly constricted part adjoining the gray commissure goes under the name of the **cervix columnæ posterioris.**

The apex or tip of the posterior column differs considerably in appearance from the general mass of the gray matter. It is composed of a material which presents a lighter hue and has a somewhat translucent look. It is called the **substantia gelatinosa [Rolandi]**, and, when seen in transverse section, it exhibits a V-shaped outline and fits on the posterior column like a cap.

A pointed and prominent triangular projection juts out from the lateral aspect of the gray matter nearly opposite the gray commissure. This is the **columna lateralis** (O.T. **lateral cornu**), and it is best marked in the upper thoracic region (Fig. 442, B). Traced upwards it becomes absorbed in the greatly expanded anterior column of the cervical swelling, but it reappears again in the upper part of the spinal medulla, and is particularly noticeable in the second and third cervical segments; followed in a downward direction it blends with the anterior column in the lumbar swelling and contributes to the thickening of that column.

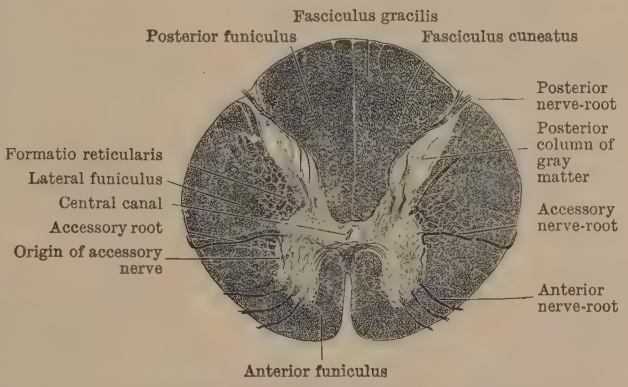

FIG. 441.—TRANSVERSE SECTION THROUGH THE SUPERIOR PART OF THE CERVICAL REGION OF THE SPINAL MEDULLA. (From a specimen prepared by the Weigert-Pal method, by which the white matter is rendered dark whilst the gray matter is bleached.)

The gray matter is for the most part mapped off from the surrounding white matter with a considerable degree of sharpness; but in the cervical region, on the lateral aspect of the crescentic mass and in the angle between the anterior and posterior columns, fine bands of gray matter penetrate the white matter, and, joining with each other, form a network, the meshes of which enclose small islands of white matter. This constitutes what is called the **formatio reticularis.** Although best marked in the cervical region, traces of the same reticular formation may be detected in lower segments of the spinal medulla.

Characters presented by the Gray Matter in Different Regions of the Spinal Medulla.—The gray matter is not present in equal quantity nor does it exhibit the same form in all regions of the spinal medulla. Indeed, each segment presents its own special characters in both of these respects. It is not necessary, however, in the present instance, to enter into this matter with any degree of minute detail. It will be sufficient if the broad distinctions which are evident in the different regions are pointed out.

It may be regarded as a general law that, wherever there is an increase in the size of the nerves attached to a particular part of the spinal medulla, a corresponding increase in the amount of gray matter will be observed. It follows from this that the regions where the gray matter bulks most largely are the lumbar and the cervical swellings. The great nerve-roots which go to form the nerves of the large limb-plexuses enter and pass out from those portions of the spinal medulla. In the thoracic region there is a reduction in the quantity of gray matter in correspondence with the smaller size of the thoracic nerves.

In the *thoracic region* (Fig. 442, B) both columns of gray matter are narrow,

although the distinction between the anterior column and the still more attenuated posterior column is sufficiently manifest. In this region the lateral column of gray matter also is characteristic, and the substantia gelatinosa in transverse section is pointed and spear-shaped.

In the **upper three segments** of the *cervical region* the anterior columns of gray matter are not large and they resemble the corresponding columns in the thoracic region. A lateral column also is present. But in these segments (and more especially in the first and second) there is a marked attenuation of the neck of the posterior column, and the posterior commissure is very broad.

In the **cervical swelling** the contrast between the two columns is most striking; the anterior column is of great size and presents a very broad surface towards the anterior aspect of the spinal medulla, whilst the posterior column remains narrow. This great increase in the bulk of the anterior column is due to a marked addition of gray matter on the lateral side of the column, and seeing that this additional matter is traversed by a greater number of fibres, it stands out, in well-prepared specimens, more or less distinctly from the part of the column which lies to the medial side, and which may be considered to represent the entire anterior column in the thoracic and upper cervical segments. Within this lateral addition to the anterior column are placed those collections of cells which constitute the nuclei of origin of the motor nerves of the muscles of the upper limb. The characteristic thickening of the anterior column of gray matter is evident, therefore, in those segments of the spinal medulla to which the nerves which enter the brachial plexus are attached, viz., the lower five cervical segments and the first thoracic segment.

In the **lumbar swelling** the anterior columns again broaden out, and for the same reason as in the case of the corresponding columns in the cervical swelling. The nuclear masses which contain the cells from which the motor fibres which supply the muscles of the lower limbs take origin are added to the lateral aspect of the columns and give them a very characteristic appearance. In this region of the spinal medulla, however, the posterior columns also are broad and are capped by substantia gelatinosa which in transverse section presents a semilunar outline. There is consequently no difficulty in distinguishing, from an inspection of the gray matter alone, between transverse sections of the spinal medulla taken from the cervical and lumbar swellings of the spinal medulla.

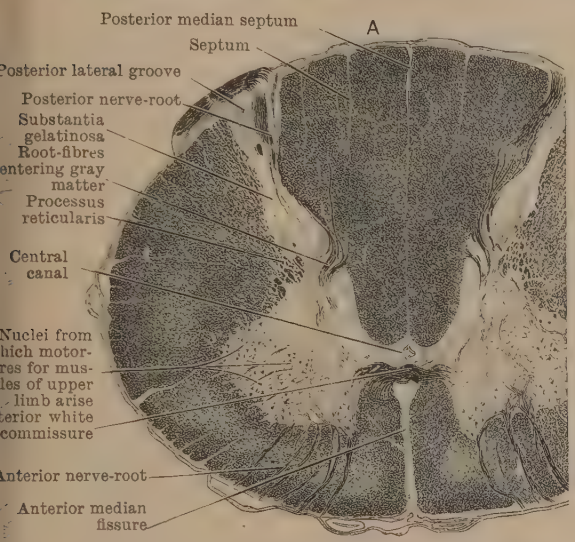
In the lower part of the **conus medullaris** the gray matter in each half of the spinal medulla assumes the form of an oval mass joined to its fellow of the opposite side by a thick gray commissure. Here, almost the entire bulk of the spinal medulla consists of gray matter, seeing that the white matter is reduced to such an extent that it forms only a thin coating on the outside.

White Matter of the Spinal Medulla.—In transverse sections of the spinal medulla the three funiculi into which the white matter is subdivided become very apparent. The **posterior funiculus** is wedge-shaped, and lies between the posterior median septum and the posterior column of gray matter. The **lateral funiculus** occupies the concavity of the gray crescent. Behind, it is bounded by the posterior column of gray matter and the sulcus lateralis posterior, whilst in front it extends as far as the most lateral fasciculi of the anterior nerve-roots as they pass out from the anterior column. The **anterior funiculus** includes the white matter between the anterior median fissure and the anterior column of gray matter, and also the white matter which separates the broad extremity of the anterior column from the surface of the spinal medulla. This latter portion of the anterior funiculus is traversed by the emerging fila of the anterior nerve-roots.

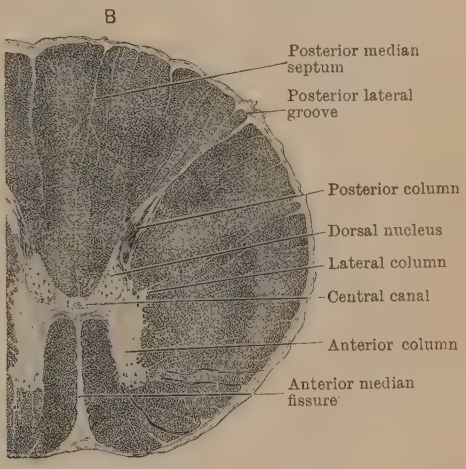
In cross-sections of the spinal medulla the partition of pia mater, which dips in at the sulcus intermedius posterior and divides the posterior funiculus into the medial **fasciculus gracilis** and the lateral **fasciculus cuneatus**, is very strongly marked in the cervical regions, but as it is traced downwards into the thoracic region it becomes shorter and fainter, and finally disappears altogether at the level of the eighth thoracic nerve. Below this point there is no visible demarcation of the posterior funiculus into two parts.

The white matter is not present in equal quantity throughout the entire length of the spinal medulla. It increases steadily from below upwards, and this increase is

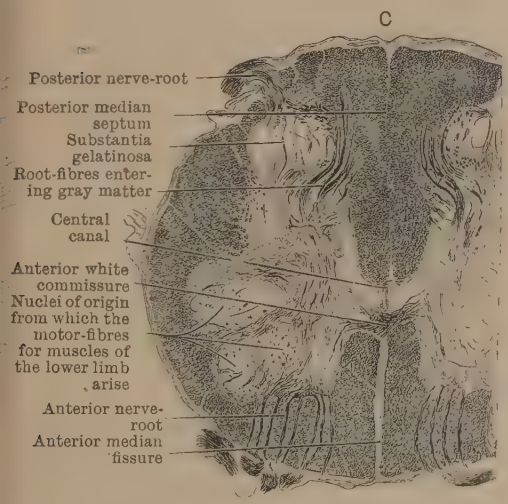
most noticeable in the lateral and posterior funiculi. In the lower part of the conus medullaris the amount of gray matter is actually greater than that of the white matter: but very soon this state of affairs is changed, and in the lumbar region the proportion of gray to white matter is approximately as 1 : 2·1 ; in the thoracic region as 1 : 5 ; and in the cervical region as 1 : 5·1. When it is remembered how the gray matter expands in the lumbar and cervical regions, and how greatly it becomes reduced in the thoracic region, the significance of these figures will become more apparent.



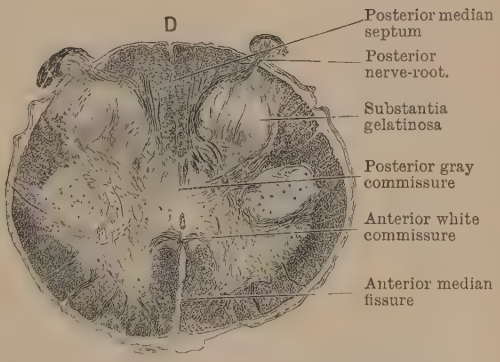
A.—Cervical region—at the level of the fifth cervical nerve. (From a specimen prepared by Dr. A. Bruce.)



B.—Through the mid-thoracic region.



C.—Through the lumbar region at the level of the fourth lumbar nerve.



D.—Through the sacral region at the level of the third sacral nerve. (From a specimen prepared by Dr. A. Bruce.)

FIG. 442.—SECTION THROUGH EACH OF THE FOUR REGIONS OF THE MEDULLA SPINALIS. (From specimens prepared by the Weigert-Pal method ; by which the white matter is rendered dark in colour whilst the gray matter is bleached.)

Canalis Centralis.—As previously stated, the **central canal** is found in the gray commissure. It is a very minute tunnel, barely visible to the naked eye when seen in transverse section, and it traverses the entire length of the spinal medulla. Above, it passes into the medulla oblongata, and finally opens into the fourth ventricle of the brain; below, it is continued for a variable distance into the filum terminale, and in this it ends blindly. Only in the lumbar region does the central canal occupy the centre of the spinal medulla. Above this level,

in the thoracic and cervical regions, it lies much nearer the anterior than the posterior aspect of the spinal medulla; whilst below the lumbar region, as it is traced down into the conus medullaris, it inclines backwards and approaches the posterior aspect of the spinal medulla. The calibre of the canal also varies somewhat in different parts of the spinal medulla. It is narrowest in the thoracic region; and in the lower part of the conus medullaris it expands into a distinct fusiform dilatation (very nearly 1 mm. in transverse diameter), which is termed the **ventriculus terminalis** (Krause).

The central canal is lined with a layer of ciliated columnar cells, the deep tapering ends of which are prolonged into slender processes which penetrate into the substance of the spinal medulla. These cells constitute the lining ependymal cells of the canal. The cilia of the epithelial cells are very early lost, and it is not uncommon to find the canal blocked up by epithelial debris.

The central canal is of interest because it represents in the adult the relatively wide lumen of the early ectodermal neural tube from which the spinal medulla is developed.

Filum Terminale.—The delicate thread to which this name is applied is continuous with the inferior tapered end of the conus medullaris. It is easily distinguished, by its silvery and glistening appearance, from the numerous long nerve-roots (**cauda equina**) amidst which it lies. It is about six inches long, and down to the level of the second sacral vertebra it is enclosed with the surrounding nerve-roots within the dura mater. Below this point the dura mater is applied directly to the surface of the filum terminale and is called **filum duræ matris spinalis.** The filum terminale proceeds downwards in the sacral canal, and finally receives attachment to the periosteum on the posterior aspect of the coccyx (Fig. 435, p. 520). It is customary to speak of the filum as consisting of two parts, viz., the filum terminale internum and the filum terminale externum, or the part inside and the part outside the tube of dura mater.

The **filum terminale externum** is simply a fibrous thread, strengthened by the prolongation it receives from the dura mater. The **filum terminale internum** is composed largely of pia mater; but in its superior half it encloses the terminal part of the central canal, and around this a variable amount of the gray substance of the spinal medulla is prolonged downwards into the filum. When transverse sections are made through the superior part of the filum terminale internum some bundles of medullated nerve-fibres are observed clinging to its sides, and with these are associated some nerve-cells identical with those in the spinal ganglia. These represent rudimentary or aborted caudal nerves (Rauber).

Summary of the Chief Characters presented by the Spinal Medulla in its Different Regions.

Cervical Region.	Thoracic Region.	Lumbar Region.	Sacral Region.
In transverse section, **outline of spinal medulla** transversely oval; in the middle of the cervical swelling the transverse diameter being nearly one-third longer than the antero-posterior diameter.	In transverse section, **outline of spinal medulla** more nearly circular; but still the transverse diameter is greater than the antero-posterior diameter.	In transverse section, **outline of spinal medulla** more nearly circular than in thoracic region.	In transverse section, **outline of spinal medulla** nearly circular, but still somewhat compressed from before backwards.
Postero-median septum very deep, extending beyond the centre of the spinal medulla; **antero-median fissure** shallow.	**Postero-median septum** very deep, extending beyond centre of the spinal medulla: **antero-median fissure** shallow.	**Postero-median septum** not nearly so deep as in regions above: **antero-median fissure,** on the other hand, much deeper.	**Postero-median septum** and **antero-median fissure** of equal depth.

SUMMARY OF THE CHIEF CHARACTERS PRESENTED BY THE SPINAL MEDULLA IN ITS DIFFERENT REGIONS—(*Continued*).

Cervical Region.	Thoracic Region.	Lumbar Region.	Sacral Region.
Gray matter greatly increased in quantity in the cervical swelling: anterior column thick and massive; posterior column slender in comparison. Lateral column evident only above the level of the fourth cervical nerve. Processus reticularis strongly marked.	**Gray matter** greatly reduced in quantity. Both columns slender. Lateral column well marked. Processus reticularis scarcely apparent.	**Gray matter** greatly increased in the lumbar swelling. Both columns very thick and massive. Lateral column absorbed in anterior column. Processus reticularis absent.	Both columns of **gray matter** very thick and massive. Lateral column apparent. No processus reticularis.
White matter in great quantity, and especially massed in the lateral and posterior funiculi.	**White matter** less in quantity than in cervical region, but bulking largely in comparison with the quantity of gray matter.	**White matter** small in quantity compared with higher regions, and very small in amount in relation to increased quantity of gray matter.	**White matter** very small in quantity in comparison with the gray matter.
Sulcus intermedius posterior and corresponding septum well marked.	**Sulcus intermedius posterior** absent; but the corresponding septum can be traced as low down as the eighth thoracic nerve.	No **sulcus intermedius posterior** or corresponding septum.	No **sulcus intermedius posterior** and no corresponding septum.
Central canal considerably nearer the anterior surface than the posterior surface of the spinal medulla.	**Central canal** considerably nearer the anterior surface than the posterior surface of the spinal medulla.	**Central canal** in the centre of the spinal medulla.	**Central canal** in the centre of the spinal medulla.

COMPONENT PARTS OF THE GRAY MATTER OF THE SPINAL MEDULLA.

Neuroglia enters largely into the constitution of the gray matter of the spinal medulla. It forms a bed within which the nervous elements are distributed. These nervous elements consist of (1) nerve-cells and (2) nerve-fibres—both medullated and non-medullated. The nerve-cells lie in small spaces in the neuroglia, whilst the nerve-fibres traverse fine passages the walls of which are formed of the same substance. The neuroglia is thus an all-pervading basis substance which isolates the nervous elements one from the other more or less completely, and at the same time binds them together into a consistent solid mass. In two situations the gray matter presents peculiar features, viz., the apex of the posterior column and the tissue surrounding the central canal. In both situations the gray matter stains more deeply with carmine and presents a more translucent appearance; in other respects the substantia grisea centralis and the substantia gelatinosa are very different.

The **substantia grisea centralis** forms a thick ring around the central canal. It is traversed by the fine processes which proceed from the deep ends of the ependymal cells which line the canal. It is composed almost entirely of neuroglia.

In transverse sections of the spinal medulla the **substantia gelatinosa**, in the cervical and thoracic regions, presents the appearance of a V-shaped mass, embracing the extremity of the posterior column of gray matter; in the lumbar region this cap assumes a semilunar outline.

In the substantia gelatinosa the neuroglia is present in small quantity, and small nerve-cells are developed within it in considerable numbers.

Nerve-Cells.—The nerve-cells are scattered plentifully throughout the gray matter, but perhaps not in such great numbers as might be expected when we note

the enormous number of nerve-fibres with which they stand in relation. They are all, without exception, multipolar, and send off from their various aspects several branching protoplasmic processes or dendrites, and one axon, which becomes the axis-cylinder of a nerve-fibre. In size they vary considerably, and as a rule (to which, however, there are many exceptions) the bulk of a nerve-cell has a more or less definite relation to the length of the axis-cylinder which proceeds from it.

When the nerve-cells are studied in a series of transverse sections of the spinal medulla, it will be noticed that a large proportion of them are grouped in clusters in certain districts of the gray matter; and as these groups are seen in very much the same position in successive sections, it is clear that these cells are arranged in longitudinal columns of greater or less length. Thus we recognise—(1) a ventral group or column of cells in the anterior column of gray matter; (2) an intermedio-lateral group or column in the lateral column of gray matter, where this exists; and (3) a posterior vesicular column of cells (nucleus dorsalis), forming a most conspicuous group in the medial part of the neck of the posterior column in the thoracic region of the spinal medulla.

Other cells, besides those forming these columns, are scattered somewhat irregularly throughout the gray matter of the posterior column and the part of the gray crescent which lies between the two columns; and although these also in some measure may be classified into groups, the arrangement thus effected is not of so definite a character as to justify us in dwelling upon it in the present instance.

Ventral Cell-Column and the Origin of the Fibres of the Anterior Nerve-roots.—The ventral cell-group occupies the anterior column of gray matter, and in it are found the largest and most conspicuous cells in the spinal medulla. It extends from one end of the spinal medulla to the other. These ventral nerve-cells have numerous wide-spreading dendritic processes, and it is to be noticed that certain of these dendrites do not confine their ramifications to the gray matter. Thus, some of the cells along the medial border of the anterior column of gray matter send dendrites across the median plane in the anterior commissure to end in the anterior gray column of the opposite side; whilst others, lying along the lateral margin of the anterior column of gray matter, send dendrites in amongst the nerve-fibres of the adjoining white matter.

The axons or axis-cylinder processes of a large proportion of the ventral cells converge together; and, becoming medullated, they form bundles which pass out from the gray matter, and through the white matter which separates the thick end of the anterior column from the surface of the spinal medulla, to emerge finally as the fila of the anterior nerve-roots. These cells, then, are the sources from which the nerve-fibres of the anterior nerve-roots proceed, and in consequence they are frequently spoken of as the "motor cells" of the spinal medulla. Whilst this is the arrangement of the axons of the great majority of the motor cells, it should be noted that a few cross the median plane in the anterior white commissure and emerge in the fila of origin of the opposite anterior nerve-root.

The ventral cells are not scattered uniformly throughout the anterior column of gray matter. They are aggregated more closely together in certain parts of the anterior column, and thus form sub-groups or columns more or less perfectly marked off from each other.

Thus, one sub-group or column of ventral cells occupies the medial part of the anterior column of gray matter throughout almost its whole length. In only two segments of the medulla is it absent, viz., the fifth lumbar and the first sacral; at this level in the spinal medulla alone is its continuity broken (Bruce). It is termed the *antero-median column* or *group* of ventral cells. Behind this cell-column there is another classed with it to which the name of *postero-median column* or *group* is given, but this column of cells is not continuous throughout the entire length of the medulla. It is present in the thoracic region of the spinal medulla, where the motor nuclei for the muscles of the limbs are absent; and it is seen also in two or three of the segments of the cervical region and in the first lumbar segment (Bruce); elsewhere it is not represented.

In the cervical and lumbar swellings of the medulla, where the marked lateral outgrowth is added to the lateral side of the anterior column of gray matter, certain groups of large multipolar cells are visible. These are the nuclei of origin of the motor-fibres which supply the muscles of the limbs, and consequently they are not represented in the upper

three cervical segments of the spinal medulla; nor in any of the thoracic segments, with the exception of the first thoracic segment; nor in the lowest two sacral segments.

These *lateral cells* are arranged in several columns, which extend for varying distances in the superadded lateral parts of the anterior column of gray matter. The two main columns are an *antero-lateral* and a *postero-lateral column*; in certain segments there is

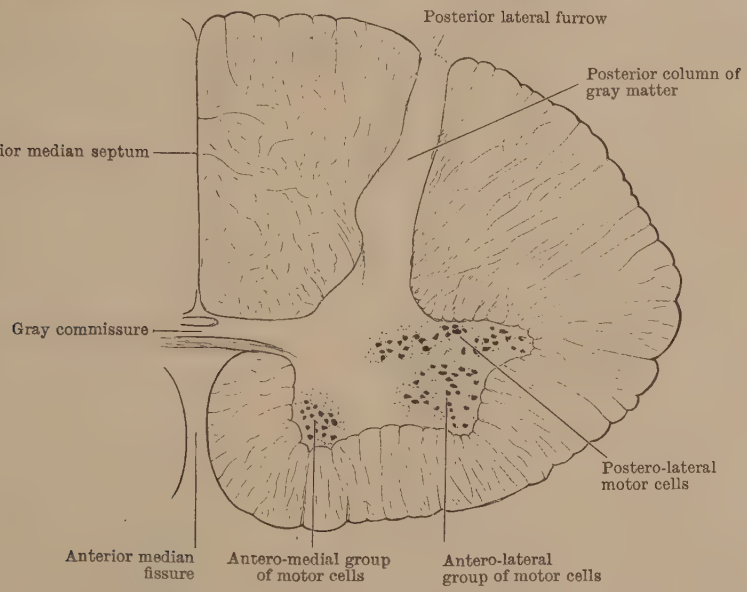


FIG. 443.—SECTION THROUGH THE FIFTH CERVICAL SEGMENT OF THE SPINAL MEDULLA. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

likewise a *retro-postero-lateral column*, and in a number of segments in the lumbar and sacral regions a *central column* of cells (Bruce).

There cannot be a doubt that the grouping of the motor cells in the anterior column of gray matter of the medulla stands in relation to the muscle groups to which their axis-cylinder processes are distributed; but from what has been said it will be apparent that sharply defined cell-clusters associated with particular muscles do not exist. Still, much can be learned regarding the localisation of the motor nuclei in the anterior column of gray matter of the medulla from the study of the changes which occur in the cell-columns after atrophy of isolated muscles or groups of muscles, and after complete or partial amputations of limbs. It has been pointed out that the long muscles of the trunk (as, for example, the different parts of the sacro-spinalis muscle) receive nerve-fibres from all the segments of the spinal medulla. Now, we have noted that there is only one cell-column, the ventro-median column, which pursues an almost uninterrupted course throughout the entire length of the medulla. It may be assumed, therefore, that the nerve-fibres which go to these long trunk-muscles take origin in these medial cells.

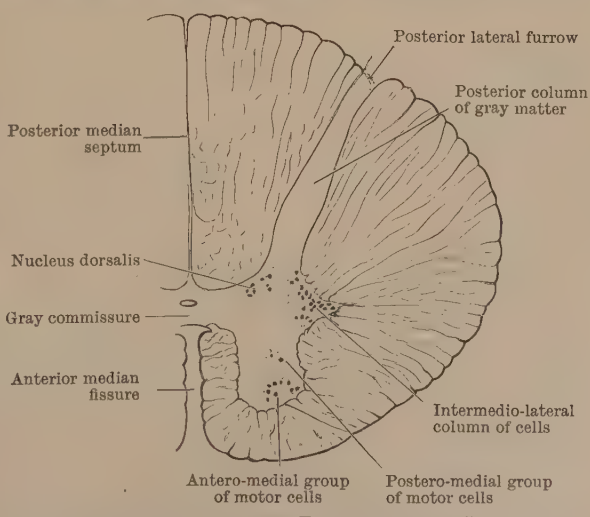

FIG. 444.—SECTION THROUGH THE EIGHTH THORACIC SEGMENT OF THE SPINAL MEDULLA. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

Edinger states that in the anterior column of gray matter the nuclei of origin of the nerves which supply the proximal muscles are medially placed; that those for the distal

muscles are in general situated laterally. If this is the case, the cells connected with the shoulder muscles will lie nearer the middle of the anterior column of gray matter than those which are connected with the hand-muscles. In cases where the forearm and hand, or the leg and the foot, are amputated, it would appear that it is the postero-lateral column of cells that shows changes in consequence of its separation from the muscles to which its fibres are distributed.[1]

Intermedio-lateral Cell-column.—The intermedio-lateral cells form a long slender column which extends throughout the entire thoracic region of the medulla in the lateral column of gray matter. It is also prolonged downwards into the first and second lumbar segments, where it disappears. In transverse sections through the spinal medulla this cell-group presents a very characteristic appearance, because the cells which compose it are small and are closely packed together. Although these cells, as a continuous column, are restricted to the region indicated, it should be noted that the same group of cells reappears above, in certain of the cervical segments, and also in the third and fourth sacral segments. From these cells very fine fibres arise and leave the spinal medulla, intermingled with the motor fibres of the anterior nerve-roots; they pass into the sympathetic ganglia, of which they constitute the white rami communicantes. They represent the splanchnic efferent fibres of the medulla spinalis.

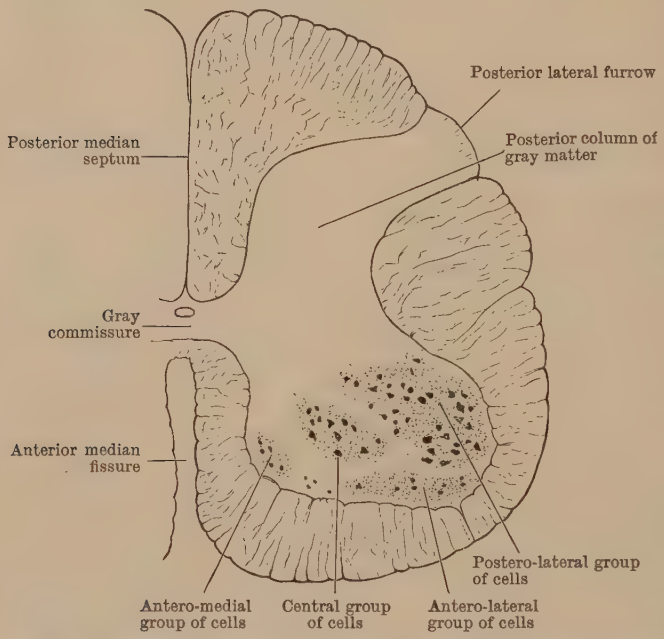

FIG. 445.—SECTION THROUGH THE THIRD LUMBAR SEGMENT OF THE SPINAL MEDULLA TO SHOW THE GROUPING OF THE MOTOR CELLS. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

Nucleus Dorsalis (O.T. **Clarke's Column**).—This occupies the posterior column of gray matter and is the most conspicuous of all the cell-groups in the medulla. It does not, however, extend along the whole length of the medulla; indeed it is almost entirely confined to the "dorsal" region, which is the reason for the designation "nucleus dorsalis." (*When, in the recent revision of nomenclature, the term "thoracic" was substituted for "dorsal" the revisers omitted to change the name of this structure to "thoracic."*) Above, it begins opposite the seventh or eighth cervical nerve, whilst below, it may be traced to the level of the second lumbar nerve, where it disappears. In transverse section of the spinal medulla it presents an oval outline, and is seen in the median part of the cervix of the posterior column of gray matter, immediately behind the gray commissure (Fig. 444, p. 531). On the lateral side it is circumscribed by numerous curved fibres from the entering posterior nerve-root, and in the lower thoracic region of the spinal medulla (opposite the eleventh and twelfth thoracic nerves) it becomes so marked that it forms a bulging on the median aspect of the posterior gray column.

The cells of the nucleus dorsalis are large, and possess several dendritic processes. The axons enter the lateral funiculus of white matter and there form a strand of fibres, which will be described later under the name of the **fasciculus spino-cerebellaris** (*wrongly called "cerebellospinalis" in the B.N.A.*).

[1] Those who seek further information regarding the grouping of the ventral cells of the medulla may with advantage study Dr. Alexander Bruce's *Atlas of the Spinal Cord*.

Nerve-fibres in the Gray Matter of the Medulla Spinalis.—Nerve-fibres of both the medullated and the non-medullated variety pervade every part of the gray matter. They are of three kinds, viz., (1) collaterals, (2) terminations of nerve-fibres, (3) axons given off by the cells. Many of the nerve-fibres which compose the funiculi of the medulla give off numerous fine collateral branches, which pass into the gray matter from all sides and finally end in relation with the nerve-cells. The majority of the nerve-fibres themselves, which thus give off collaterals, finally enter the gray matter, and end similarly. The axons of the majority of the cells leave the gray matter and emerge either for the purpose of entering a peripheral nerve or for the purpose of entering a strand of fibres in the white matter of the spinal medulla.

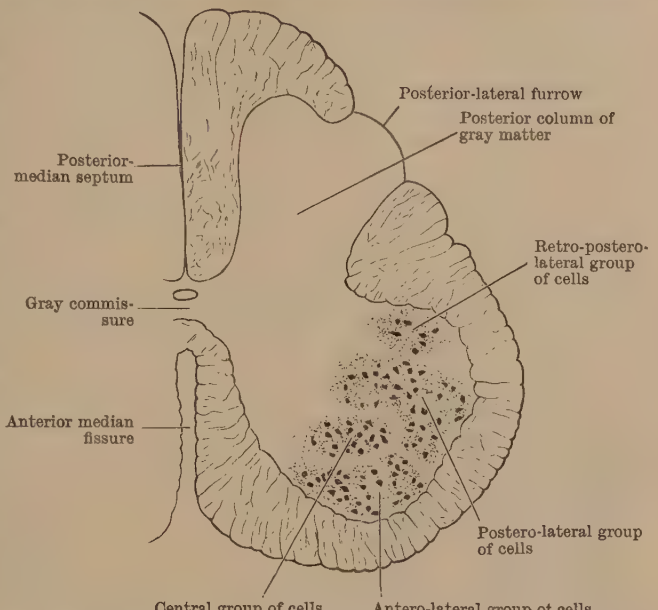

FIG. 446.—SECTION THROUGH THE FIRST SACRAL SEGMENT OF THE SPINAL MEDULLA TO SHOW THE GROUPING OF THE MOTOR NERVE-CELLS. (To a large extent founded on Plates in Dr. Bruce's *Atlas*.)

The nerve-fibres thus derived are interwoven together in the gray matter in a dense inextricable interlacement.

COMPONENT PARTS OF THE WHITE MATTER OF THE SPINAL MEDULLA.

The white matter of the spinal medulla is composed of medullated nerve-fibres, embedded in neuroglia. The fibres, for the most part, pursue a longitudinal course; and, from the deep surface of the pia mater which surrounds the medulla, fibrous septa or partitions are carried in along vertical planes between the fibres so as to form an irregular and very imperfect fibrous framework of support. The neuroglia is disposed in a layer of varying thickness around the medulla, subjacent to the pia mater, and is carried into the medulla so as to give a coating to both sides of the various pial septa. The neuroglia is disposed also around the various nerve-fibres, so that each of these may be said to lie in a canal or tunnel of this substance. The nerve-fibres are all medullated, but they are not provided with primitive sheaths. It is the medullary substance of the nerve-fibres which gives to the white matter its opaque, milky-white appearance. When a thin transverse section of the medulla is stained in carmine and examined under the microscope the white matter presents the appearance of a series of closely applied circles, each with a dot in the centre. The dot is the transversely divided axis-cylinder of a nerve-fibre, and the dark ring which forms the circumference of the circle represents the wall of the neuroglial canal which is occupied by the fibre. The medullary substance is very faintly seen. It presents a filmy or cloudy appearance between the axis-cylinder and the neuroglial ring.

Arrangement of the Nerve-fibres of the White Matter in Fasciculi or Tracts.—When the white matter of a healthy adult spinal medulla is examined, the fibres which compose it are seen to vary considerably in point of size; and although there are special places where large fibres—or it may be small fibres—are present in greater numbers than elsewhere, yet, as a rule, both great and small fibres are mixed up together. No conclusive evidence can be obtained in such a

spinal medulla, by any means at our disposal, of the fact that the longitudinally arranged fibres are grouped together in more or less definite tracts or fasciculi, the fibres of which run a definite course and present definite connexions. Yet this is known to be the case, and the existence of these separate tracts has been proved both by embryological investigation, as well as by the examination of the effects of injuries produced experimentally or accidentally on the nervous system in living beings.
